The history of modern operations for the removal of malignant growths involving the tonsils, soft palate, tongue, and floor of the mouth—as distinguished from those implicating the larynx, which form an interesting chapter by themselves—may be said to begin with the courageous and successful removal of such a growth by external incision by CHEEVER, of Boston, an account of which he published in the *Medical and Surgical Reports of the Boston City Hospital*, first series, 1870. In this case he made an incision along the base of the jaw, meeting another one parallel to the sterno-mastoid muscle, and enucleated the morbid growth. After the publication of this case, it was claimed that both Langenbeck and Hueter had operated in a similar way in 1865, combining division of the lower jaw bone with the incisions in the soft parts. But no report of these operations had been published at that time. Resection of the jaw bone to facilitate access to a malignant growth of the isthmus of the fauces, was first practised by Billroth, in two cases, in 1861, and next by Boeckel, in 1863. In 1878, Cheever reported in the *Boston Medical and Surgical Journal*, a second case, in which he operated by external incision, and divided the jaw also. In this operation he did a preliminary tracheotomy, and sutured the jaw bone with wire. This patient also recovered, although the morbid growth soon recurred.

In 1883, POLAILLON did the first of six operations for malignant growth of the throat, which is fully reported, with other cases, in the *Gazette Médicale de Paris*, July 17, 24, and 31, 1866, adopting in three cases the plan of resecting part of the lower jaw, and in one, of simply dividing it. Four of his patients died on the 3d, 4th, 18th, and 47th day after the operation, and two recovered, one to die the next year of recurrence of the tumor, and one in four months from a like cause. Polaillon practised preliminary ligation of the external carotid artery in five cases, two of which recovered, and three were fatal. In one case he ligated the common carotid artery, and the patient had paralysis of the opposite side, which persisted until he died of secondary hemorrhage on the 47th day, after a second ligation of the same vessel. As early as 1836, Velpeau, before removing through the mouth a cancer of the fauces, passed a thread around the common carotid artery, so as to be prepared for any excessive hemorrhage which might occur. As no such hemorrhage took place, the thread was removed on the day after the operation.

In 1883, MIKULICZ did the first of four operations for malignant disease of the throat. In this he resected the ascending ramus of the lower jaw bone. His patient made a good recovery in six weeks, but had a recurrence of the growth two years afterward. This fact, together with a report of the three other operations for the same disease, is recorded in the *Deutsche med. Wochenschrift*, Nos. 10 and 11, 1886. Of these three patients, one died of exhaustion in two and a half hours, one recovered in four weeks and died of recurrence in three months; and in one Mikulicz was not able to remove a portion of the growth which occupied the posterior nares, and which progressed in spite of the operation.

In 1884, KENDAL FRANKS reported in the *Lancet* of June 28, an operation for the removal of the tongue, left tonsil, and part of the soft palate for cancer. He made the incision from the angle of the mouth backward and through the cheek. His patient died of recurrence, nine weeks after the operation.

On June 16, 1886, VERNEUIL reported to the Societé de Chirurgie, of Paris, an operation which he did in February of this year for an adeno-myxoma of the pharynx attached to the basilar bone. A few days after a preliminary section of the soft palate, made for diagnostic purposes, he made an incision from the angle of the mouth down to the lower border of the jaw and then along this border to its

angle. Turning up the flap, he sawed through the bone at the site of the groove for the facial artery, and removed the tumor. He left the wound open, and dressed it simply with a solution of phenic acid. The wound always looked well under the influence of frequent washings and spraying with phenic acid solution; and the patient was able to feed himself without the use of a tube. But he became discouraged, would not eat enough, and died two months after the operation. Verneuil's plan of leaving the wound open to facilitate its disinfection has been sharply criticised, and has not been imitated.

One of the most valuable contributions to the literature of the subject is an elaborate paper by Castex, in the *Revue de Chirurgie*, for Jan., Feb., and April, 1886. In this paper the nature and treatment of malignant tumors of the throat are fully and ably discussed. Another important study of the subject is contained in the thesis of Paul Faure, "*De l'epithelioma du plancher de la bouche*," published in 1884. We have space at present only to refer to these, and to the interesting discussions as to the value of tracheotomy in operations for tumors of the throat before the Société de Chirurgie of Paris, in the beginning of this year, in which Monod, Verneuil, Trélat, Polaillon, and Le Fort took part.

Malignant growths in the throat are fortunately very rarely met with. By a combination of various statistics they appear to occur only about once in 1000 cases of malignant growths in all situations. When encountered, they should, if possible, be removed early and radically. An operation is plainly indicated when such a growth is isolated, circumscribed, movable, and unaccompanied by glandular involvement. An operation is justifiable when the growth is more extensive, and when there is moderate glandular involvement. It is forbidden when to the conditions just stated is added advanced cachexia.

Unhappily, there is not much evidence as to the final result of operations undertaken before the disease has made decided progress. And still more unhappily, there is scarcely any reason to expect a cure at a later period. Of the cases we have mentioned above, not one is known to have lived more than a few years, and almost all died of recurrence within a few months after the operation. The best results on record occurred in a case of sarcoma of the tonsil, operated upon by Genzmer, by external incision, in 1869, which showed no trace of recurrence three years afterward; and in a case of tumor of the tonsil and soft palate removed by Rizzoli, through the mouth, in which there was no recurrence twenty-four years after operation. But there is no positive evidence as to the nature of this tumor. Nevertheless, we believe operation to be justifiable in a considerable number of cases. There is a small hope of prolonging life for some months, or even for one or two years. And there is almost a certainty, if the patient survive the operation, that his condition will be materially improved. As Gosselin has said, in speaking of operations for the removal of cancer of the breast, "It is much to substitute a wound which is seen to heal for a disease which is seen to increase incessantly." And, even if the hope infused by a seemingly successful operation prove delusive, still it is a blessed delusion to the patient.

Finally, as to the proper method of operating: it appears, from the experience so far accumulated, that the best plan is to operate from the outside of the neck, as has been done by Cheever, Polaillon, Mikulicz, and others. An incision may be made in front of the sterno-mastoid muscle, from the mastoid process to the hyoid bone, and another from the upper end of the former along the base of the jaw. After clearing and raising the flap, the lower jaw may be divided or resected, and the growth enucleated, or excised with the galvano-cautery wire and the thermo-cautery knife. After controlling any hemorrhage which may occur, the flap may be replaced and sutured, leaving an iodoform tampon inside the mouth, attached by a thread to another on the outside in such a way as to effect compression. The throat must be frequently and thoroughly disinfected. The patient may be nourished through an œsophageal tube—which should be inserted while the patient is still under the influence of the anæsthetic—or by nutritious enemata, or in both ways.

The value of preliminary tracheotomy in these operations is not clear, but it may be resorted to in order to prevent the access of blood and débris to the lungs during or soon after the operation.

Ligation of the carotid artery adds a new element of danger to the operation, and we cannot see that it improves the chances of recovery. This seems to be proved positively by the experience of Polaillon, and negatively by that of other operators.

In conclusion, a remark as to the diagnosis of malignant growths in the throat may not be amiss. Before ulceration takes place, it is easy to make a mistake in this respect. As late as 1885 Mikulicz operated on a case which he supposed to be one of carcinoma of the tonsil, and, after removing an enlarged gland which *was* carcinomatous, he found the tonsil smooth, soft, and healthy, and was able to spare his patient the intended resection of the lower jaw and pharyngotomy. And years before, Blandin mistook a syphilitic ulceration of the pharynx for a malignant growth and operated upon it. For this reason it may be well, in case of doubt, to make a reasonable trial of antisyphilitic treatment before having recourse to the grave surgical procedure suitable to malignant disease.

IS CIRRHOSIS OF THE LIVER CURABLE?

THIS question has been discussed recently at La Société Médicale des Hôpitaux, according to the *Gazette Hebdomadaire*, Nos. 31 and 34, and answered affirmatively by several members, who quoted cases which seemed to bear out the view that the disease may be arrested or even cured. The diagnosis of cirrhosis is rarely reached until the onset of symptoms of obstructed portal circulation, although before this stage the condition may be reasonably suspected. The cases of cure are those in which the ascitic fluid has not reaccumulated after treatment, or, after a hæmatemesis, the symptoms have been relieved and the patient has had years of tolerable, or even good, health. Most physicians have met with such instances among their alcoholic patients.

In the discussion referred to, eight cases were reported by four or five members, and from the details we can reasonably infer that the ascites depended upon cirrhosis. But we must be careful not to confound the relief of a symptom with the cure of the disease. The post-mortem room affords examples of advanced cirrhosis in persons dying of intercurrent affections in whom there has never been any history of hepatic trouble, and, on the other hand, the most extensive dropsy may exist with a very moderate grade of interstitial change. We must look beyond the liver for an explanation of these facts. In the first place, unquestionably, we must take into account the collateral circulation carried on by the diaphragmatic, œsophageal, and lumbar plexuses, the hemorrhoidal anastomoses and the veins of the round ligament; if enormously enlarged, these may partially, or even fully, compensate for the narrowed portal channels, as in the rare instances of obliteration of the vena portæ. The degree to which this collateral circulation is established varies extremely in different cases, and is a very important factor in the duration of life in this disease. It will be found that the very instances in which advanced cirrhosis has been accidentally discovered post-mortem are those in which there are numerous supplementary blood-channels.

The two most striking symptoms of cirrhosis are ascites and hæmatemesis, in both of which the venous radicles of the portal vein are directly concerned. We are apt to consider them as immediate results of the heightened blood pressure, due to the narrowing and obliteration of the interlobular vessels; but Cohnheim's experiments indicate that this alone cannot induce either diapedesis or serous exudation. The condition of the vessels themselves must be taken into account, and in altered states of their walls we must seek an explanation of the sudden and profuse hæmatemesis, or the rapid dropsy. The abruptness with which one or other of these symptoms may supervene, as possibly the very first manifestation of the disease, points plainly to disturbances in the radicles of the portal veins, and not in the central hepatic branches, which, in the indurated organ, must be much less subject to variations in calibre.

Heretofore we have been in the dark as to the nature of these peripheral changes, but Dieulafoy has determined, in certain cases, the existence of a subacute peritonitis, and in four instances periphlebitis of the walls of the rootlets of the portal veins. These lesions have not been fully described, but their existence throws light on the origin of the dropsy and the hemorrhage, and they possibly furnish the additional factor which, as Cohnheim insists, is needed to permit transudation of blood corpuscles or plasma under heightened blood pressure. The dropsy may be due to transitory and remediable causes, anæmia for example, and does not necessarily indicate that the contraction of the portal canals has reached a high grade. These are points which must be considered in discussing the curability of cirrhosis, and, as we remarked, the relief of a symptom may not mean the removal of the disease.

We probably have not any remedies at our command which are capable of curing a cirrhotic liver. The nature of the tissue change is such as almost to preclude the possibility of restoration, but in the early stage many practitioners place great reliance upon drugs, particularly the salts of gold, phosphate of sodium, chloride of ammonium, and, as recommended by Dujardin-Beaumetz, hippurate of lime. Unfortunately the diagnosis in the cases in which these remedies have been reported to be successful is often a matter of doubt, and we very strongly suspect that when a case of cirrhosis presents features clearly enough marked for detection, the interstitial hepatitis is probably beyond arrest, as it is certainly past cure.

AN APPEAL FROM CHARLESTON.

As we go to press, we are in receipt of a letter informing us that the Medical College of the State of South Carolina has suffered considerable damage to its building, from the late earthquakes in Charleston, and that it will require $5000 to make the repairs necessary for the resumption of teaching. The College itself is without means, and the members of the profession in Charleston have been so severely crippled by their individual losses that they are unable to give it the requisite pecuniary aid. The Faculty are, therefore, compelled to appeal to their more fortunate brethren outside of the earthquake district, for immediate assistance, to enable them to repair the building in time for the ensuing winter course. The profession of medicine has always been noted for its generosity in times of distress, and the present appeal is sure to elicit a prompt and liberal response. THE MEDICAL NEWS will be happy to receive and forward contributions,

and acknowledge the same in its columns, and its proprietors take pleasure in starting the list with a subscription of one hundred dollars.

At the meeting of the American Social Science Association, Dr. Grace Peckham, of New York, read a paper on "Nervousness of Americans." This condition, she said, was due mainly to the higher form of civilization, the excitement due to self-government and progressive ideas, and the struggle to win large fortunes, and not due to climate or to diet. It was further stated that it should be looked upon as an attribute, not a stigma.

This view of the case is of interest, and is well worthy of consideration, but it is not a complete view. Granting that the "attribute" of American nervousness exists, and granting also that it is the outcome of a worthy national striving and ambition, it by no means follows that the condition is either right or inevitable. And the effort for amelioration of such a national trait lies distinctly within the province of the medical profession.

The Lancet this week, within its mourning-bordered cover, conveys the sad intelligence of the death of its editor Dr. James G. Wakley, which occurred on the morning of the 30th ult., from epithelioma of the tongue. This announcement is of more than passing moment, for it chronicles the demise of one who for more than a quarter of a century has guided the course of a journal which has exerted a marked and goodly influence on the profession of medicine in Great Britain.

Dr. Wakley was the youngest son of Mr. Thomas Wakley, the founder of *The Lancet*, and he proved a worthy successor to his distinguished father in its editorial control, which he assumed about the year 1859. He never engaged in medical practice, but was wholly absorbed in his editorial labors. He took an especial and active interest in boldly exposing in his columns medical abuses and public evils, and the direct impress of his character largely contributed to give to *The Lancet* the commanding position in medical literature which it has held for many years.

SOCIETY PROCEEDINGS.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Annual Meeting, held at Buffalo, August, 1886.

(Specially reported for The Medical News.)

(Concluded from page 276.)

Dr. Theobald Smith, of Washington, spoke on

THE VARIABILITY OF PATHOGENIC ORGANISMS, AS ILLUSTRATED BY THE BACTERIUM OF SWINE PLAGUE.

By inoculation into mice, a bacterium was inoculated from one of a number of spleens taken from swine plague in Nebraska, which resembles the bacterium of swine plague found in the east, in regard to its morphological and pathogenic characters, and yet differs from it in certain minor histological features, so that it seems justifiable to regard one as a variety of the other, or both varieties of a third form.

This new bacterium resembles the bacterium of swine plague in form, size, and mode of staining. Like the former, it is motile when cultivated in liquid media and fails to liquefy gelatine. Both grow alike on agar-agar and potato, and both fail to affect the microscopic appearance of milk in which they multiply. The thermal death point of both is about 58° Centigrade. Cultures of various ages are killed by an exposure to this temperature for fifteen or twenty minutes. In neither is there any indication of spore formation. Both produce the same lesions in mice, rabbits, and pigeons after the subcutaneous injection of pure cultures.

This bacterium differs from the bacterium of swine plague in the following minor but constant features: 1. In liquid cultures of the former the surface was covered by a complete membrane within one or two days, which is invariably absent in cultures of the latter, but may occasionally appear in advanced old cultures. 2. It is more sensitive to the reaction of the culture media, as it failed to grow in neutral gelatine but grew vigorously in the alkaline medium. 3. This microbe failed to induce the disease in guinea-pigs.

The study of these two related microbes presents the first evidence as to the possibility of the variation of pathogenic forms. It raises a number of questions as to the causes of variation, whether dependent on external conditions, such as climate, soil, etc., or upon the organization of the susceptible animals, which, in turn, depends upon their food, mode of life, race, etc.

These facts suggest the possibility of the variation of other pathogenic microbes and may offer an explanation of the varying virulence of epidemics of the same disease at different time and in different localities.

Very recently a third form was obtained from swine plague in Illinois, which resembles the two forms compared in its microscopic characters, its motility in liquids, its failure to liquefy gelatine, and in its powerfully narcotic effect on muscular tissue at the place of inoculation. It is fatal to mice, rabbits, and pigeons only when a larger quantity of virus is injected than is needed in case of the two other forms. Of the three forms, it seems to be least adapted to a true parasitic existence.

Dr. D. E. Salmon, of Washington, made some remarks on

THE THEORY OF IMMUNITY FROM CONTAGIOUS DISEASES

He discussed the antidote theory, the exhaustion theory, and the vital resistance theory, and cited experiments to show the latter to be the true one. The tissues of the body when normally active are not suited to the growth of microbes; the former are overcome by a poison produced by the latter. Immunity is a tolerance of the tissues for this poison and can be produced by injecting into the tissues the poison which contains no living germs.

Dr. Sternberg claims priority for having originated the vital resistance theory of immunity. Dr. Law

claims to have reached the same conclusion independently and at the same time, and to have demonstrated that immunity might be produced with sterilized virus.

Dr. Salmon showed that the theory under consideration was offered several years before the time claimed by either of these gentlemen; also that Law's demonstration was unsatisfactory, that his experiments repeated by the writer do not sustain his claims, and that it is not probable that immunity can be granted under the conditions of this experiment.

DR. SALMON then offered some remarks on the

IMMUNITY FROM CONTAGIOUS DISEASES PRODUCED BY PRODUCTS OF BACTERIAL MULTIPLICATION.

When children have recovered from the measles they conclude that one of the troubles of life have been overcome, and no matter how much they are exposed to that disease in the future, they rely upon their power to resist it without inconvenience. As a rule, their expectations are correct. The first attack has granted them an immunity from the effects of the contagion, which, while it is not absolute in every case, is certainly very remarkable. It is also a matter of the most common observation that other contagious fevers to which people are subject grant a similar immunity—a power to resist those particular forms of contagion for the remainder of the individual's life. The same is true of certain contagious fevers of other species of animals.

The nature of such acquired immunity has long been an interesting subject for speculation, and until comparatively recent times it has been mysterious and incomprehensible. Since the demonstration of the germ theory of disease it has become evident that there were three possible explanations.

1. Something had been deposited in the body during the attack of disease that was unfavorable to the specific germ.

2. Something had been exhausted which was essential to the development of this germ.

3. The living tissues had acquired such a tolerance for the germ, or for a poison which it produces, that they are no longer affected by it.

If either the first or the third of these explanations were correct, it would appear possible that immunity might be granted by introducing into the tissues the liquid in which the specific germs had been cultivated, and from which they had been removed by filtration, or in which they had been killed by suitable methods. He has long been convinced of the correctness of this supposition, but it is only recently that he has been able to make a satisfactory demonstration of the principle.

In these experiments he has used the virus of the contagious fever of hogs, known as swine plague. This virus, cultivated in the laboratory in suitable liquids, is very destructive to pigeons when injected hypodermatically in the region of the pectoral muscles, in doses of three-quarters of a cubic centimetre. To test the protective effects of the products of bacterial growth, the virus referred to was cultivated in a one per cent. solution of peptone. After a number of days' cultivation, the culture was raised to 58° to 60° C.—a temperature which soon kills the microbe; but to make sure that all life was destroyed, he invariably transferred a few drops of the heated liquid to a fresh tube of culture fluid. If any multiplication of the germs occurred, it was of course evident that the temperature had not been high enough, or was not maintained for a sufficient time. This made it necessary to repeat the operation. As the thermal death point of the microbe had been carefully determined, and as care was used to raise the temperature somewhat beyond this point, it was seldom that any of the organisms remained alive. No liquid was used in these experiments, however, which had not been tested in this way and found free from living organisms. The necessary details will be found embodied in the table below.

Of the nine experiments included in the table, five, viz., the first, second, fifth, seventh, and eighth, give very positive results. In these 27 pigeons were used.

[1] Evap. virus.

Résumé of Experiments.

	No. inoculated.	Died.		Recovered.		Not affected.	
		No.	per ct.	No.	per ct.	No.	per ct.
Protected with more than 1 c.c. sterilized virus . . .	29	3	10.3	4	13.8	22	75.9
Unprotected . . .	15	10	66.7	2	13.3	3	20.0

Of the 19 protected pigeons not one died from inoculation, and 18 had acquired perfect immunity; while of the 8 unprotected pigeons, which were used as checks, 7 died and but 1 resisted. The ninth experiment is almost equally positive. In this case, the virus used for the birds was evaporated over a water-bath to learn if a boiling temperature destroys the protective power. One of the pigeons so treated did not gain immunity.

The negative results of the other experiments were partly due to changing the conditions in order to learn those which were favorable and unfavorable to the production of the desired effect.

Dr. Joseph Jastrow, of Baltimore, read a paper on

THE DREAMS OF THE BLIND AND THE CENTRES OF LIGHT.

The object of the paper was to determine the extreme age at which a child may become blind and yet lose all memory of the visible world, so that it no longer sees in dreams.

Almost all dreams of normal persons are sight-dreams, and a dream is often spoken of as a vision. The blind are deprived of this most important sense; but if they have not been born blind, they may remember enough of what they have seen to enable them to imagine how things look, and, when the imagination has free play in sleep, to picture themselves as in full possession of all their senses. Physiologists would explain this by saying that during the years in which they saw, a certain part of the brain has become educated to receive and interpret all these messages which the eye sends, and that, when this part of the brain acts spontaneously in sleep, the person dreams of seeing. Such a portion of the brain would be called the sight-centre.

If, now, we find out the latest age at which blindness may set in, and yet the person keeps on dreaming of seeing, we will find out the time it takes for this sight-centre to develop; for, of course, it is not present in the newborn infant. For this purpose about two hundred blind persons of both sexes were questioned at the institutions for the blind in Philadelphia and Baltimore, and it was found that those who became blind before their fifth year never dreamed of seeing; of those whose sight was lost between the fifth and the seventh year, some did and some did not see in their dreams; while all whose eyesight was destroyed after the seventh year had quite as vivid dream-visions as seeing people. The fifth to the seventh year is thus shown to be the critical period. This period corresponds with the age which authorities assign as the limit at which a child becoming deaf will also become dumb; and also with the age of one's earliest continuous memory of one's self.

It is interesting to note that blind persons dream quite as frequently as people with normal sight, and that with those who do not see in their dreams, hearing plays the principal part. When dreaming of home, for instance, they will hear their father's voice or their sister's singing, and perhaps will feel the familiar objects in the room and thus know they are at home. We, in such a case, would see it all.

CORRESPONDENCE.

THE HYPODERMATIC ADMINISTRATION OF MORPHIA FOR AUTUMNAL CATARRH.

In the *American Journal of the Medical Sciences* for Jan. 1873, I called attention to the hypodermatic administration of morphia for autumnal catarrh. Experience has confirmed the efficacy of this treatment in relieving the paroxysms of this disease, and in moderating the severity of its annually recurring attacks. I venture to report a typical case, though unfinished, because the season is still at its height, and the treatment is available to those practitioners who have not the opportunity to use local means for the radical cure of this distressing ailment.

September 2, 1886. Mrs. A., æt. thirty; disease dates back many years; attack began August 10th, several days earlier than usual; went to the seashore for a fortnight, during which time the severity of the symptoms diminished; returned on the 30th, with immediate bad results.

Present condition: Violent sneezing, eyes and nose itching, swollen, and streaming; incessant wheezing cough during the day; at night, severe asthma, necessitating the upright position, and entirely preventing sleep. One-fourth grain of morphia sulph., hypodermatically gave instant and entire relief, which lasted nearly forty-eight hours. This was repeated on the 4th, 6th, 8th, 10th and 11th, with like result (on the last date, sooner, on account of the conjunctival irritation). I shall probably be able during the remainder of the period to keep the attack under control, with half-weekly injections. I have not in this, and other cases, obtained relief by the local application of a six per cent. solution of cocaine hydrochlorate.

Wm. Moss.

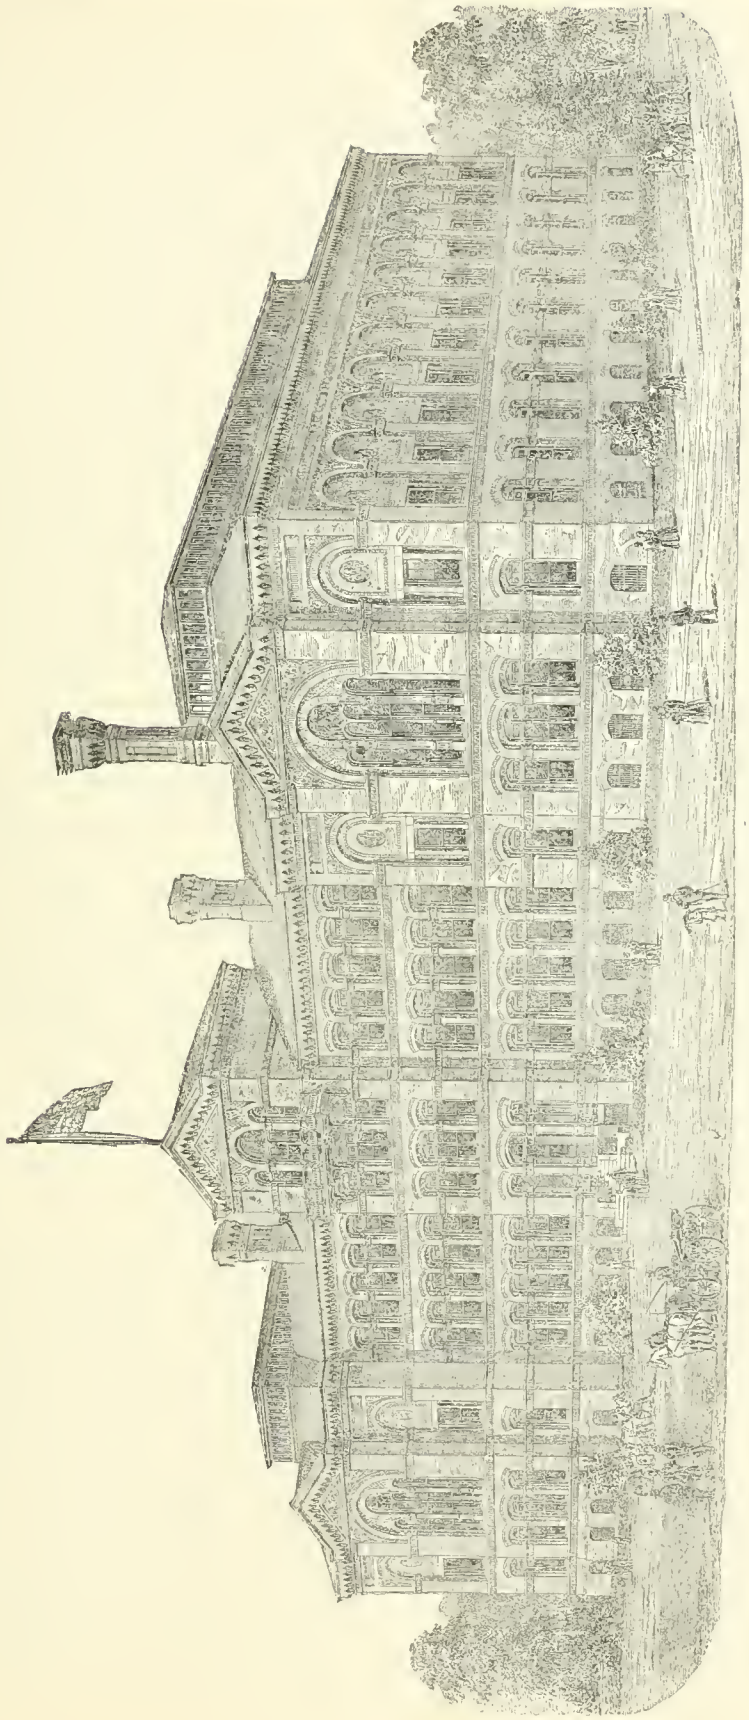
Chestnut Hill, Philadelphia, September 12, 1886.

NEWS ITEMS.

WASHINGTON.

(*From our Special Correspondent.*)

The Building for the Army Medical Museum and Library is being erected on the southeast corner of the grounds occupied by the Smithsonian Institution, and will, when completed, be in close proximity to the National Museum and the Smithsonian Institution. This site is readily accessible by the street cars, but is a little out of the way of ordinary travel either for business or pleasure. The reservation comprehends 270 x 160 feet, facing B Street which is south, and abutting on 7th Street. The plans for the building were prepared by Cluss, the architect, under instructions from Dr. Billings, acting for the Surgeon-General. According to the plans, the building is to cover a space of 232 x 136 feet. The appropriation granted by Congress for building purposes was $200,000, being $50,000 less than was asked for, and required a modification of the plans and a plain severity of style of finish, devoid of ornamentation.



MEDICAL LIBRARY AND MUSEUM, U.S. ARMY
Washington, D.C.

The accompanying cut gives an idea of the exterior of the building as it will appear when completely finished with pressed brick and terra cotta, the roof being constructed of rolled iron beams and trusses.

As to the general arrangement and construction of the building, the complex consists of a centre building 112 feet in length, 55 feet in width, and four stories high above the basement. It is arranged for the administration clerks and photographer. This structure is flanked by two wings of 60 x 131 feet. They contain a basement, a first story allotted to offices, and a second story, open to the roof and surrounded by galleries. This second story accommodates the museum in the east wing and the library in the west wing. Both wings have continuous ventilating lantern skylights. A smaller wing in the courtyard, will hold the steam-boilers, steam-pumps, and coal cellar. The basement is eleven feet in height; the first story fifteen, the second story fourteen, and the third and fourth stories thirteen and twelve feet high respectively. The museum and library are thirty-one feet high to the eaves and forty-seven feet to the ridge of the lanterns. The placing of such an enormous quantity of books in the library will produce a very heavy weight which will require unusually strong supports on the floors below; the first floor just below the library being intended to be used for pension records.

The foundations consist throughout of concrete, the walls are built of brick, constructed with a bonded internal lining of hollow bricks for all walls exposed to the weather. The moulded work and the cornices consist of pressed brick and terra cotta. The floors of the first story are constructed of brick arches between rolled iron beams, the floors above are formed of flat arches, built of hollow bricks between rolled beams. The roofs of the centre building are constructed similarly to the floors, but of lighter material. The columns used are of fire-proof sectional wrought iron. The library and the museum are constructed so as to form fire-proof compartments separated from the other parts of the building. The stairs are of wrought and cast-iron.

The contract calls for the completion of the building by February 1, 1887, but unanticipated difficulties which have arisen in securing suitable brick during the present season, will cause a delay of some weeks. The basement and first story walls of the building are up, and the first tier of iron beams laid. The appropriation asked for, sixty thousand dollars, is mainly for the iron frames and shelving of the book stacks, and similar furnishing for the pension records, exhibition cases of museum, etc., and, a very important item, for the construction of an addition, for the disposition of all material such as is used in laboratory work, as may by its fumes or gases tend to injure the contents of the main building; and for the laboratory and work-rooms.

The library wing (west) is provided with thirty-four stacks, solely for the accommodation of the books and library material; where the wing is joined to the centre building, and where consequently the light is less in amount, tables will be placed for the accommodation of large atlases of plates, portfolios of engravings, etc.; readers and casual visitors being provided for by suitable reading-rooms close at hand, where books can be brought to them as desired. These stacks have each three stories, and each story, which is seven feet nine inches high, has four divisions, the lower two giving shelf room of twelve inches in depth for the more ponderous tomes, the upper two of eight inches depth, well lighted by windows, making thirty-four shelves to each story of a single stack; and an estimated total capacity of 170,000 books. The classification of these books and their proper positions upon the shelves for readiness of access, are the problem which is now being considered. When we refer, a little further on, to the museum wing and its arrangement, it will be seen that a classification has been prepared there which seems to meet the requirements fairly and satisfactorily; and a similar classification will be attempted with the library, modified, of course, by the different nature of the material to be utilized.

The museum wing is lighted for the first story by its side windows, but for the second story, formed by a gallery, has to depend upon the skylight, consequently the exhibition cases will be varied in their arrangement for each story, the gallery having side or wall cases as well as those placed transversely, and along the central border of the gallery platform it is proposed to place those beautiful dissections made under spirits, after Turner of Edinburgh, which are placed in porcelain bowls with cemented glass covers, familiar to those who have visited the English museums—of which Dr. Billings has obtained fine specimens from Dr. Cunningham, of Dublin, and which have been most admirably followed by Mr. J. S. Wortman, the anatomist of the museum. Dr. Billings proposes to have about 150 of these so placed. When one sees these specimens for the first time, he is very apt to become enthusiastic over them, but they are probably well known to many of the readers of The News.

The microscopical material, although belonging to the museum, must, of course, be handled in a way peculiar to itself, and has its own room off from the museum in the central building, where probably the curiosity-seeker will not find much to attract him, but the student will have suitable instruments and ample opportunities to take full advantage of the collection. Near the microscope room, is a room still in the centre building—third floor—which will be fitted up with apparatus corresponding to Galton's views upon the subject, as an anthropometric room. This is likely to prove a very interesting feature of the new building. At first its use will probably be limited, as its records would be confined to a few occasional and well-known visitors, but, as its usefulness and importance become better known and more widespread among the throng of visitors to the National Capital, there may be an imperative demand for an extension of its scope, and its records become voluminous and correspondingly valuable. To complete the usefulness of the museum itself, upon the first floor, adjoining the rooms set aside for the pathologist and anatomist, is a large and suitable room fitted up with drawers and cabinets to contain the study collection, that is, specimens of osteology which are disarticulated and prepared in the rough to show certain characteristics, and other specimens and preparations that can be handled by the student.

In going further and attempting to give an idea of the mode of handling and classifying the material to be displayed in this museum, I cannot do better than to

refer to the remarks made by Dr. Billings at a recent meeting of the Philosophical Society in this city.

The subject under consideration was the management of museums, and the whole discussion was well worthy of being reported in full. Material illustrating the subject was exhibited, and the argument was sustained by Dr. Billings on the part of the Army Medical Museum, Prof. G. Brown Goode and Mr. Lucas on the part of the National Museum, and by Mr. Merrill giving his ideas of a Geological Museum. Dr. Billings stated the special scope and purposes of the Army Medical Museum to be:

1. To illustrate the effects, immediate and remote, of wounds, and of those diseases prevalent in the army—that is, the diseases and injuries of adult males.

2. To illustrate the work of the medical department of an army, modes of transporting the sick and wounded, hospitals, medical supplies, instruments, etc.

3. To illustrate human anatomy and pathology of both sexes and of all ages. This requires many specimens in comparative anatomy and pathology, which are indispensable for the correct understanding of the structure, development, abnormities, and diseases of man. This would not form a museum of comparative anatomy, which belongs to the functions of the National Museum.

4. To illustrate the morphological basis, or want of such basis, for ethnological classification, more especially of the native races of America, including anthropometry and craniology.

5. To illustrate for medical investigators and teachers the latest methods, the newest apparatus, etc., for biological investigations, and various modes of preparing and mounting specimens. In connection with this it is hoped to induce original workers to deposit in the museum type specimens, or series of specimens illustrating their discoveries and methods.

With this outline before us it is easy to see the importance of a clear and well-defined classification to work upon before the first specimen is placed in position. It was well said at the meeting referred to, that a museum should be a museum of labels as well as of specimens; how forcible the application must be to the classification. Accordingly, the classification is given in the following general plan:

A. General and regional anatomy, physiology, and pathology:

a, Head and neck; *b*, thorax; *c*, abdomen; *d*, pelvis (for female pelvis see M.); *e*, upper extremity; *f*, lower extremity.

B. Skeleton (bones, ligaments, and joints):

a, Skull; *b*, vertebræ, ribs, sternum, and hyoid; *c*, pelvis; *d*, upper extremity; *e*, lower extremity.

C. Muscular system (muscles, tendons, and fasciæ):

a, Head and neck; *b*, trunk; *c*, upper extremity; *d*, lower extremity.

D. Circulatory system:

a, Heart and pericardium; *b*, arteries; *c*, veins; *d*, capillaries.

E. Lymphatic system and ductless glands:

a, Lymphatics; *b*, spleen; *c*, supra-renal capsules; *d*, thyroid gland; *e*, thymus gland.

F. Nervous system:

a, Encephalon (exclusive of medulla); *b*, medulla oblongata and spinal cord; *c*, peripheral and sympathetic nerves.

G. Respiratory system:

a, Larynx and trachea; *b*, lungs and pleura.

H. Digestive system:

a, Teeth; *b*, mouth; *c*, pharynx and œsophagus; *d*, stomach and duodenum; *e*, intestines (exclusive of anus and rectum); *f*, anus and rectum; *g*, salivary glands; *h*, pancreas; *i*, liver; *k*, peritoneum.

I. Organs of sense:

a, Eye and appendages; *b*, nose; *c*, tongue; *d*, ear.

K. Urinary organs:

a, Kidneys and ureters; *b*, bladder and urethra.

L. Male generative system:

a, Scrotum, testes, and vasa deferentia; *b*, vesiculæ seminales, prostate, and Cowper's glands; *c*, penis.

M. Female generative system and pelvis:

a, Pelvis; *b*, ovaries; *c*, uterus, ligaments, and Fallopian tubes; *d*, vagina and vulva.

N. Tegumentary system.

O. Microscope.

P. Weapons, missiles, and foreign bodies.

Q. Transportation and care of sick.

R. Anthropology.

S. Materia medica and chirurgica.

T. Miscellaneous.

The above comprise the main heads of the division into subjects; to make this available there follow the numbered subdivisions coming under the lettered headings:

1. Embryology and development.
2. Anatomy and physiology.
3. Abnormities and deformities.
4. Diseases.
5. Injuries and foreign bodies.
6. Repair and restoration.
7. Surgery.

To make the subdivisions clearer, they, too, must in some cases undergo further division. Take for example:

4. *Diseases*; under this head will be found
41. Disorders of the circulation.
42. Hypertrophy and dilatation.
43. Atrophy, degeneration, and mortification.
44. Inflammation and its sequelæ.
45. Parasites, parasitic and infectious diseases.
46. Tumors and concretions.
47. General diseases.
48. Diseases peculiar to the system or organ.
49. Other diseases.

One or two illustrations will suffice, I think, to show clearly the practical working of this system. For instance, here is specimen No. 1052. A wet preparation of the heart with the left ventricle perforated by gunshot near the apex. It is marked D. *a*, 5., or D. Circulatory system; *a*, heart; 5. Injuries and foreign bodies.

Another is specimen 5700. A wet preparation of the cancerous integument of a hand. This is marked A. *e*, 46., or A. General and regional anatomy; *e*, upper extremity; 46. Tumors and concretions. It has also a cross reference, N. 46., or N. Tegumentary system; 46. Tumors and concretions.

It is not proposed to place specimens illustrating normal anatomy in one place, and pathological specimens in another, but to place together as far as possible all the specimens illustrating the morphology, development,

and pathology of a particular organ or system, including both wet and dry preparations, models, casts, etc.

It remains for time to show how far this system will answer its purpose.

A Wise Precaution.—Before undertaking an autopsy, Dr. Clevenger recommends holding the hands over strong liquid ammonia, when the smarting which ensues will reveal all sensitive or abraded places that need a touch of caustic or other protection before beginning the examination.

New Metric Abbreviations.—The International Committee of Metric Weights and Measures has adopted the following system of abbreviations. Italics are employed, with the exponents 2 and 3 to denote square and cubic measure: Metre = *m*, decimetre = *dm*, centimetre = *cm*, millimetre = *mm*, kilometre = *km*. Metre square = m^2, metre cube = m^3, and so for the rest. Litre = *l*, decilitre = *dl*, etc. Kilogram = *kg*, dekagram = *dkg*, gram = *g*, decigram = *dg*, centigram = *cg*, and milligram = *mg*.

A New Infirmary.—The corner-stone of a new infirmary for the Five Points House of Industry, in New York, was recently laid with appropriate exercises. The building, which will be ready for occupancy in October, is to be four stories high, and will have a frontage of twenty-five feet and a depth of eighty feet; with accommodations for about eighty patients. The erection of this infirmary was rendered necessary by an act of the Legislature, passed at the last session, requiring children suffering from infectious eye disease to be isolated.

Lunacy Commission.—At the meeting of the Philadelphia County Medical Society on September 8, Drs. Mills, French, and Henry, were appointed a committee to visit all asylums for the insane in the county of Philadelphia, in accordance with the request of the State Commission in Lunacy.

The Pasteur Institute has received a donation of 100,000 francs from the Russian Government.

The Second Congress of Russian Physicians will be held in December of this year, in Moscow. The president of the association is Professor Sklifassovski.

Condemnation of a Midwife.—In Altenburg, recently, a midwife was sentenced to imprisonment for two years, because she advised the parents of an infant suffering from ophthalmia not to seek medical advice. The only treatment consisted in local applications of chamomile tea, and the child lost one eye in consequence.

A Two-pound Child.—Dr. S. L. Post reports in *Daniel's Texas Medical Journal* that he delivered a woman, twenty-three years of age, and the mother of three children, of a fœtus weighing only two pounds. There were no pulsations in the cord, which was cold and atrophied, and wholly detached from the placenta. After diligent work the child was made to breathe, and it is now as well as any infant. The woman menstruated regularly during her entire period of gestation, and during the last four weeks flooded so profusely that she was unable to attend to her domestic affairs.

Homo Caudatus.—Dr. Elisseyeff reported the following case at the meeting of Russian physicians held in St. Petersburg in April (*Vratch*, No. 16, 1886). A woman, twenty-three years of age, consulted him on account of a projection in the coccygeal region, which had become very painful from the irritation of a bandage which she had used to prevent its growth. The tail was nearly two inches long and over half an inch broad, and was composed of two vertebral segments covered by fat and hairy integument.

Medical Inspection in Brooklyn.—The Brooklyn Commissioner of Health, Dr. Andrew Otterson, has inaugurated in that city an admirable system of medical inspection and relief in the tenement-house districts, with special reference to the diseases of infants during the heated season. Ten physicians have been appointed, each assigned to a special locality, who are instructed to search for sick children needing attention, and to care for them, furnishing medicine gratuitously where parents are unable to pay for it, and at a reduced price to those who can. They are to note the condition of premises, and report where sanitary improvements are needed, give advice as to healthful manner of living, urge parents to take their children into the fresh air as much as possible, and give orders on the diet dispensaries for proper food when it cannot be obtained otherwise. The salaries of the physicians ($75 a month) are to be paid out of the emergency fund. As a contrast to this beneficent movement in Brooklyn, the New York Board of Appointment this year refused to allow the appropriation devoted last year to similar uses, with the result of a marked increase of infant mortality in the crowded districts of that city.

Repeated Vaccinations in the Incubation Stage of Smallpox.—A Russian medical student, M. Gubert, recently performed a series of experiments with calf vaccine, chiefly making use of dogs as subjects, for the purpose of deciding whether there is any use in vaccinating persons (1) who have already been infected by smallpox, (2) who are in the incubation stage, or (3) in whom the disease may have actually begun to manifest itself. This question, he says, has generally been decided in the negative, on the ground that insusceptibility to smallpox is only obtained thirteen or fourteen days after vaccination—that is, after a period at least equal to that of the incubation stage. Having somewhat modified the method of vaccinating, M. Gubert, who describes his experiments in the *Zemskaya Meditsina*, was able to obtain vaccine vesicles in a shorter time than usual. By repeating the vaccination on three successive days he was able to produce mature vesicles in four or five days. This rapid saturation of the organism with the vaccine virus enabled M. Gubert to arrest the development of the disease in twenty-seven persons, in whom, he states, he was quite certain that the smallpox was incubating, while in twelve others the disease was so modified as to be considered only varioloid. The vaccination was performed in some cases when the temperature had already reached 40° C. It should be remarked that all the experiments were

carried out with calf lymph, so that we are as yet without information as to whether humanized vaccine could be made to "saturate the organism" sufficiently to produce mature vesicles in four or five days. At all events, M. Gubert's observations are interesting, and worthy of repetition by other practitioners.

MEDICAL EDUCATION IN CHINA.—The attempts which have hitherto been made to promote medical education in China have failed, in consequence of the inability of natives to acquire a sufficient mastery of English; these difficulties, however, it is hoped, have at last been surmounted, due largely to the persistent energy of Dr. Myers. About two years and a half ago, through the kindness of some officials in Hong Kong, the matter was laid before the boys at the Central School, and two of the senior scholars, named Chan Chun-kai and Li Tsun-fan, volunteered to go to Formosa, and enter upon the course of study prescribed. The following is the scheme: the subjects for study—anatomy, physiology, elementary surgery, and inorganic chemistry—forming the topics of the first professional examination. No candidate is allowed to present himself unless he produces a certificate from a legally qualified medical man of having studied these subjects for the full period of two years, the examination to be held at either Hong Kong or Shanghai, before a board of the most eminent men within reach. After having passed this, the candidate returns to the hospital, and studies for a further term of two years the following subjects: practice of medicine, midwifery, clinical medicine, and clinical surgery, including operative surgery, use of instruments, medical and surgical, and bandaging, with materia medica and pharmacy. Having obtained a certificate to this effect, and also one of his identity with the candidate who passed the first examination, he would be entitled to present himself before a similar board in either Hong Kong or Shanghai, accordingly as either port had been selected for the first professional. Should he be found proficient, he will then be entitled to receive a certificate of competency or diploma from the hospital setting forth these facts in English, Latin, and Chinese. In accordance with this scheme, Dr. Myers recently brought down the two students, who underwent the examination with the following results: Li Tsun-fan obtained 72.6 per cent., and Chan Chun-kai 70.5 per cent. of possible marks. The presentation by his Excellency, the acting governor, of certificates granted to the two successful candidates for the first professional examination for the license from the David Manson Memorial Hospital, took place on May 28th at the Central School.

AMERICAN CANNED GOODS are being imported into France so rapidly and in such quantities as to alarm the producers of that country. As a result of this, we shall probably see a revivification of all the instances reported in the daily papers in past years of poisoning from these articles, some of which may have been due to the negligence of those engaged in the canning process, but most of which were undoubtedly due to carelessness or want of thought in the consumer. That the contents of some of the millions of cans annually put up for market in the United States should spoil is not to be wondered at, inasmuch as every housewife has the same experience in her domestic preserving. But in most of the instances where sickness has occurred from the consumption of such goods, the color or the taste gave ample warning.

SIR SPENCER WELLS has been elected, by the Section of Scientific Medicine, a Member of the Royal Leopold-Caroline German Academy of Naturalists in Halle.

DISINFECTION OF BILGE-WATER.—Following the results of experimental work conducted in the *Deutsche Reichsgesundheitsamt*, the German navy is instructed to disinfect the holds of vessels and contents with corrosive sublimate. The results of the investigations referred to are:

1. Sublimate destroys the most resistant microörganisms, and it is safe to assume that the special infectious agents that may have become established in a ship-hold can be so destroyed.

2. The sublimate should be evenly distributed. To this end so much should be added to the bilge-water that a distinct mercury reaction can be shown.

3. Complete disinfection is accomplished after eighteen hours.

4. The hold should be washed and pumped dry four successive times. Thereafter only traces of sublimate remain, that can be of no danger to the crew.

5. The ship is not injured by these sublimate disinfections.

DEATH OF ANOTHER PATIENT OF M. PASTEUR.—A child, three years and a half old, is reported, in the *Semaine Médicale*, to have died lately from rabies at Teste. He was bitten by a mad dog on June 14th last. On the 16th, he was brought to Paris, where, during ten days, he was submitted to Pasteur's treatment. After his return to Teste on June 28th, the child was seized on August 12 with the first symptoms of hydrophobia, to which he succumbed in a few days.

LAY DIAGNOSTICIANS.—A druggist in a town of 3000 inhabitants in the northern part of Iowa requires all applicants for liquor to state for what special "necessity for medicine" the liquors are to be used, and their statements are written on the application which they sign, Glancing over this druggist's report for the last month beer is found to have been purchased as a remedy for the following "diseases:" Loss of appetite, general debility, overheating, sour stomach, indigestion, biliousness, headache, rheumatism, sick headache, ague, consumption, dyspepsia.

A majority of the patients were troubled with "loss of appetite," "general debility," or "dyspepsia." For the first-named complaint thirty-three quarts of beer were required, while general debility demanded thirty-four quarts, and the dyspeptics forty-nine quarts. Sixty-nine quarts are reported as having been purchased for "family use." Whiskey also appears to be a remedy for the same line of disorders, as the following list shows: Overheating, ague, loss of appetite, colds, pain in stomach, colic, rheumatism, headache, dyspepsia, sideache, general debility.

Wine and brandy were both needed in cases of overheating, while alcohol was purchased by one man to cure corns. These facts are gleaned from the report of

one druggist only, and, as the law does not require that a record of this kind be kept, probably but few druggists in the State take the trouble to inquire for what disorders the liquors purchased of them are used. The Iowa Board of Pharmacy Commissioners lately issued a cautionary notice to pharmacists in regard to the sale of beer by them, and recent prosecutions of pharmacists who have failed to obey the spirit of the law will probably have a tendency to make them more cautious in the future.

LEASING OF AN UNSANITARY HOUSE.—A very interesting case recently came up in an English court. An owner let to a tenant a house in an unsanitary condition. Shortly after the tenant had taken the house, several members of his family were seized with an illness due, it was alleged, to the escape of sewer gas, and the illness proved fatal to his wife. He claimed damages for the expenses he had incurred in medical attendance and removal, and also for the loss of his wife, at whose death an income of £800 per annum ceased, and the trial ended in favor of the plaintiff, with a verdict for £2240.

An appeal was had and the verdict set aside, and the case now goes to the Court of Appeals. The *Sanitary World*, a high English authority, in discussing the case says: "A person about to take a house is not in a position to know much, if anything, as to the state of the drains. On the other hand, the landlord does, or should, and we take it that it is his duty to see that it is properly trapped and in good order, and should certainly ascertain this before letting his house, and if he fails in this respect we certainly think he ought to be held responsible for any ill effects his tenants may suffer through his negligence."

If, however, the Court of Appeals decides for the defendant, then, the same writer continues, it will "behoove every one who is about taking a house to have it properly surveyed before committing himself by signing an agreement even for a yearly tenancy, or to have a clause inserted in the deed that the drainage of the premises is in perfect order, which possibly would be the better way, as defects in drains are not found out at once. It is possible that the landlord will object to putting in a clause of this kind. We know that it is an unusual one, but that is no reason why it should not be made a usual one, which it would be as well to adopt at once, for even if the plaintiff does appeal, we should have to wait a very long time for the decision, and, in the meantime, houses will have to be taken; therefore, to make sure, and save after-expense, we should advise our readers to follow the course we suggest. If the drainage is all right, surely no owner would object to say so, and have it put in black and white; if he objects to this very reasonable request, his house would be better to remain empty."

A DEFINITION OF GOUT.—Dr. Milner Fothergill gives the following succinct account of the pathology of gout: "When kidneys first appear in the animal kingdom, the form of urinary secretion is uric acid. Uric acid belongs to animals with a three-chambered heart and a solid urine (reptiles and birds). The mammalia possess a four-chambered heart and fluid urine, the form of urinary secretion being the soluble urea. When the human liver becomes depraved or degraded, it has a tendency to form primitive urinary products. To the question, "What is gout?" the answer is: "Gout is hepatic reversion, when primitive urine is formed by a mammalian liver."

NOTES AND QUERIES.

CORRIGENDUM.

IN our abstract of Prof. Wilder's paper on "Cerebral Fissures," September 4th, p. 275, the omission of the word *never* between *has been* and *wholly interrupted*, reversed the author's statement.

MACROSCOPIC OR MEGASCOPIC.

To the Editor of THE MEDICAL NEWS,

SIR: In your report of the recent meeting of the American Neurological Association (August 7th, p. 165, top of second column), I am credited with having "found alcohol to answer all the requirements for the purpose of microscopical examinations" of the human brain. I am sure that I was very careful to say *macroscopical*, because, as stated by me, in *The Medical Record*, February 23, 1884, p. 207, histologists differ respecting the neuro-histological efficacy of alcohol, and I am not prepared to affirm its sufficiency, although I anticipate much when it is properly combined with a low temperature. Since the error is very likely to occur, excepting where, as on p. 142 of THE NEWS, the employment of both *microscopic* and *macroscopic* in the same paragraph protects the latter from the interference of some printer or proof-reader whose "little knowledge" is, in this case, really "dangerous," permit me to suggest that *macroscopic*, as a technical synonym of *gross*, *naked-eye*, etc., be replaced by *megascopic*, which is given by the later dictionaries, has been used by Spitzka, and some other anatomists, and cannot be mistaken for any other word.

BURT G. WILDER, M.D.

ITHACA, N. Y., September 4, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 7 TO SEPTEMBER 13, 1886.

WAKEMAN, WM. J., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for three months' extension, to take effect when his services can be spared in the Department of the Platte.—*S. O. 207, A. G. O.*, September 6, 1886.

WALES, PHIL. G., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for an extension to November 5, 1886.—*S. O. 70, Division of the Pacific*, August 31, 1886.

BANISTER, WM. B., *First Lieutenant and Assistant Surgeon* (recently appointed).—To report by letter to the Commanding General of the Department of Arizona, for assignment to duty.—*S. O. 208, A. G. O.*, September 7, 1886.

WALKER, F. V., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Fort Adams, Rhode Island.—*S. O. 131, Division of the Atlantic*, September 8, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING SEPTEMBER 11, 1886.

WOODRUFF, C. E., *Assistant Surgeon.*—Ordered to Receiving Ship "Vermont," October 4, 1886.

ATLEE, L. W., *Assistant Surgeon.*—Detached from the "Vermont," and ordered to the "Quinnebaug," per steamer of 25th instant.

BOGERT, E. S., *Medical Inspector.*—Detached from the "Trenton," and placed on waiting orders.

FEREBEE, N. McP., *Surgeon.*—Detached from the "Trenton," and placed on waiting orders.

BIDDLE, C., *Passed Assistant Surgeon.*—Detached from the "Trenton," and placed on waiting orders.

SCOTT, H. B., *Assistant Surgeon.*—Detached from the "Trenton," and placed on waiting orders.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIX. SATURDAY, SEPTEMBER 25, 1886. No. 13.

ORIGINAL LECTURES.

ON AZOTIZED ALIMENTS.[1]

A Lecture on Hygienic Therapeutics.

By PROFESSOR DUJARDIN-BEAUMETZ,
OF PARIS, FRANCE.

GENTLEMEN: In a previous lecture we have considered the complete aliments—*i. e.*, foods which, by the proper association of their primordial alimentary principles, suffice for all the needs of nutrition. To-day we shall take up the complex aliments, a subject of much vaster extent, for man, being omnivorous, the variety of foods which he employs for his sustenance is very large.

First in order come foods from the animal kingdom. These constitute the azotized aliments *par excellence*, and comprehend meats, fish, mollusks, and crustaceans.

As for aliments of vegetable origin, we shall study successively cereals, vegetables, and fruits. Fatty foods present three divisions: fats, oils, and butter. Lastly, beverages are divisible into water, aromatic beverages, and spirituous beverages. The following table gives a summary of these divisions:

Complex aliments	Azotized aliments	Meats.
		Fish.
		Mollusks.
		Crustaceans.
	Vegetable aliments	Cereals.
		Vegetables.
		Fruits.
	Fatty aliments	Oils.
		Fats.
		Butter.
	Beverages	Water.
		Aromatic beverages.
		Alcoholic beverages.

Before entering upon the study of each of these divisions, I must say a few words about nutribility and digestibility.

If the first of these terms is easy to define, and means simply the nutritive value of the aliment, being estimated by the quantity of reparative forces which the aliment furnishes, it is not so with digestibility—and of all the definitions which have been given of this word the best is that given by Trousseau, in one of his theses: "The most digestible food is that which furnishes to the economy the largest quantity of reparative elements while demanding the least labor on the part of the digestive organs."[2]

Numerous have been the experiments made to determine the relative digestibility of foods. To mention only those practised on man, some have taken advantage of fistulous openings made in the stomach, the result of accident or surgical operation, as in the case of Beaumont with his Canadian, Alexis St. Martin; of Charles Richet with Marcellin; of Herzen of Lausanne, with Henri Baud. Others, as Londe, Lallemand, and Braune, have made their observations on patients that were the subjects of artificial anus situated in some part of the intestinal canal more or less distant from the stomach. Others, like Goss, of Geneva, have profited by the faculty which they possessed, of vomiting at will; still others, like Leube, have made use of the operation of lavage of the stomach for purposes of experimentation.

All these physiologists aimed to see with what rapidity a substance introduced into the stomach will disappear from the digestive tube. But from the fact that certain aliments when ingested by the mouth rapidly traverse the alimentary canal, it does not follow that they are speedily digested; it is, above all, necessary that they shall yield to nutrition the primordial alimentary principles which they contain. The state of cohesion of foods has a great deal to do with their digestibility; the feebler this cohesion, the easier of digestion is the substance. This explains why it is that the flesh of young animals is more digestible than that of old—*i. e.*, veal than beef, chicken than old fowl. We see, also, why it is that meat-powders, by reason of their state of minute division, are more readily assimilated than meat. We also understand from this fact the necessity of mastication, and how it is that when persons are deprived of their teeth they are likely to become dyspeptical. This is what you will often observe in old people, and in people who eat too rapidly. Mialhe considers imperfect mastication as the most frequent cause of indigestion. I am inclined to think that he is not far from right, and will show you how you can easily remedy this evil in certain cases of dyspepsia by means of special instruments.

I place before you two of these apparatuses, called *meat pulpifiers*, or *pulverizers*, which are of great service in these forms of dyspepsia. They are both of Collin's invention. One is designed to reduce to pulp a great quantity of raw meat. The other is an instrument for the table, which is applicable to cooked meat. I shall say but little about the first of these apparatuses, which, despite the ease and thoroughness of its working, is too costly for ordinary use. The other instrument, called the *table pulpifier*, is a very simple and convenient one. I have ordered it in a great many cases, and it has always given good satisfaction. As you see, it is a veritable meat shearer. (Fig. 1.)

You place the piece of roasted meat in the open part of the apparatus, and cover it with the movable lid; you close the instrument with your left hand, and with your right you work back and forth the handle of the mobile lid, and in a few seconds you have in your plate a meat-pulp of exceeding fineness, which has lost nothing of its aroma or savor.

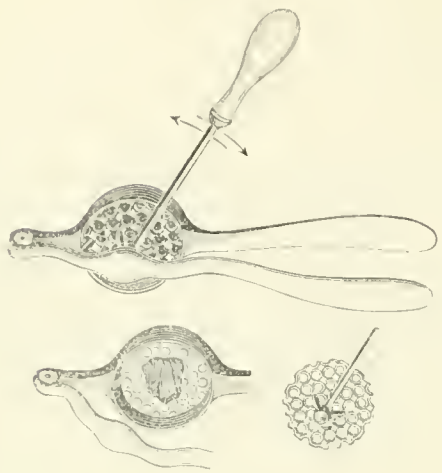
The other instrument has been modified by Galante, under the direction of Debove, from an American apparatus in use by pork-butchers. It is a very handy instrument, easily taken to pieces and cleaned, and acts

[1] Translated, from advance sheets, by E. P. Hurd, M.D., of Newburyport, Mass.

[2] Trousseau, Thèse de Concours, 1838.

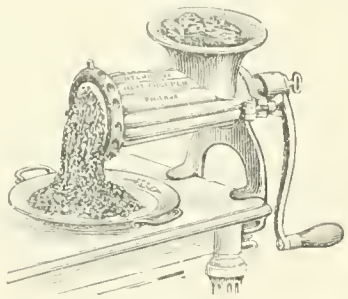
equally well on both raw and cooked meats; with cold boiled meat it produces a fine meat powder, with raw

Fig. 1.



meat, a homogeneous pulp. You here see the ease with which it works, and how perfectly the meat which enters at the fnnnel is converted into pulp. (Fig. 2.)

Fig. 2.



I cannot too highly recommend these instruments whenever you have to do with dyspepsia from imperfect mastication, or the so-called atonic dyspepsias; you will by this means favor the peptonization of albuminoid aliments and render them more assimilable.

Nutribility and digestibility rarely go together. We may even say that there is generally opposition between the two terms, the most digestible foods being ordinarily the least nutritive. Thus, fat, which plays so prominent a reparative part in our economy, is one of the alimentary principles the dissociation and assimilation of which are the most slow and difficult. Fatty aliments are very nutritious, but of little digestibility, and you will find sufficient confirmation of this fact in the details into which I am going to enter *à propos* of the different complex aliments.

But I shall now in this connection acquaint you with the results of some very curious experiments recently made by Bikfalvi. This physiologist in operating on dogs, and in employing the old method of Spallanzani, which consists, as you know, in making animals swallow little bags containing alimentary substances, has shown that in the dog the following quantities of certain aliments were digested in the space of two hours:

Uncooked casein	25	per cent.
Cooked white of egg	48	"
Uncooked cervical ligament	49.5	"
Uncooked liver	52.5	"
Uncooked kidney	55.33	"
Cooked beef	58	"
Raw unstriped muscular tissue	68.5	"
Raw beef	79.5	"
Raw hyaline cartilage	81	"
Raw fibrin	97.5	"
Uncooked pulmonary tissue	99.5	"
Raw tendons	99.5	"

Hence Bikfalvi concludes that gelatinous substances are the most speedily digested in the stomachs of carnivora. But these substances, if they are very digestible from the point of view of the stomachal digestion, furnish a very small sum of reparative elements to nutrition.

I pass now to the study of foods derived from the animal kingdom; we have divided them, as you know, into meats, fish, crustaceans, and mollusks. Do not expect of me a complete study of the various kinds of meat, and what I have here to present will be in the form of a brief summary.

Here is the analysis of a fillet of beef, according to Berzelius. You see the prominent part which water has in its composition. I shall return to this point when I come to speak of meat powders, as compared with raw meat, the former in equal bulk being much the more nutritious.

Muscular fibrin	16
Albumen	2
Gelatine	2
Osmazome and alkaline lactates	3
Water	77
	100

Cast your eyes over the following table borrowed from Moleschott. It gives you the centesimal composition of the different meats:

	Beef.	Veal.	Pork.	Venison.	Birds in general.
Soluble albumen and hæmatin	2.25	2.27	1.63	2.10	3.13
Musculine and like principles	15.21	14.30	15.50	16.68	17.13
Substance gelatinizing by heat	3.21	5.01	4.08	0.50	1.40
Fats	2.87	2.56	5.73	1.90	1.95
Extractive matters	1.39	1.27	1.29	2 52	1.92
Creatine	0.07	.. ...	.....	.....	0.20
Ash	1.60	0.77	1.11	1.12	1.30
Water	73.39	73.75	70.66	76.17	72.98
					100.00

The nutritive value of these meats is estimated by the quantity of musculine which they contain. This is almost equal for all the meats, oscillating between 14 and 16 per cent. As the fat was removed from these meats prior to analysis, we have not here exactly their nutritive value, for in this respect pork should have the first place, which, in the table, is assigned to venison. The latter meat is especially rich in nutritive elements, from the fact that it is not deprived of its blood when slaughtered, as is the case with the domestic animals, and this circumstance explains why game is so much more nourishing than butcher's meat.

I ought here to make a special mention of horse-flesh, which is extremely nutritious, and in respect of its nutritive value resembles venison. The consumption of this meat increases every day, as you can judge from the following table, which gives the number of horses sold for food in the shambles of Paris during the last ten years.

Years	Number of horses butchered for food.
1876	8,713
1877	9,908
1878	10,800
1879	10,081
1880	8,602
1881	8,684
1882	10,365
1883	12,267
1884	14,432
1885	16,137

I can but commend this extension given to the consumption of horse-flesh, which is a very nourishing meat, and renders great service to the poor population of our large cities.

Meats are prepared in a thousand ways, and the question has long been discussed whether cooking adds to their nutritive value. This question seems to-day to be decided, and if cooking does not augment the nutritiousness of meats, it nevertheless add to their digestive value by the appetency which it excites in persons who make use thereof. I will explain :

The primitive man used to eat raw meat, but as soon as he discovered fire, cooking came into fashion. The Troglodytes, the prehistoric men of Vezère, ate roasted meats, and we have the proof of this in the bones dug up at the entrance of their caves. This preference for cooked meats is due to the agreeable odor, and to certain products, such as osmazome, which are formed during cooking, and which constitute an aroma which promotes a more abundant secretion of gastric juice.

The popular saying, "one's mouth waters at the sight of a good meal," is absolutely conformable to the data of physiology, and we have here a phenomenon of reflex origin, which takes place whenever we see or smell savory meats. The salivary secretion is not the only one which is augmented under such circumstances; there is also a hypersecretion of gastric juice, as is noticed in persons who are subjects of a fistula of the stomach. This reflex complexus constitutes what has been described under the name of *appetency*, a condition which is not realized in the case of raw meat, which is not agreeable to taste, or sight, or smell, and is repugnant to most patients.

At the same time, raw meat has rendered and still renders us great service from a therapeutic point of view, and since first Weiss of St. Petersburg showed us all the advantages which we might derive from this kind of food in affections of the stomach and intestines, it has come into general use, not only in diarrhœa and certain forms of dyspepsia, but even in consumptive complaints, and, in particular, in pulmonary tuberculosis, where it has proved to be an excellent nutrient and restorative agent. Hence it is that the modes of preparation of raw meat have been multiplied.

With regard to this aliment, the most appropriate form for its administration to young children is the combination with fruit jelly, whether of currants or prunes, as in Trousseau's famous *Conserve of Damas*, which he prescribed so often in infantile diarrhœas; such a mixture is not, however, so suitable for adults, hence other expedients have been resorted to to render the food palatable. Some propose to administer it in little boluses about the size of bullets, a great many of which are to be swallowed during the day, or the raw meat is incorporated with broth, or in a kind of porridge, called by Laborde, *medicinal tapioca porridge*. To prepare it, you incorporate with a thin and well-flavored porridge of tapioca from one to two ounces of raw beef; you have thus a mixture which resembles, by its color, tomato soup, and is quite agreeable to the taste ; you can also combine the raw meat with mashed eggs, potato stew, or spinach.

But whatever be the procedure adopted, it is necessary that the meat shall be reduced to a very fine pulp, and for this purpose you can make use of a simple knife, or of the special apparatuses of which I have just spoken.

As you are well aware, the ingestion of raw meat may be a cause of tapeworm in the human subject, and doubtless the frequency of the unarmed tænia of late years is due to the use of raw meat; therefore, when Debove proposed to substitute meat-powder, there was a general disposition to accept the substitution.

I cannot, in this place, repeat what I have many times said as to the preëminent utility of meat-powders, both in my Clinical Therapeutic lectures and in my *New Medications*.[1] The advantages of these powders result from that molecular state which permits their easy peptonization, and from their special nutritiousness, since they are deprived of the 77 per cent. of water which fresh meat contains. Quite recently, Poincarré has taken up again this question of the nutritive value of meat-powders, and the conclusions which he has deduced from his experiments are contradictory to the results which Debove and I have obtained, and, I believe, to his own researches.[2]

Poincarré's experiment consisted in taking three dogs and subjecting them during equal and alternate periods, at one time to the ordinary meat-diet, at another to a diet of bread soaked in plain water, at another to a diet of meat-powder, at still another to a mixed diet of meat-powder and bread; successive weighings enabled him to note the results obtained. These results were as follows: the meat-powder, while possessing a nutritive value superior to that of bread, even when accompanied by broth, was inferior to fresh meat. But Poincarré takes the pains to tell us that the dogs loathed the meat-powder, and that it was only when driven to extremities of hunger that they would eat it. So that, for the experiment to be a fair one, he would have been obliged to perform forced feeding, in which event he would have seen the incontestable advantage of meat-powder, an advantage which no one to-day disputes. The results which Debove has witnessed, those recorded in the thesis of my pupil, Pennel, those of Broca and Wins, and those which I have inva-

[1] Diseases of the Stomach and Intestines Wm. Wood & Co) p. 38. New Medications (G. S. Davis), chap. iii.

[2] Poincarré, Experimental Researches on the Nutritive Value of Meat Powders; Annales d'Hygiène, 1886.

riably obtained, have recently been confirmed by Peiper, at the clinic of Greifswald.

If the dog loathes the powder of meat, it is the same with man, and it is only by artifices that we can render this aliment acceptable. These artifices consist, as you know, in incorporating the meat-powder with chocolate, or in giving it in the form of meat-grog, and which is made in the following way: Place in an empty bowl a couple of tablespoonfuls of meat-powder, add one or two tablespoonfuls of old rum or Bourbon, and half a pint of milk or water, sweetened sufficiently.

The fabrication of meat-powder is, to-day, carried out on a large scale; some of these preparations are peptonized before being delivered to the market. You can easily make it yourself if you prefer, by taking a certain quantity of boiled meat, cutting it into little pieces and drying it thoroughly by a water-bath; the desiccated product is then reduced to a powder in a coffee-mill, or in Galante's apparatus. These meat-powders do us excellent service in forced alimentation, as I shall hereafter have occasion to show you.

There has been much difference of opinion as to the alimentary value of broth, some denying its nutritiousness, which others persist in affirming. When you glance over the following analysis by Chevreul, you will see that broth by itself is of little nutritive value, containing 98 per cent. of water, and only 1.6 per cent. of organic matter:

Water	985.600	per 1000.
Solid organic substance dried in vacuo at 20° C.	16,917	28 per 1000.
Soluble salts, chlorides, phosphates, and sulphates of potash and soda	10,720	
Phosphates of magnesia and lime (insoluble, or but slightly soluble)	0.539	

Hence, from this point of view, we might affirm that soup is not nutritious, but, as Schiff has shown, its *rôle* is quite different. Soup is a peptogenous substance which increases the secretion of gastric juice, and the experiments of Herzen of Lausanne are, in this respect, decidedly confirmatory of those of Schiff. By experiments made on a man who was the subject of a gastric fistula (Herzen, *Stomachal Digestion*, Lausanne, 1886), the former obtained the following results, which put in clear light the value of "peptogens" in digestion.

Duration of the digestion.	Percentage of albumen digested.	
	Without peptogens.	With peptogens.
One hour	2.33	12
Two hours	23.66	45
Three hours	51.00	76

You know that dextrine, like broth, possesses these peptogenous properties. We have here the scientific justification of a common culinary custom of adding bread to broth, and particularly toasted bread, which, by the presence of dextrine, augments the peptogenous properties of the broth. It is on the same principle that soup is an excellent preparation for the meal that is to come, as it augments the secretion of gastric juice necessary for digestion.

I shall not here take up the various formulæ which have been prepared for making broth. At the same time, as you will often be consulted as to the proportions respectively of meat and of water to employ, I will give you a few suggestions. For a quart of water the quantity of meat should vary between half a pound and a pound, according as meat with bones or without bones is used. The following is the formula of our hospital broth:

Take of

Raw meat freed from bones	1 kilo.
Water	4 litres.
Fresh vegetables	400 grammes.
Common salt	10 grammes.

In England great use is made in the hospitals of beef-tea, which is made in the following way: Take one pound of beef freed from all fat, add its own weight of water and boil for several minutes, then strain with compression; add salt and other seasoning which may be deemed necessary, the taste of the product being always insipid.

Lastly, we make great use of a kind of broth called "American bouillon," which is of considerable nutritive value, and is made as follows: Place in an iron kettle alternate layers of meat and of vegetables, cover the pot, and subject the whole, without the addition of water, to prolonged cooking over a hot water-bath; at the end of six hours or so, you strain off the contents of the kettle, and you thus obtain a true meat-jelly, which is very palatable and nourishing, and which you may administer by itself, a small cupful at a time, or dissolved in ordinary broth.

I shall have finished what I purposed to say about meats, after making a brief allusion to blood.

Taking too literally the assertion in Leviticus, "The life of all flesh is the blood thereof," many have thought that blood must be an exceedingly nutritious food, and that it might be advantageously applied to the treatment of a great number of affections, and, in particular, anæmia and all wasting diseases. Various ways have been proposed for thus utilizing blood as food: some have recommended that the blood shall be drank just as it flows from the living animal, and hence it is that we see at our slaughter-houses, every morning, great numbers of people flocking there to drink the warm blood of the animals as they are killed. Others, as Paul Bert, Regnault, Guerder, and Le Bon, have counselled desiccated blood, and have made thereof powders which are now in use, like the meat-powders.[1] In Italy, Emilio, of Naples, has given the name of *trefusia* to this powder of dried blood, and he has obtained from it good effects as a food and as a medicament. Still others, as my pupil, Deschiens, have extracted from blood the coloring part of the globules, the hæmoglobin, and have made preparations of it, which you have seen used to advantage in my hospital.

As an exclusive aliment, blood is absolutely insufficient, and the experiments of Magendie and of Payen have shown that, despite the ingestion of 1000 grammes of blood per day, their dogs succumbed to starvation

[1] Guerder: On the Use of Blood powder in Forced Alimentation, Therapeutic Gazette, Feb. 1884; D. Emilio, Trefusia, Naples, 1886.

about the twenty-fifth day when fed on blood alone. I recognize, however, that in the treatment of anæmia certain of these preparations, and in particular those of hæmoglobin, are perfectly indicated, but here it is not as a food, but as a medicine, that such preparations do good.

Meats are subjected to the action of the gastric juice, and when this secretion is not sufficient to peptonize them, the work is completed by the pancreatic juice. Richet has given us a good description of the action of gastric juice on the muscular fibril: First, there is imbibition, then dissociation of the fibrils, rupture of the sarcolemma, and finally, the myolemma itself is attacked and converted into fibro-peptone. The portions which escape the action of the gastric juice pass into the intestine, and there undergo the action of the myopsin, which completes the work of peptonization; and if the meat does not contain too much of foreign substances, such as tendons and cellular fibres, the whole passes into the circulation in the state of peptone, leaving very little waste.

Schmidt-Mulheim has studied this question of the residue which albuminoid substances leave when they are digested. He took horse-flesh, well freed from fat and from tendons; this meat was hashed, weighed, and the nitrogen in it was estimated; it was cooked a few minutes; it was then fed to a dog which was killed at the end of a certain time; the contents of the stomach and intestine were then analyzed with the following results:

	Dogs killed after			
	1 hour.	2 hours.	4 hours.	12 hrs.
Stomach dissolved:				
Albumen	2.26	1.79	2.08	0.04
Peptone	3.08	3.65	3.31	0.08
Meat not attacked	50.38	24.49	25.92	0.12
Intestine dissolved:				
Albumen	0.48	0.13	0.43	0.20
Peptone	0.51	0.31	0.49	0.82
Meat not attacked	1.91	1.64	1.91	1.93
Meat ingested (calculated as albumen)	61.15	51.01	65.81	61.70
Albumen absorbed	2.40	18.48	31.19	58.51

These azotized substances are eliminated in the form of urea and uric acid. I cannot pursue this subject further now, requiring, as it does, certain details which will more properly come under the head of superalimentation, and I pass on to the second group of azotized aliments, namely, that of fishes.

From the point of view of its composition, fish resembles meat, and it may be affirmed that its nutritive value is nearly the same. In my *Diseases of the Stomach and Intestines*[1] (page 26), I have given Prof. Almen's table, which shows that, as compared with beef, the flesh of fish is almost as rich in protein matters. The following table from Moleschott shows the similarity which exists between the different white meats, chickens, birds, and fishes:

	Chicken.	Birds in general.	Carp.	Salmon.
Soluble albumen and hæmatin	3.03	3.13	2.93	4.34
Musculine and the like, matter gelatinizing by boiling	16.69	17.13 1.40	10.21 2.02	10.96
Fat	1.42	1.95	9.84	4.79
Extractive matters	0.94	1.92	1.45	1.78
Creatine	0.32	0.20	.....	.....
Ash	1.38	1.30	2.00	1.26
Water	76.22	72.98	78.54	76.86

[1] American edition.

Fishes are divided, from a nutritive point of view, into three groups: fishes with white meat, such as the whiting and the sole; fishes with yellow meat, like the salmon; and fishes with fatty meat, like the eel. Here, too, as in the case of meats generally, it is the fatty meats that are the most nutritious, while they are, at the same time, the least digestible.

The great nutritive value of fish explains why it is that entire populations are able to subsist on this food alone. This ichthyophagy has its advantages and disadvantages; it has been maintained that it predisposes to diseases of the skin, and, we see, even to-day, the school of St. Louis exclude all fish from the dietary of individuals affected with, or predisposed to, cutaneous diseases, while the school of Hebra is much less rigid in this respect, and here it doubtless has reason on its side.

There is no scientific evidence that an exclusive fish diet favors affections of the skin, and if the Norwegians are notoriously subject to leprosy (*spedolskeld*), this is due not to the fact that they live on fish, but to their filthy habits, their utter neglect of the care of the skin, and the rank, greasy garments which they wear.

It has, also, been affirmed that fish, by reason of its richness in phosphorized compounds, augments the reproductive faculties in persons who make free use of this diet, and in support of this statement we are referred to the extraordinary fertility of fish-eating communities. You all know the Oriental story, cited by Brillat-Savarin, where some dervishes who had made a vow of chastity, and who had resisted the charms of a seraglio, and this, despite a full azotized diet, succumbed in an astonishing manner when subjected to a regimen composed exclusively of fish and oysters. For my part, I do not believe in these special properties attributed to a fish diet, and if the populations of our sea coasts are extraordinarily prolific, this is due to other causes than those supposed. Equally unfounded is the notion that piscatorial food favors the predominance of one sex over another, a predominance which Balzac has expressed in the following words: "Salt water fish give girls, butcher's meat produces boys." There are no statistical data in support of this view.

Oysters constitute a very digestible food, and this is due largely to the fact that the "dainty" part of the oyster—the eatable portion—is composed almost exclusively of the liver. The mere crushing of the hepatic parenchyma by the teeth brings the contained glycogen in contact with its digestive ferment, the hepatic diastase, so that the substance of the oyster becomes self-digesting, imposing but little work on the digestive tube. But if its digestibility is great, its nutritive value is feeble. Payen has, in fact, shown that a dozen oysters, weighing 1410 grammes, give in nutritive substance 111.6 grammes, representing 2.3 grammes of nitrogen, or one-tenth of the daily ration of a man, so that ten dozen of oysters would be needed to furnish the azotized elements of a day's alimentary supply.

Payen has also analyzed the integral water of oysters, of which some persons are so fond, and he finds it different from ordinary sea-water in being albuminous, containing 0.86 per cent. of nitrogen. He therefore concludes that oyster-water may be useful as a nutrient, His analysis is as follows:

	First analysis.	Second analysis.
Water	95.38	95.71
Salts (by incineration)	3.02	4.24
Azotized organic substances	0.56	4.24
Organic non-azotized substances	0.52	4.24
	100.00	100.00

[In some parts of the world, and in particular on the coasts of New England, the clam abounds in the flats of river-mouths which are every day overflowed by the tide, and in these localities this little bivalve forms an important article of food. The esculent properties of the clam resemble those of the oyster. Clam-water is an admirable albuminous beverage, suiting the weakest stomachs, and being often tolerated when no other nutrient is borne.]

The mussel is also a bivalve mollusk much used for food. From the point of view of its richness in nitrogen, it is inferior to the oyster—nor is this all, the mussel is likely to contain a poisonous principle.

The danger of poisoning from mussels has given rise the last few years to some very interesting researches.

Brieger, more successful than Salkowski, has isolated a toxic principle, to which he has given the name of *mytilotoxine*, and which has the following composition: $C_6H_{15}NO_2$. He considers this toxic principle as belonging to the group of ptomaines, and believes that these ptomaines form in the liver of these mollusks. Schmidtmann, Virchow, and Salkowski have regarded this shell fish as having a curarizing action, and Langgaard has shown that one of the most powerful antidotes for this toxic agent is caffeine.

By the side of these lamellibranchiate mollusks of the genera Ostria and Mytilus, we must place a gasteropod mollusk, a land snail, to which has been given the name of *poor man's oyster*. I refer to the *Helix pomatia*, or the common snail of the vines. This snail is not only employed for food, but has been supposed to be of use medicinally.

Payen has given us a very complete analysis of the eatable portion of this mollusk, which would seem, from a nutritive point of view, to be superior to the oyster and mussel. The table is as follows:

	Oyster.	Mussel.	Snail.
Water	80.385	75.74	76.17
Nitrogenous matter	14.010	11.72	16.25
Fatty matter	1.515	2.42	0.953
Salts (by incineration)	2.695	2.73	2.925
Non-azotized substances	1.395	7.39	4.602
	100.000	100.00	100.000

As for the therapeutic properties, and in particular, as for the curative virtues of the snail in bronchitis and in consumptive affections of the chest, I do not know on what scientific basis such properties can be affirmed. Figuier has, indeed, pretended that the snail contains a sulphuretted principle, which he has described under the name of *helicine*, but there is nothing to confirm this statement. However this may be, we have in this mollusk a popular remedy, employed especially in the country, and administered with sugar, in the form of confections or as a broth. This snail broth is made in the following way:

Take of

Edible snails	120 grammes.
Water	1000 "
Capillary leaves	5 "

The snails are placed in the water, which is subjected for two hours to the heat of a water-bath, and the capillary leaves are added and infused for a short time.

The confections, mucilages, and syrups are made by rubbing up the snails in a mortar along with five times their weight of sugar; the resulting liquid is reduced in a water-bath to the desired consistency.

By the side of these mollusks we may place certain crustaceans, represented by the cray fish; the lobster, and the spiny lobster (*langouste*).

Payen has given us a very good analysis of the various eatable parts of the lobster, which shows the considerable nutritive value of these podopthalmian crustaceans, of which the cray fish is the type. If these crustaceans are very nutritive, they are also very indigestible, and they favor, to a certain extent, the appearance of erythematous eruptions, and, in particular, of urticaria in the gouty and rheumatic, hence they should be eaten with moderation.

	Meat.	Soft part	Eggs.
Water	76.618	84.318	62.983
Azotized matters	19.170	12.140	21.892
Fatty matters	1.170	1.144	8.234
Salts (by incineration)	1.823	1.749	1.998
Non-azotized matter and loss	1.219	0.354	4.893

From this analysis we see the great nutritive value of the eggs of the lobster. This remark is also applicable to the eggs of fishes as well, and the spawn of certain fishes, as that of the sturgeon, constitutes a very nutritious aliment, which goes by the name of *caviar*.

I shall finish this lecture by a brief allusion to the edible reptiles, which consist of the tortoise and the frog.

Despite the sneers of the English, who call us a nation of frog-eaters, it is a fact that we make but a very moderate usage of the *rana esculenta*, which really hardly deserves its epithet of *esculent*, for its nutritive value is very feeble, and inferior to that of our lighter meats. As for the turtle, the consumption of this reptile is also very limited; at the same time, Payen has shown that the flesh of the turtle contains in every 100 parts, 16.25 of nitrogenous matters representing 2.5 of nitrogen.

I have now concluded the study of the azotized substances which serve for the food of man, and whose sum constitutes the azotized regimen. The advantages and disadvantages of this regimen will be considered when I come to speak of alimentary rations. In the next lecture I shall take up the subject of vegetable diet and of fatty foods.

CASES OF MILK-POISONING, WITH REMARKS ON TYROTOXICON.

By WILLIAM K. NEWTON, M.D.,

SANITARY INSPECTOR AND ANALYST TO THE STATE BOARD OF HEALTH OF NEW JERSEY,

AND

SHIPPEN WALLACE,

ANALYST TO THE STATE BOARD OF HEALTH OF NEW JERSEY.

INQUIRIES concerning the cases of illness at Long Branch due to noxious milk have been so very numerous and solicitous, and the interest manifested in the subject has been so great, that we feel warranted in publishing the following account of the investigation carried out to ascertain the cause of the trouble.

It is seldom that the investigator has the opportunity to trace to its source the milk or other food that has caused sickness, but we have, in these cases, been very fortunate in being able to follow every step in the management of the milk, from the farm to the consumer. In similar cases of poisoning by cheese and ice cream which have been investigated by Vaughan and others, although chemical analysis has revealed the probable cause and the toxic substance has been isolated, some link in the chain of evidence has been wanting. But the history we are now to relate seems unique, because every portion of the evidence is before us and we are able to demonstrate what the injurious material really is, besides offering other proof as to the possible cause of the formation of this substance.

On August 7th twenty-four persons at one of the hotels at Long Branch were taken ill soon after supper. At another hotel, on the same evening, nineteen persons were seized with the same form of sickness. From one to four hours elapsed between the meal and the first symptoms. The symptoms noticed were those of gastro-intestinal irritation, similar to poisoning by any irritating material—that is, nausea, vomiting, cramps, and collapse; a few had diarrhœa. Dryness of the throat and a burning sensation in the œsophagus were prominent symptoms.

While the cause of the sickness was being sought for, and one week after the first series of cases, thirty persons at another hotel were taken ill with precisely the same symptoms as noticed in the first outbreak.

Drs. S. H. Hunt and Williams, of Long Branch, attended all the patients on both occasions. Dr. Hunt kindly furnishes the following account of the cases:

"The symptoms were very similar to those of any case of gastro-intestinal irritation. I was impressed with this fact although there was an unusual absence of diarrhœa in many of the cases. A few would have several active movements and no vomiting, the poison or cause being thus immediately removed; while in many cases it produced violent emesis which was followed by collapse and failure of the heart's action. Both occurred in a few instances, but the rule was the persistent and obstinate nausea and vomiting, with a tendency to exhaustion and collapse as seen in cholera. The convalescence and recovery were prompt, and in a few hours all were in their usual health, and no untoward symptoms followed the attack." The remedies employed were those usually indicated in such cases, such as antacids, stimulants, and in a few instances small hypodermatic injections of morphia were administered.

When the news of the outbreak was published one of us immediately set to work, under the authority of the State Board of Health, to ascertain the cause of the illness. The course of the investigation was about as follows:

The character of the illness indicated, of course, that some article of food was the cause, and the first part of our task was to single out the one substance that seemed at fault. The cooking utensils were also suspected, because unclean copper vessels have often caused irritant poisoning. Articles of food, such as lobsters, crabs, blue fish, and Spanish mackerel, all of which at times, and with some persons very susceptible to gastric irritation, have produced toxic symptoms, were looked for, but it was found that none of these had been eaten at the time of the outbreak. The cooking vessels were examined, and all were found clean and bright and no evidence of corrosion was presented.

Further inquiry revealed the fact that all who had been taken ill had used milk in greater or less quantities, and that persons who had not partaken of milk escaped entirely; corroborative of this it was ascertained that those who had used milk to the exclusion of all other food were violently ill. This was prominently noticed in the cases of infants fed from the bottle when nothing but uncooked milk was used. In one case an adult drank about a quart of the milk, and was almost immediately seized with violent vomiting followed by diarrhœa, and this by collapse. Suffice it to say that we were able to eliminate all other articles of food and to decide that the milk was the sole cause of the outbreak.

Having been able to determine this, the next step was to discover why that article should, in these cases, cause so serious a form of sickness.

The probable causes which we were to investigate were outlined as follows: (1) Some chemical substance such as borax, boric acid, salicylic acid, sodium bicarbonate, sodium sulphate, added to preserve the milk or to correct acidity. (2) The use of polluted

water as an adulterant. (3) Some poisonous material accidentally present in the milk. (4) The use of milk from diseased cattle. (5) Improper feeding of the cattle. (6) The improper care of the milk. (7) The development in the milk of some ferment or ptomaine, such as tyrotoxicon.

At the time of the first outbreak we were unable, unfortunately, to obtain any of the noxious mik, as that unconsumed had been destroyed, but at the second outbreak a liberal quantity was procured.

It was soon ascertained that one dealer had supplied all the milk used at the three hotels where the cases of sickness had occurred; his name and address having been obtained, the next step in the investigation was to inspect all the farms, and the cattle thereon, from which the milk was taken. We also learned that two deliveries at the hotels were made daily, one in the morning and one in the evening; that the milk supplied at night was the sole cause of sickness, and that the milk from but one of the farms was at fault. The cows on this farm were found to be in good health, and, besides being at pasture, were well fed with bran, middlings, and corn-meal.

So far, we had been able to eliminate as causes diseased cattle and improper feeding, and we were then compelled to consider the other possible sources of the toxic material.

While the inspection of the farms was being made, the analysis of the milk was in progress. The results of this showed that no chemical substance had been added to the milk, that it was of average composition, that no polluted water had been used as a diluent, and that no poisonous metals were present. This result left us nothing to consider but two probable causes: improper care of the milk, and the presence of a ferment.

As to the former, we soon learned much. The cows were milked at the unusual and abnormal hours of midnight and noon, and the noon's milking—that which alone was followed by illness—was placed, while hot, in the cans and then, without any attempt at cooling, carted eight miles during the warmest part of the day in a very hot month.

This practice seemed to us sufficient to make the milk unpalatable, if not injurious, for it is well known that when fresh milk is closed up in a tight vessel and then deposited in a warm place, a very disagreeable odor and taste are developed. Old dairymen speak of the "animal heat" as an entity, the removal of which is necessary in order that the milk shall keep well and have a pleasant taste. While we do not give this thing a name, we are fully convinced that milk should be thoroughly "cured" by proper chilling and aëration, before it is transported any distance or sold for consumption in towns or cities.

This opinion is based on a study of the methods prevalent among experienced dairymen, who ship large quantities of milk to our great cities. The usual practice is to allow the milk to stand in open vessels, surrounded by ice or cold water, for from eight to twelve hours before transportation, and when placed on the cars it has a temperature of from 50° to 60°, and is delivered to the consumers in a perfectly sweet condition. The city of New York receives about 200,000 gallons each day from the surrounding country, and much of it brought in by the railroads has been on the cars for a time varying from six to twelve hours, yet we seldom hear of any of this milk undergoing the peculiar form of fermentation set up in the Long Branch milk. We may account for this by assuming that the proper care of the milk after it was taken from the cow, and the low temperature at which it was kept, have prevented the formation of any ferment; this opinion seems to be endorsed by all dairymen and managers of large creameries with whom we have consulted. They all agree in stating that milk maintained at a low temperature can be kept sweet and in good condition for many days.

We have dwelt on this branch of our topic somewhat extensively, because we are fully persuaded that the improper care of the milk had much to do with the illness it produced.

The results of our inquiry having revealed so much, we next attempted to isolate some substance from the poisonous milk, in order that the proof might be more evident. A quantity of the milk that had caused sickness in the second outbreak was allowed to coagulate, was then thrown on a coarse filter, and the filtrate collected. This latter was highly acid, and was made slightly alkaline by the addition of potassium hydrate. This alkaline filtrate was now agitated with an equal volume of pure, dry ether, and allowed to stand for several hours, when the ethereal layer was drawn off by means of a pipette. Fresh ether was added to the residuum, then agitated, and, when separated, was drawn off and added to the first ethereal extract. This was now allowed to evaporate spontaneously, and the residue, which seemed to contain a small amount of fat, was treated with distilled water and filtered, the filtrate treated with ether, the ethereal solution drawn off and allowed to evaporate, when we obtained a mass of needle-shaped crystals. This crystalline substance gave a blue color with potassium ferricyanide and ferric chloride, and reduced iodic acid. The crystals, when placed on the tongue, gave a burning sensation. A portion of the crystals was mixed with milk and fed to a cat, when, in the course of half an hour, the animal was seized with retching and vomiting, and was soon in a condition of collapse, from which it recovered in a few hours.

From these experiments with this material, we were able to identify it as *tyrotoxicon*, a substance discovered and described by Prof. Victor C. Vaughan, of the University of Michigan. Although much has been published during the past two months concerning this substance, it will not be unprofitable, in this connection, to review the statements of the chemist who first described it.

In the year 1883 about three hundred persons were taken violently ill after eating cheese, and Prof. Vaughan was requested by the Michigan State Board of Health to ascertain the cause. While engaged with this work, he discovered the substance which answered to the tests mentioned above, and which he called "tyrotoxicon" (cheese poison).[1]

[1] Ein Ptomain aus giftegem Käse. Zeitschrift für Physiologische Chemie, Band x. Heft 2, 1886.

During June, of this year, Prof. Vaughan was able to obtain this substance from ice-cream that had sickened some eighteen persons.[1]

We are now able, for the first time, to demonstrate this new substance in poisonous milk, thus endorsing the views of Vaughan, who stated in his report that, doubtless, it would be discovered in cases in which milk had caused sickness.

As to the chemical character of tyrotoxicon, we have little to say, for a sufficient amount for an ultimate analysis was not obtained by us. Vaughan says: "The circumstances under which tyrotoxicon develops require further study. As has been shown, it may develop in normal milk, kept in a clean bottle for three months; but it is evident that in some instances it appears much earlier." (In our cases it appeared in five hours.) "The production of this ptomaine is, in all probability, due either directly or indirectly to the growth of some micro-organism."

From a close analysis of the facts in the cases recorded in this article, we are of the opinion that the substance is allied, chemically, to butyric acid; that it is formed in the milk by fermentation; and that its formation may be prevented by keeping the milk at a low temperature; or by properly cooling the milk soon after it is drawn from the cow. It seems, also, important that the so-called "animal heat" be allowed to escape. Boiling may dissipate the poison from milk that contains it; this opinion is based on the fact that tyrotoxicon is changed and driven off at a temperature of 180° F.

Conclusions.—We are justified in assuming, after weighing well all the facts ascertained in the investigation, that the sickness at Long Branch was caused by poisonous milk, and that the toxic material was tyrotoxicon.

The production of this substance was no doubt due to the improper management of the milk—that is, too long a time was allowed to elapse between the milking and the cooling of the milk; the latter not being attended to until the milk was delivered to the hotel; whereas, if the milk had been cooled immediately after it was drawn from the cows, fermentation would not have ensued, and the resulting material, tyrotoxicon, would not have been produced.

ON THE TREATMENT OF PAINLESS FACIAL SPASM.[2]

BY WHARTON SINKLER, M.D.,
PHYSICIAN TO THE INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

THE treatment of tic non-douleureux is very unsatisfactory. Erb[3] remarks that it is one of the most thankless problems of medical practice, and all authorities agree that therapeutic means are of but little use in the treatment of this most annoying condition. M. Francois, in an exhaustive article on "Facial Tic," in the *Edinborough Medical Journal*, vol. lxxv., speaks of the incurability of the disease. Even if a remedy is found which does check or control the spasms, it is more than probable that a relapse will occur at an early day.

A number of cases have been reported by different writers as cured, but what has helped one patient will be found utterly ineffectual with the next. Hammond speaks of having cured a case of facial spasm with the bromide of zinc and galvanism. Remak[1] has cured cases by galvanism applied to "pressure points" on the spine. But Althaus says that, in his experience, galvanism is without value, except in recent cases.

Chisolm[2] describes a case treated at Port Royal, in 1800, with "oxygenated muriate of potash," which was cured. After four months the patient had a relapse, but was again relieved by the same drug after other means had failed. He does not say how long the patient was under observation.

Various drugs have been spoken of favorably in the treatment of this disease, but I can find no reports showing that there are any cases known to have been cured for a length of time by any remedy. From this want of success with medicines, it has become necessary to resort to surgical means for aid. Erb states that neurotomy of sensory nerves is often followed by good results in mimetic spasm, even when no reflex irritation proceeds from these nerves, and quotes Romberg and Gräfe in this connection. Althaus also speaks of cases of facial spasm being usually cured by section of branches of the fifth. I have known blepharospasm to be cured for the time by section of the supraorbital nerve; but I do not know how long the relief lasted. In the case which I shall relate, resection of the infraorbital nerve was not productive of any good result.

Excision of branches of the fifth nerve for the relief of tic non-douleureux seems to have been practised for many years. Chisolm, in the paper quoted above, says "Is not this the disease described by Dr. Haighton (*Medical Records and Researches*, 1798), cured by the division of the fifth pair of nerves?" I cannot find, however, that it has been successful, except in cases of limited spasm, as, for instance, blepharospasm. In cases reported by Putnam and Godlee, the supraorbital had been fruitlessly divided prior to stretching of the seventh. In each of these, however, the relief from the stretching lasted but a few months.

Section of the facial nerve has been performed in some cases, but, of course, this is followed by complete paralysis of all the muscles supplied, which is permanent. In one case which has been reported, the twitching of the facial muscles did not cease after division of the nerve, although the paralysis was absolute. Dieffenbach[3] divided subcutaneously most of the muscles affected with spasm, in an inveterate case, and obtained a very favorable result.

The possibility of stretching the facial nerve naturally suggested itself after other nerves had been stretched with good results, and the operation was first done by Baum, for the relief of facial spasm, in 1878.[4] This case was very successful. The patient

[4] Keen, Annals of Surgery, vol. iv.

was cured for eight or nine months, and then had a slight relapse, but after two years she was comparatively free from the disorder. There have been, since Baum's operation, twenty others, the last of which being the following case:

Mrs. A. S., æt. forty-nine years, was sent to my clinic at the Orthopædic Hospital and Infirmary for Nervous Diseases, by her physician, Dr. Bartleson, on July 23, 1883. The following history was obtained. She is a native of England, is married, and has had ten children, nine of whom are living. Her mother died of dropsy, at the age of about fifty years, and her father died of inflammation of the stomach. When a child of six years, she had an attack of nervous trouble, which was in all probability chorea. She remembers but little about it, except that it lasted several months, and that she was scarcely able to walk. She recovered entirely, after coming to this country at about the age of seven. Her catamenia were established at sixteen years, and at about the the same time she had another attack of chorea. This affected the right side, and was of several months' duration. After getting well of this attack, she had excellent health, with the exception of more or less frequent attacks of migraine. She has lived in a malarious region, and has had intermittent fever several times in the past sixteen years. The menstrual flow has been regular, but she has had severe pain at each period. Her last child was born in 1880. The labor was easy and rapid, not lasting much more than an hour. Since this confinement the catamenia have become more frequent, and the flow has been profuse, at times excessive.

When her baby was about six months old she noticed one day slight quivering of the right under eyelid. In a day or two this became constant and more marked, and soon extended to other muscles of the right side of the face. In two or three weeks after the tremor began, she first had pain in the right parietal region. It was dull and continuous; but she had no pain in the brow or in the face. In two or three months she thinks that all of the muscles of the right side of the face, and some of the neck muscles were affected with the spasms. It became steadily more severe, and the pain in the head increased in intensity. At times she has been so worn out by the continual spasms of the face, that she was confined to bed.

About the time that the pain in the head began, she had pain in the right biceps. This lasted for about two years and made the arm weak and helpless.

Her general health remained fairly good, although she lost flesh and color.

On first coming under observation it was noticed that attempts at speaking brought on spasmodic twitching of all the muscles of the right side of the face. The mouth was drawn strongly to the right, the eye was closed, and the fibres of the platysma myoides twitched. The spasm would last from thirty seconds to about three minutes, and she said that it was not accompanied with pain. Pressure over the supra- or infra-orbital nerve did not check or keep off spasms, nor did pressure over the facial in front of the ear affect them. The sensation was not impaired. Hearing was good. The eye ground did not present any unusual feature. Emotions or excitement increased the twitching, and eating or talking would almost certainly bring on an attack. Season of the year seemed to exert no influence on the severity of the disease. She had had all of the teeth on the right side of the mouth extracted, but without relief.

I used a large number of therapeutic means with but little or no benefit. Conium when pushed to drachm doses of the fluid extract did control the twitching to some extent, but the effect seemed soon to wear out. Gelsemium was given and so was Cannabis indica. Quinine in large doses relieved the pain in the head somewhat, but did not help the spasms. Galvanism was used faithfully and intelligently by Dr. G. Betton Massey, the electrician to the hospital, but did not show any good effect. Blisters to the nucha, as advised by Anstie in epileptiform tic, were used without avail. Other drugs, as iodide and bromide of potassium, eserine, and nitroglycerine, were given with no perceptible result. Finally, at a consultation of the medical staff of the hospital, it was decided that stretching of the facial nerve would afford the best prospect of relief; but at the desire of our surgical colleagues it was decided to try first the effect of division of the infraorbital nerve. Accordingly, in June, 1884, Dr. T. G. Morton resected about half an inch of the right infraorbital. The result of this operation was diminution of the twitching and spasms for a few days, and the pain in the head became less; but in two or three weeks they were as severe as ever.

Another course of drugs and electricity was now pursued, but the patient's condition became worse. In the summer of 1885 she began to have pain in the back of the right thigh, in the course of the sciatic nerve, and in the calf of the leg. The muscles of the leg felt to the patient as if they were drawing and twitching, and there were often severe cramps of the calf muscles. All of the symptoms were intensified at the menstrual periods, which occurred every two or three weeks with profuse flow.

In March, 1886, I had a consultation with Dr. W. W. Keen, as to the advisability of stretching the facial nerve in Mrs. S.'s case. He agreed with me that it was desirable to perform the operation, and admitted the patient to the Woman's Hospital, where the nerve was stretched, on April 2, 1886. Dr. Keen reported the case at the meeting of the American Surgical Association, in May, 1886, and his paper is published in *The Annals of Surgery* for July. The following is his account of the operation:

"Began etherizing at one o'clock, Dr. Sinkler present and assisting. At 1.10 an angular incision was made, two and one-half inches long. The centre of the incision was at the apex of the mastoid process, passing upward behind the ear, and downward in a line parallel with the border of the sterno-cleido-mastoid muscle. Ligated the posterior auricular artery; the parotid was dissected and pushed forward until the prevertebral muscles and their aponeuroses were reached. A very weak current of electricity was then applied by a wet sponge to the cheek, and fine wire to various points in the wound, until the nerve was found. Immediately a spasm of the facial muscle followed the application.

The nerve was then laid bare. A hook was next passed under it, and the nerve stretched several times from the face outward, pulling the head to the right side. When the nerve was stretched, marked contraction of the facial muscles was seen. The force used was estimated at between four and five pounds. No more force was used, because a few fibres were felt giving way when an attempt was made to lift the head. Horsehair drainage was used, and four silver sutures were introduced. Complete paralysis of the facial muscle was noted after the stretching, and before she had recovered from the ether. Upon recovering consciousness, the patient remarked the absence of pain in the head. Before the operation, pulse 90, temperature 98.8°. After the operation, pulse 82, temperature 98.6°.

"A carbolized gauze dressing was applied, and the operation was completed at 1.50 P.M. At 6 P.M. complained of severe pain in the ear, which soon passed away. After operation there was complete paralysis of the facial muscles. The right eyelid did not close of itself.

"*April 3.* First day after operation, 6 A.M., pulse 77, temperature 99¼°. Paralysis of facial muscles not so marked as immediately after the operation. No pain in the head, but complaining of soreness in the leg. Wound was dressed at 2.30 P.M. Slight oozing was found on the dressing.

"*4th.* Second day, 6 A.M., pulse 85, temp. 98.6°. Took more nourishment. No pain in the ear. Leg and side still painful.

"*5th.* Third day, 6 A.M., pulse 85, temp. 98.7°. Eyelid nearly closed and facial muscles seem a little less relaxed than before. There has been no twitching of the facial muscles, platysma, or of the leg since the operation. Sat up for an hour.

"*6th.* Fourth day, out of bed. All stitches removed, and the horsehair drainage; a few drops of sanious discharge followed."

Dr. G. Betton Massey made an electrical examination on the tenth day after the operation. He found farado-contractility greatly weakened at this time, and on the seventeenth day it was totally abolished. The galvanic responses are tabulated below. Dr. Massey used great care in this examination, and eliminated all errors from changes in resistance by the use of a milliampère meter.

"It will be noted by a reference to the table, that the frontalis showed the serial changes indicative of the reaction of degeneration in a slight degree on the seventeenth day. This remained the same on the twenty-fourth, when a slight modal change, consisting of a slow, wave-like contraction, instead of a sharp, quick one, was noted. The orbicularis palpebrarum showed quantitative diminution of excitability on the tenth day, and serial changes on the seventeenth. The levator labii superioris showed slight serial change on the tenth day, which has increased since, amounting, on the twenty-fourth day, to more than a complete reversal of the normal figures. This was also true of the zygomaticus major, orbicularis oris, and levator menti, in all of which increasing serial change has been found, together with great modal alteration of contraction. The lower muscles of the face show greater change than the upper."

In the following table it will be found that the figures of the normal formula of each muscle are given. These were obtained by making an examination of the sound side of the face.

	Minimum contraction at		Remarks.
	Kathodic closure.	Anodic closure.	
Frontalis:			
Normal	1	1½	
10th day	1	1½	Slight modal change.
17th day	1½	1	
24th day	1½	1	
Orbicularis palbebrarum:			
Normal	½	1	
10th day	2½	3	Slight modal change.
17th day	2	1	
24th day	2½	1½	
Levator labii superioris:			
Normal	2½	3	
10th day	2½	2½	Modal change.
17th day	4	2	
24th day	3	1½	
Zygomaticus major:			
Normal	2½	3	
10th day	2½	3	
17th day	5	3½	Modal change.
24th day	2½	1½	Great modal change.
Orbicularis oris:			
Normal	2½	3	
10th day	2½	3	Slight modal change.
17th day	1½	1½	Great " "
24th day	1½	1½	" " "
Levator menti:			
Normal	2½	3	
10th day	2½	3	
17th day	1	1½	Great modal change.
24th day	1	½	" " "

Dr. Massey made a final electrical examination on the one hundred and ninth day after the operation, with the following results:

	Minimum contraction at	
	Kathodic closure.	Anodic closure.
Frontalis	1	1½
Orbicularis palpebrarum	½	1
Levator labii superioris	1½	2½
Zygomatics	2½	3
Orbicularis oris	1½	2
Levator menti	½	1

Showing a return to normal in several muscles. There was some response to the faradic current at this examination.

I examined Mrs. S. four weeks after the operation. There was then complete paralysis of all of the muscles supplied by the right seventh nerve. There was no twitching and no pain, and there had been none since the stretching of the nerve. Sensation was not impaired except on the posterior edge of the right ear. This was probably from the division of a cutaneous nerve by the incision made in the operation. The patient was in excellent spirits, and said she felt perfectly well. She was free from headache, and had no pain or twitching in the leg.

On June 18, ten weeks after the operation, the paralysis was beginning to disappear. The eye could be partially closed, and there was some power to draw the angle of the mouth to the right. There

was hyperæsthesia on the posterior edge of the ear, where there had been previously loss of sensation.

On July 19, fifteen weeks after the nerve stretching, there was scarcely a trace of the paralysis left. Mrs. S. reported that at the time of her last menstrual period she had a severe headache and felt slight quivering of the right lower lid. This lasted but a short time, and she has not experienced it since. She has had no pain in the head, and has had no return of spasms or cramps in the right leg, but still has some pain in the right thigh and calf.

Dr. de Schweinitz kindly examined the eyes and reported:

R. E. V. $\frac{15}{LXXX}$ with a $+ 3^{\circ}$ $\frac{15}{XXV}$.

L. E. V. $\frac{15}{L}$ with a $+ 1.75^{s}$ $\frac{15}{XL}$.

Excursion of eyeballs good in all directions. No muscular paralysis. Insufficiency of the interni 7°. Pupils react normally. *Ophthalmoscope, R. E.:* Small nerve, the lower edge slightly veiled by striated retina. Nerve color a little gray. Choroid extensively disturbed, and its pigment epithelium absorbed.

L. E.: Nerve larger. Similar striation of retina. Choroid more disturbed than in R. E. Pigment epithelium absorbed: and down and in from the disk one mass of choroidal pigment. Lymph sheaths along vessels marked. Hypermetropia 1.75°.

A uterine examination revealed a deep bilateral laceration of the neck of the womb. The lips were not everted or ulcerated. The depth of the uterus was three inches. The organ was in normal position and was not sensitive to the touch.

Dr. Keen has tabulated with great care all of the cases in which stretching of the facial nerve has been done. The tables which he has made are much more accurate and full than any which have heretofore been published. From these it will be found that there have been twenty-one cases of tic convulsif in which the facial nerve has been stretched. Of these twenty-one, complete relief from the spasmodic contractions has followed the operation in seven cases. In two of these the patients had been under observation two to three months, and in three the patients had been seen at periods varying from two to five years after the operation. One case was not seen after three days, and in my own case almost four months have passed since the operation, and there has been no return of the trouble except the trifling twitching of the lower lid referred to above.

Of fourteen cases, in three complete relief lasted only one week, and after that time in one the improvement continued for two years; but in the other two the benefit did not continue after the first week.

In five cases complete relief lasted from three weeks to four months. Of these, four continued better and one relapsed to the same condition as before the operation.

Finally, in six cases there was absolute relief for from four months to one year. Of these, improvement continued in three, and in the remainder the spasms returned with their former severity.

Of the whole number of cases there were but six in which it was reported that the patients relapsed to a condition as bad as that prior to the operation. There was not one case in which there had not been complete relief for a longer or shorter time. The shortest time that relief lasted was one week.

It is true that none of these cases was under observation long enough to make a thorough test of the value of the operation; and it is also true that a large number of the patients relapsed to a greater or less extent; but we know of no other means which has given relief in so large a proportion of cases. Of the half-dozen cases of tic non-douleureux which I find in the books at the Infirmary for Nervous Diseases, in not one was there absolute cessation of the spasms from any form of treatment used, and, as I have before shown, nearly all of the writers on the subject are unanimous in the opinion that treatment is without avail. It is for this reason that I feel that stretching the facial nerve is to be recommended for tic-convulsif. When we consider the small amount of risk and suffering in the operation, and the large degree of relief afforded by it, we would certainly be derelict in our duty to our patient in not performing it when other means have failed.

When I saw Mrs. S., four weeks after the operation, the right side of the face was entirely palsied. She could not close the right eye, and the corner of the mouth drooped. She assured me that, notwithstanding this condition, the relief from the twitching and pain was so great, that she would willingly remain as she was rather than have a return of the spasms.

I am inclined to believe that in this case the disease was peripheral in origin, from the fact of the two attacks of chorea which she had had early in life and from the influence of the menstrual periods on the convulsive twitchings.

Note.—I saw Mrs. S. on August 16th, four and a half months after the operation. The facial paralysis was entirely relieved, and there was not a symptom of the twitching.

A PRIMARY OPERATION FOR TORN PERINEUM AFTER EMMETT'S METHOD.

By FRANCES HATCHETT, M.D.,
RESIDENT PHYSICIAN, MATERNITY HOSPITAL, PHILADELPHIA.

The patient, a primipara, was confined July 26, 1886. Perineum ruptured, the laceration, externally, extending to the sphincter ani muscle; internally, the tear extended along both sides of the posterior column of the vagina to the extent of an inch and a half. The stitches were introduced on each side of the column according to Emmett's directions, and the rest of the tear was united by three deep stitches knotted externally.

On the twelfth day the stitches were removed. union perfect. There was no deformity of the parts whatever. The case is interesting because the primary tear corresponded to the denudation made by Emmett, as represented in his diagram, in performing the secondary operation.

August 18, 1886.

THE REACTION AGAINST THE BACILLUS TUBERCULOSIS IN GERMANY.

By THOS. J. MAYS, M.D.,
of Philadelphia.

It is very exceptional that a new idea finds such general acceptance as that which greeted the discovery of the tubercle bacillus by Koch in 1882. It was not only new, but it threatened to revolutionize all existing notions of the causation and treatment of pulmonary consumption. It placed this disease in the contagious list, and the victims of the former were to be regarded as objects of suspicion, rather than of pity. The idea took root at once in Germany, and before very long had disseminated itself throughout the civilized world. Everybody was infected by it, so that Prof. Virchow recently said that it "not only swayed the ideas, but also the dreams of many old and of nearly all young physicians." It is very difficult to account for this phenomenal course of things, unless it was partly due to a feeling of weakness on the part of the members of the profession to cope with the destructiveness of the tuberculous malady; and hence they were ready to welcome anything which contained so much apparent "promise and potency of" renewed "life."

It must be admitted that the parasitic doctrine of the cause of tuberculosis is very beautiful and simple, but it unfortunately collides with too many well-established facts apparent to every practical observer. If it were true that consumption is a contagious disease, then it should conform with the laws which are known to govern contagious disease. This is not the case, for observation has settled beyond cavil, that it is not those who are most exposed to the disease who are most liable to it, which is in direct opposition to the behavior of contagious disease. Prof. Lichtheim, in the transactions of the second medical congress, which met in Wiesbaden in 1883, says that "it must be admitted that there are many facts which contradict the contagious nature of pulmonary phthisis. As a rule, intercourse with phthisical people is not attended with danger. We hospital physicians spend much time among such people. We have such confidence in the innocuousness of the disease, that we do not hesitate to mix healthy persons with them in institutions devoted to its treatment, and we must confess that this procedure is practically unattended by any unfavorable results." He stated that the mortality of the attendants in the principal hospitals for consumption was surprisingly low; and that he could, from investigation, confirm the belief that there is no relation between the increase of the number of phthisical patients at a health resort, and the number of deaths from consumption occurring among the native inhabitants. This ground is also substantiated by the statistics of the Brompton Hospital for Consumption in London, as collected by Drs. William and Humphreys. This is a large institution, and had been in operation for thirty-six years up to the year 1883, yet not a single clearly authenticated case of pulmonary consumption among the many attachés of the hospital occurred within its walls. The statistics of the Brompton Hospital in regard to the non-contagiousness of phthisis are probably not more striking than those which relate to the influence of the Consumption Hospital of Görbersdorf, Germany, on the death-rate from phthisis among the inhabitants of that town. Dr. Brehmer, who has been in charge of that institution for twenty years, says[1] that the mortality among the native residents has diminished fifty per cent. during that time, and that, too, in the face of the constant exposure to the expectoration and exhalation of the many phthisical patients residing there.

Virchow, in his famous address "Der Kampf der Zellen und Bacillen," says:

"After Dr. Koch had found the tubercle bacillus many *affected to believe* that all the arduous labors of previous observers were superfluous. Unity of the bacillus—therefore unity of phthisis. Pulmonary phthisis, however, remained as before: A significant process commencing in many ways,—sometimes in the mucous membranes of the air-passages, sometimes on the inner surfaces of the alveoli, and sometimes in the parenchyma of the lung—and which may at one time engender simple inflammatory products, and at another time specific tubercles, and he who wishes to form an intelligent conception of it must do more than familiarize himself with the staining of bacilli."

In the *Correspondenzblatt für Schweizer Aerzte*, Nos. 10, 11, and 12 for 1886, appears a most interesting and instructive paper entitled "Eine Statistiche Studie als Beiträg zur Aetiologie der Lungenschwindsucht," by Dr. H. Schnyder. It is based on an observation of 3461 cases of pulmonary consumption under his professional care whilst resident physician at the health resort of Weissenburg, in Germany. He classifies them into city and country patients—those coming from cities numbered 2549, and those coming from agricultural districts numbered 912. Of the whole number there were 2194 males, and 1267 females; or 63.4 and 36.6 per cent. respectively. The patients from the cities numbered 1659 males and 890 females; or, 66.87 and 34.13 per cent. respectively; while those from the country numbered 537 males and 377 females; or, 58.66 and 41.34 per cent. respectively—showing that the male sex is absolutely and relatively more liable to the disease, both in city and in the country, than the opposite sex, while the reverse is true in regard to females, for 7.21 per cent. more of this sex suffer from the disease in the country than in the city. This result is still more surprising when we reflect that on the whole there are more females than males in the city, and more males than females in the country.

In order to confirm or refute this last observation, Dr. Schnyder compares the phthisical death-rates of the cities of Geneva, Basle, and Zurich, with those occurring in the cantons of Wallis, Waadt (without Lausanne and Vivis), Freiburg, and Lucerne (without the city), during the eight years from 1877 to 1884, and he obtained the following confirmatory results: In the above-named cities there were 2583 males

[1] Die Aetiologie der Chronischen Lungenschwindsucht, p. 492. Von Dr. Hermann Brehmer, sr. Berlin, 1885.

and 2142 females; respectively 54.7 and 45.3 per cent.—and in the above-named cantons there were 2822 males, and 2549 females—respectively 52.5 and 47.5 per cent.—who were suffering from pulmonary phthisis.

Now it would be perverting reason to contend that there are more bacilli in the relatively purer country air; hence, it is very evident that there exist producing causes of phthisis in the country at least in which the bacilli do not share. The author attributes this greater liability of the female country population to the disease, to the fact they are more exposed to all kinds of weather and temperature, and perform more laborious work than their city sisters.

In this connection it is very interesting to note in the second volume of *Mittheilungen aus dem Kaiserlichen Gesundheitsamt* that the phthisis mortality among females in the city and country is greatly influenced by age. It appears here that females in the city are more liable to phthisis in their youth, and those in the country when they are past middle life. This is believed to be due to the faster life among city people, and consequently a more rapid exhaustion of strength than is the case in the country.

Dr. Schnyder's cases of hereditary phthisis among his city patients are 62.08 and 73.71 per cent., males and females respectively; and among his country patients 61.31 and 72.15 per cent., males and females respectively. Therefore, about two-thirds of all his cases were traced to heredity as a cause. This is somewhat lower than the rates of Homann, who gives 70 per cent.; as well as those of Rufz, who gives 87 per cent., but higher than those given by Williams based on 500 cases, than those of Cotton based on 1000 cases, and than those of Albert Müller based on 988 cases—which were 45, 36.7, and 28.6 per cent. respectively. The higher percentage of heredity in Dr. Schnyder's cases may be due to his tracing the family histories to grandparents, uncles, and aunts. His cases of acquired phthisis in cities numbered 37.92 per cent. males, and 26.92 per cent. females, and those in the country numbered 36.69 per cent. males, and 27.85 per cent. females.

The question of the infectiousness of phthisis between husband and wife is probably the most instructive portion of this most interesting investigation, and is very conclusive in regard to the non-etiology of the tubercle bacillus. The table records 844 cases of phthisis occurring among married people. In 445 of these cases the husband only was affected, in 367 cases the wife only, and in 32 cases, or about 3 per cent., both husband and wife were affected. In 812 of these cases the question of contagion is entirely excluded, while this cannot be stated with equal certainty of the 32 cases. Yet if we reflect that more people suffer and die from phthisis than from smallpox, which is unquestionably contagious, that only a very small fraction of those who are exposed to the former disease take it, and that all the unprotected who are exposed to the latter disease invariably fall a prey to it, it does not argue much in favor of the theory that phthisis is conveyed from one person to another through contagion.

To take refuge in the theory that "a proper soil" in, or "a disposition" of the body is necessary to the contagiousness of the tubercle bacillus, is merely shifting the question from a higher to a lower plane. What matters it, whether it is the "disposition" or the "proper soil," or anything else in the body on which the germ is presumed to act? If it fails to act when it comes in contact with any of these elements, it loses an opportunity which is never unimproved by a genuine contagious disease. The crucial question concerning the contagiousness of phthisis in these cases can therefore be stated in the following terms: If the "disposition" or "proper soil" existed in the 32 cases, why was it absent in the 812 cases?

Then again in connection with the "disposition" and "proper soil" theories, it may be stated that we have numerous instances where physicians who suffered from phthisis themselves, spent many years of hard labor among consumptive patients principally, and never experienced any injurious consequences. Dr. Schnyder is an example of this himself. He says that he has a chronic affection of his right apex, which has not given him any trouble during all the years he has been engaged and overworked among phthisical patients at Weissenburg. Surely in agreement with Dr. Schnyder, we can say that if anywhere, in such cases, there should be a nidus or "soil" to tempt the most fastidious bacilli to colonize.

But is it beyond doubt that even the 32 cases were clearly engendered through contagion? We think not, for Dr. Schnyder says that it is a notorious fact, that in spite of all entreaties and warnings young people are often wedded while suffering from active lung disease. Dr. Schnyder relates four such cases in his own experience in which both the bride and bridegroom came to Weissenburg fresh from the matrimonial altar to be treated for phthisis, from which they both suffered. How many of the cases of phthisis which are supposed to be due to the communicability of the disease between husband and wife through contagion, are free from this element of uncertainty? To say nothing of those who are wedded while suffering from the acute forms of the disease, it cannot be denied that many young people of both sexes carry the hereditary taint of phthisis in their constitution, which only awakens from its slumber to assert its power when the many varied demands of family life begin to exhaust the vital resources.

It is evident that the standpoint from which we view the origin of phthisis is the fulcrum on which its successful treatment depends. If we believe that the bacillus is the cause of the disease, then the indications are toward the extermination of this parasite. If we believe, with Dr. Schnyder and many others, that it is merely a concomitant—a scavenger—of the disease, then we should trace the latter to other causes and modify our treatment accordingly. We hope that enough has been said to prove that the theory that the bacillus as a causative factor of pulmonary phthisis is encountering formidable opposition in the land of its birth, and trust that it will receive a most rigid investigation before it becomes the foundation-stone of pneumo-therapy in this country.

1716 Chestnut St., Philadelphia.

MEDICAL PROGRESS.

Simplification in the Technique of the Sänger Operation.—At the recent meeting of the German Gynecological Association in Munich, Dr. Sänger stated that, while the classic simplicity of the Cæsarean section was irretrievably a thing of the past, there was not necessarily any great complexity in the modern modified operation. His rules as to technique are as follows:

1. *Preparation.* No especial instruments are needed. The abdomen, vulva, and vagina are disinfected with sublimate solution,—the instruments with carbolic acid. Sponges may be substituted by large cotton wads dipped in the antiseptics just named or in chlorine water, or by napkins of sublimate gauze, etc. Two assistants are sufficient. In case of need the narcosis may be intrusted to a layman.

2. *The abdominal section* is in the linea alba. The application of hæmostatic clips and the introduction of provisional sutures may be dispensed with. Unless there has been death of the fœtus, rolling out of the unopened uterus is not advisable on account of the increased length of the incision involved and the likelihood of intestinal prolapse.

3. *The uterine section* is the anterior middle median incision, the lower uterine segment being avoided. The deep diagonal incision advised by Kehrer is not commended. In Cæsarean placenta prævia, the placenta may either be rapidly cut through or it may be loosened laterally. The author has followed the first method in one case and the second in two cases; in neither were there any resultant difficulties in suturing or in arrest of hemorrhage. The removal of the fœtus is best begun at the feet. If the head be retained the operator waits a short time and, if then necessary, enlarges the incision upward.

4. *Eventration of the uterus.* A napkin is spread over the intestines and the uterus enveloped in another. In the absence of elastic rubber tubing, an artificial bloodlessness of the uterus may be produced by manual compression or by torsion on its long axis. The placenta is separated by the fingers, and the patulency of the collum is ascertained. The uterine cavity is now disinfected with iodoform and is filled by sponges or strips of gauze until the introduction of the deep sutures.

5. *Sutures.* The deep sutures include the serous and muscular coats, but not the decidua. They are wide, eight to ten in number, and best made with flexible silver wire. The superficial stitches are taken with fine silk at the edges of the wound, and are from sixteen to thirty in number. In the absence of silver, which is highly commended, strong, aseptic silk may be employed.

6. *Washing out the uterus* is effected with sublimate, five parts to the thousand. Iodoform is applied to the line of suture, and the uterus is replaced as soon as all bleeding has ceased. There is no abdominal toilet except under especial indications, and *no drainage*. The abdominal wound is closed with silk knot sutures, iodoform and a thin adhesive plaster covers all. Ice bladders are placed upon the abdomen and several ergotin injections are given.

7. *The after-treatment* is to be as inactive as possible.

Sänger maintains that while uterine suture is not strictly speaking easy, yet suturing the intestine is more difficult.—*Centralblatt f. Gynäkologie*, July 10, 1886.

Two New Tests for Sugar.—The two reactions about to be described are common to cane-sugar, milk-sugar, glucose, levulose, and maltose, and to the carbohydrates and glucosides capable of yielding glucose by the action of sulphuric acid. They do not, however, produce any result with inosite, mannite, or quercite.

1. From one-half to two cubic centimetres of the suspected liquid are treated with two drops of a fifteen or twenty per cent. alcoholic solution of alpha-naphthol, and the mixture is shaken. A slight turbidity results from the precipitation of a little naphthol; sulphuric acid is then added in quantity equal to or even double the volume of the fluid, and the whole is briskly shaken. In the presence of sugar a deep violet color is developed, and dilution with water throws down a violet-blue precipitate, soluble in alcohol and ether with a yellow color, or in caustic potash with a golden-yellow color. In order that the reaction may occur as described, the test must be made exactly as stated.

This test will permit the detection of 0.00001 per cent. of sugar, and, with the exception of vanillin, anethol, methyl salicylate, and a few similar substances, gives no reaction when sugar is not present. These substances, however, either produce the color with sulphuric acid alone, or the precipitate formed when the violet solution is diluted with water, differs totally in character from that formed in saccharine liquids. The limit of sensibility of Fehling's test is 0.0008 per cent., and that of Trommer's test is 0.0025 per cent.

2. If, instead of the alpha-naphthol in the preceding test, an alcoholic solution of thymol of similar concentration be employed, the remaining manipulations being the same as before, a deep red varying from cinnabar to carmine is produced; dilution with water brings the color to carmine, and after a time there separates a flocculent precipitate, which dissolves with a pale yellow color in alcohol, ether, and caustic potash, but with a bright yellow in ammonia.

The delicacy of this reaction is about the same as of that with alpha-naphthol.

After many experiments had shown the trustworthiness of the results given by these tests, it was interesting, on account of their exceeding delicacy, to apply them to the solution of the disputed question whether normal human urine does or does not contain sugar. The results of the first attempts were so decided that the urine examined appeared to be diabetic. The urine of a number of perfectly healthy individuals was therefore examined, but with precisely the same results. The tests were made with alcoholic solutions of alpha-naphthol and thymol, exactly as has been described, and the extraordinary delicacy of the reactions can be better understood by the statement that normal urine diluted to from one hundred to three hundred times its volume with water still gives a recognizable reaction. When the urine is diluted to four hundred times its volume, the test shows no result.

In order that there might be no question as to sugar being the actual cause of the reaction, the following substances were examined and gave negative results

with both alpha-naphthol and thymol: urea, creatine, xanthine, uric acid, allantoine, hippuric acid, succinic acid, phenol, pyrocatechin, and indican.

These results fully confirm the opinion advanced by Brücke, and supported by many other observers, that normal urine constantly contains sugar.

These tests may be applied in two different ways in order to distinguish a normal from a diabetic urine.

1. A specimen of normal urine and of that to be tested are equally diluted with water to about one hundred times their volume; the same quantity of each is then tested just as has been described; if the suspected urine give a deeper violet than the normal specimen, it may be considered as diabetic.

2. The urine under examination is diluted with water to from four to six hundred times its volume. Even in this enormous dilution diabetic urine will sharply respond to the reactions of the tests described, while normal urine would give no result when diluted to four hundred times its volume.

After carefully studying the various tests for sugar in urine, F. Penzoldt came to the conclusion that the fermentation test is worthy of the greatest confidence in doubtful cases. All experiments, however, seem to show that the two new tests are decidedly more certain than the fermentation test. They leave but one thing to desire: they do not enable a distinction to be made between glucose and levulose, and although the sugar found in urine will in nearly all cases be glucose, yet various instances have occurred in which levulose was detected also.—*Phila. Med. Times*, Aug. 7, 1886.

Cocaine in Angina Pectoris.—Prof. Laschkewitch has found good results from the internal administration of cocaine (in doses of one-half to one-third of a grain three or four times daily) in cases of angina. It does not cut short an attack, but diminishes its intensity, and after a few days' consecutive administration it gradually diminishes the force and duration of the seizures until they may wholly disappear (*Rev. de Méd.*, August, 1886). He details four cases; one was that of a man thirty-five years of age, the subject of aortic regurgitation and dilatation of the aorta. Anginal attacks occurred as frequently as eight times daily, and were of the characteristic kind. He was obliged to keep his bed, but the attacks also occurred during the night, preventing sleep. The disease had lasted two years, and had not been much benefited by oxygen inhalation. Half-grain doses of cocaine were prescribed, with the result that the attacks became less frequent and shorter, eventually disappearing. The patient died subsequently of an infectious disease. Another case was that of a man aged sixty-three, with mitral disease, aortic dilatation and general arterial sclerosis. Anginal attacks had occurred during the past six months on physical or mental exertion, and were only subdued by morphia. Here, again, cocaine acted admirably, the angina ceasing after three days' administration. In a third case the patient, aged fifty-eight, presented marked arterio-sclerosis; the angina disappeared after two days' administration of one-third of a grain four times a day. The fourth case, a man about forty years of age, was one of aortic regurgitation, with marked dilatation of the aorta; and the administration of cocaine speedily cut short the anginal attacks, which had become severe and frequent. Prof. Laschkewitch says that the remedy produces slowing of the pulse, which gains in volume; at the same time the quantity of urine is increased. He thinks that by combining this treatment with that by inhalation of oxygen, which acts immediately in an attack, the anginal seizure may be arrested, and its reappearance prevented.—*The Lancet*, Sept. 4, 1886.

The Proper Use of Ergot.—In a paper by Dr. F. H. Potter, which appears in the *Buffalo Medical and Surgical Journal* for September, 1886, the following conclusions are presented:

1. Ergot is a drug, which in any of its preparations, tends to deteriorate rapidly, and should never be used excepting when prepared from a pure and fresh specimen.

2. It is a stimulant to the tubular and non-striated muscular structures of the body, causing them to contract.

3. It acts especially upon the muscular structure of the uterus, throwing it into a state of tonic spasm.

4. Its action on the uterus is, however, uncertain; sometimes it contracts the entire organ, at others only a small part of it.

5. If the entire organ is contracted, labor may be delayed through the rigidity of the os, and the child destroyed by the interference with the placental circulation.

6. Or the contractions may be so powerful as to force the child at once into the world, causing any or all of the lacerations of the soft parts of the mother.

7. The life of the child may be endangered, also, through absorption of the essential oil of ergot.

8. If given after the birth of the child, and before the expulsion of the placenta and membranes, it may prevent the removal of the latter, and thus be indirectly a cause of puerperal septicæmia.

9. It may act in a similar manner in cases of abortion, actual or threatened, and cause a similar result.

10. The proper use of ergot in obstetrical practice is limited to those cases in which, after the expulsion of the placenta, the uterus refuses to contract, or having once contracted shows a tendency to secondary relaxation. Even in these cases, however, reliance should not be placed upon it alone, but its action should be supplemented by the other means used to provoke uterine contraction.

A Case of Acute Mania, in which there was Complete Remission of the Symptoms during a Temporary Plugging of the Sinuses.—A married woman, aged forty-one, with neuropathic antecedents, became depressed and nervous, and after some weeks this culminated in an attack of acute mania. Symptoms of commencing hæmatoma developed in the left auricle, but abated, followed, however, by a fully developed hæmatoma of the right ear. The mania persisted for six months, accompanied with considerable failure of bodily health, but at the end of that time she became suddenly quiet and composed, and this marked remission of the maniacal symptoms was coincident in point of time with the appearance of a painless tumefaction over the mastoid cells, and a general puffy and œdematous condition in the orbital region of the right side. Seventeen days afterward the œdematous swelling had

quite disappeared, and the maniacal symptoms reappeared as suddenly as they had subsided.—*Glasgow Medical Journal*, September, 1886.

The Treatment of Paronychia.—Dr. Sellden writes in the *Eira* that he has for years made a special study of this subject. The greater number of his patients have been miners, smiths, machine laborers, servants, and others whose fingers are exposed to injury. The disease commences in the subcutaneous tissue, and spreads to the periosteum. There are differences of opinion as to the varieties of this disease, some authors asserting that there are four, others that there are only two—the deep and superficial inflammation. Dr. Sellden, after a series of trials, found the following method most efficacious in the treatment of paronychia. When the patient will consent to an incision, the finger, after it has been opened, is instantly plunged into a tumblerful of hot water, which is then allowed to cool until it is nearly lukewarm. Half a teaspoonful of arnica is poured in, and a teaspoonful of the usual ten per cent. solution of potash is added. This mixture is highly anæsthetic; the finger is held in it for from fifteen to thirty minutes, when the "bad matter" comes out. This expression is very characteristic of the phenomenon. The blood and pus exude in a thin stream about the size of a knitting needle, which forms circles in the alkaline liquid, and finally settles in a thick mass at the bottom of the glass. Fifteen minutes or half an hour after the finger is dried, it is rubbed with vaseline ointment containing ten per cent. of sulphide of potassium. The finger is then immediately enveloped in a poultice which continues warm until the next finger-bath, and thus hastens the cure. These finger-baths are taken from two to four times daily, and the wound is covered during the earlier days with sulphur ointment, and later with a boracic ointment. The finger is then bound up with a wadding compress and a bandage. Carbolic acid may be used in the finger-bath, but Dr. Sellden gives the preference to arnica, which he finds particularly useful in all sorts of injuries. —*The Lancet*, August 28, 1886.

Treatment of Divided Tendons. — In a paper recently read before the Orthopedic Section of the Academy of Medicine, Dr. R. H. Sayre presented the following conclusions:

1. That after tenotomy the parts should be immediately restored as nearly as possible to the normal position, and there retained during ten days or two weeks; after which time, whatever subsequent treatment may be necessary to vitalize paralyzed muscles, or complete the restoration of natural functions, should be carried out as may be necessary.

2. That this proceeding is accompanied by the least discomfort to the patient, and annoyance to the surgeon, and causes a vast saving of time.

3. That there is no more danger of non-union of the ends of the divided tendon in this manner than by other modes of proceeding.

4. There is less apt to be a thin, imperfect bond of union between the ends of the tendon than when gradual reduction of the deformity is practised.

5. That this mode of operation is applicable at the foot, knee, thigh, or neck, where there is no ankylosis to be overcome, but that in cases of long-standing ankylosis at the knee when tenotomy is but preparatory to *brisement forcé*, the latter should be deferred for forty-eight hours, to avoid possible risk from gaping of the external wound due to the violence of the manipulations.

Should the deformity at the knee be due simply to contractured muscles, immediate replacement may be practised here also.

The Treatment of a Form of Diarrhœa in Children.—There is a form of diarrhœa in children, usually occurring after weaning, and from that period to four or five years of age, which is characterized by the most horrible offensiveness of the motions. This is so marked that it is generally at once mentioned by the parents. It is commonly met with in summer, but is not strictly what is known as infantile diarrhœa, in which disease the stools are sour, but not necessarily fetid. Probably this form of diarrhœa differs from the diarrhœa of younger infants in being caused by the growth of the ordinary bacteria of putrefaction. It is not amenable to treatment by any astringent, nor has any alteration of diet much effect upon it.

Dr. James Braithwaite (*British Medical Journal*, July 17, 1886), however, states that it may be successfully treated by disinfecting the bowel contents by means of salicylate of iron as in the following prescription, which is suitable for a child two years of age: Sulphate of iron, ℈j; salicylate of sodium, ℈j; glycerine, ℥iij; water to three ounces. The iron and the salicylate should be dissolved separately and the solutions mixed. The color is darker than that of port wine, and the taste not unpleasant. One teaspoonful must be given every hour, until the stools become well blackened, which happens in about twenty-four hours; or a larger dose may be administered at longer intervals. The medicine should then be given every three or four hours, and occasionally a small dose of castor oil, to clear the bowels well out, and to get the secondary constipating effect of the oil.

In hospital practice, and amongst the poor, it is not so successful as it would be if it were possible to remove the child from the family living-room, the air of which is usually very impure, and is made worse by the smells incidental to cooking, and the presence of a sink.

Electrolysis for the Treatment of Urethral Stricture.—At a recent meeting of the Academy of Medicine in Ireland, Mr. P. J. Hayes read a paper on the treatment of urethral stricture by electrolysis, the comparatively novel method practised by Drs. Robert Newman, of New York, and S. T. Anderson, of Bloomington. He gave the details of three cases, in which he had himself adopted the method with encouraging results (*British Medical Journal*, July 17, 1886). He strongly advocated the trial of electrolysis even for the most complicated forms of stricture. It does not at all interfere with the subsequent employment of other measures, minor or serious. Electrolysis is best adapted for the treatment of annular strictures rather limited in length. Having ascertained the situation of the stricture, the tip or exposed metal bulb of an electrode ought, if possible, to be lodged within it; or if this

is impracticable, the tip must be in close contact with the anterior face of the stricture. Then a small galvanic battery is connected by its negative pole with the urethral electrode, while the positive may be attached either to a moist sponge electrode or, better still, to a thin metal plate covered with moistened chamois leather. The positive electrode will be advantageously applied either to the patient's perineum or against the inner side of one thigh. As to the strength of the current to be employed, the patient's own sensations will prove the best guide. The current should be perceived, but it ought not to be pushed to cause pain, nor should the surgeon attempt more than it is needful to effect at each sitting, using only mild currents, and manipulating the electrode with gentleness, and never pushing it through the stricture, as it accomplishes more by being allowed to remain in the stricture than by being caused quickly to traverse it. The sittings may be repeated every ten days, if desired. Cauterization results when strong currents are employed, but with mild currents the gradual breaking up of fibroid tissue is effected by a combination of chemical decomposition and vital absorption until but a thin lamella of cicatricial tissue remains to mark the seat of the stricture.—*Therapeutic Gazette*, September 15, 1886.

TREATMENT OF PHTHISIS.—In the August number of *The Journal of Nervous and Mental Disease* DR. LEONARD WEBER, after emphasizing the fact that great nervous depression may frequently accompany the phthisical state, speaks as follows regarding treatment:

So long as we do not know of a remedy which will be at least as good an antidote to the tubercle-virus as mercury is to syphilis, we had better give no drugs to such patients, except for special purposes. But as much good has been accomplished in phthisis and therapeutics by sea and mountain air, the patient ought to be sent to a sanitarium selected with due regard to his individuality and the peculiar features of his case, and into the care of an accomplished physician who has learned to treat and manage phthisical patients rather than phthisis. I am afraid that many physicians are not aware that the phthisical patient needs often a good deal of moral treatment and management before we can depend upon him to carry out systematic and painstaking treatment for months—for years. A careful hygiene, continual supply of fresh air night and day, and yet scrupulous care in avoiding cold in the routine of daily life, proper clothing, frequent baths, and even douches to counteract the bad effects of and limit the profuse sweating, gentle and graduated exercise to invigorate the heart, I consider to be among the principal measures to help the patient in his fight with the disease. Of the utmost importance is the frequent supply of nutritious food by the mouth and by the rectum, combined with the judicious use of stimulants. Feeding, nay, over-feeding, as Debove advises, is indeed the *sine qua non* of an improvement or a possible cure in the case of a patient suffering from so chronic and debilitating a disease as pulmonary tuberculosis.

THERAPEUTICS OF DELIRIUM TREMENS.—PROFESSOR LEUDET, of Rouen, in a valuable article in *La Normandie Médicale*, gives a *résumé* of twenty-two years' hospital practice in the treatment of delirium tremens. He says that long ago he gave up the indiscriminate use of opium and its alkaloids as doing more harm than good. The mortality, which, while using opium, was sixteen per cent. of all cases received, fell to six per cent. after the abandonment of the routine opium treatment. In the commencement of an attack he now makes use of an infusion of quinquinia (from sixty to ninety grains to the pint). This is given freely, is well borne, and seems to cut short an attack. Bromide of potassium and chloral hydrate are both valuable drugs, rendering real service in quieting nervous symptoms and producing sleep. Leudet concludes with Gardner, that where opium is used to the extent recommended by some practitioners the patients as frequently succumb to the toxic effects of the remedy as they do to the delirium itself.—*St. Louis Medical and Surgical Journal*, August, 1886.

TREATMENT OF EPILEPSY.—DR. E. D. FISHER writes as follows in the *Journal of Nervous and Mental Disease* for August, 1886:

In reference to the treatment of epilepsy I depend on the bromides exclusively, usually commencing with thirty grain doses three times a day.

I prefer, as a rule, the mixed bromides, in the proportion of four parts of the potassium bromide to two parts each of the sodium and ammonium bromide; when cardiac weakness is present, employing digitalis or aromatic spirits of ammonia.

I have not found, as some affirm, that iron acts deleteriously, that is, when anæmia is present. Nor does the continued use of the bromides for years even, in my experience, lead to any mental disturbance; in fact, I find a gradual improvement in this respect whenever I succeed in controlling the disease.

In regard to cure of the disease, in my opinion that is less often accomplished than amelioration of the condition.

CLINICAL STUDIES OF THE PUPIL.—SCHMEICHLER has recorded the results of over 5000 observations made upon the pupils of persons in health, of those suffering from acute and chronic diseases, and of the dying and dead. There were observed:

1. Pulsations of those vessels of the iris which are in direct connection with the intracranial vessels showed a systole and diastole occurring from sixty to eighty times in the minute.

2. A movement of the iris dependent upon rhythmic impulses from the vasomotor centre, occurring from two to six times per minute.

3. Protrusion and depression of the iris, coincident with respiratory movements. These correspond with the "spontaneous pupillar movements" described by the author. Such movements were noted during an attack of hystero-epilepsy in a girl of twenty-one years. In this case such variations in the rhythmical movements of the iris occurred in the complete absence of pupillary reaction to light, and were coincident with the forced respiratory movements of the patient. The spontaneous pupillary movements were most marked in excitable, neuropathic individuals.—*Centralblatt f. klin. Med.*, July 10, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 25, 1886.

MILK-POISONING AT LONG BRANCH.

IT will be remembered that some weeks ago considerable excitement was created at Long Branch by the sudden development, at several hotels, of a number of cases of severe illness, with all the appearances of acute poisoning, and the distribution of the cases speedily caused suspicion to attach to the milk as the vehicle. In this issue of THE MEDICAL NEWS we present a careful study of this epidemic and its causes by DR. W. K. NEWTON and MR. SHIPPEN WALLACE. The paper is a most important contribution to sanitary science, and its deductions must command widespread attention, since it is evident that this cause of poisoning is liable at any moment to be called into existence, with the same direful results.

The practical value of the investigation lies in the fact that, by a careful process of exclusion, there was obtained a rigorous demonstration not only of the origin of the late wholesale milk-poisoning at Long Branch, but, also, of the precise conditions under which the poison in question was developed. It is now conclusively shown for the first time that milk, warm from the cow, when placed in tight cans, under conditions which greatly retard the dissipation of its heat, will undergo change with the development in the course of five hours of enough of a poisonous ptomaine to cause alarming toxic symptoms in those partaking of the milk even in small quantity.

In view of the fact that tyrotoxicon, the poison thus developed, is volatilized at the temperature of 180° F., we find increased reasonableness in the routine practice of thoroughly boiling all milk intended for the use of infants, especially in summer. Not only does such treatment destroy the germs of lactic acid fermentation, but it dissipates an actively irritant poison which is not unfrequently present in greater or less amount.

This investigation, further, teaches the important practical lesson that milk, immediately after being drawn, should be placed in open vessels and rapidly cooled by being surrounded by ice or cold water before transportation. In this way fermentation, with the resulting production of poisonous ptomaines, such as tyrotoxicon, is prevented, and the milk is delivered in a condition proper for consumption.

THE CHOLERA.

THE present outbreak of cholera in Europe is, as we have before had occasion to point out, very different in its course from that of previous epidemics. Beginning in Toulon, in the early part of June, 1884, it appeared in Italy in July, and in Spain in August of the same year, spreading toward the south, rather than, as has usually been the case, to the north. During that year it caused about 7800 deaths in France, 14,300 deaths in Italy, and 600 deaths in Spain. In 1885 it was most violent in Spain, where it caused nearly 120,000 deaths, the mortality being from fifteen to thirty per cent. of the whole population in some localities, more especially in the smaller villages. During the same year it caused 2545 deaths in France. Disappearing almost entirely during the winter, it was again reported in the spring of the present year in Brittany, where it caused about 500 deaths, and at scattered points in Italy and Spain, where it has continued throughout the summer.

Its marked peculiarity, this year, has been the slowness of its spread, both from place to place, and within the larger towns in which it has been reported. In some places the mortality has been reported as very small in proportion to the number of cases; but in others the disease preserves its usual deadly character—as, for instance, in Ravenna, where over half the cases have died. At present the disease seems to be disappearing in Northern Italy, and we hear little of it farther south; but there is reason to think that it is still prevailing in some of the villages and small towns in Southern Italy, to a much more serious extent than the press dispatches would indicate.

What is the reason for this unprecedented lingering of cholera in Southern Europe, for three years, without spreading to the North, and what are the prospects for next year? There is nothing to indicate that the power of the virus is any way weakened or attenuated; if the disease depends on a micro-organism, that organism appears to be just as lively,

to multiply just as rapidly, and to produce as fatal results, as shown in San Giovanni Rotundo during the last week in August, as ever. Nor can the slow progress of the disease be entirely explained by meteorological conditions, for, although the summer has been everywhere cool, it has not prevented sharp attacks in some localities. It seems difficult to come to any other conclusion than that the spread of cholera has been hindered by the precautions taken, by the increased and better disinfection which has been practised, by the greater care which has been taken of the sources of water supply. It is a noteworthy fact that it is not in the large cities of Italy and Spain that cholera has spread most rapidly, and has been most destructive, but in the villages, where the risks of water contamination are greatest, and where the people are most ignorant of modern methods of dealing with contagion.

As to future prospects, we can only conclude that the germs of the disease will linger in Southern Europe throughout the coming winter, and that it will probably again appear next spring in Italy, and possibly in Austro-Hungary. The danger to this country is, therefore, by no means over. At the same time there is more ground for hope that sanitarians will be able to stamp out the disease in Europe before it has been brought to us than there was in 1884 and 1885, when we had only the experience of previous epidemics to guide us. It must not be forgotten that cholera exists now as an epidemic in some parts of Japan, and that there is some risk of an invasion of this country from the West as well as from the East. This outbreak of cholera in Europe has induced a vast amount of cleaning up, and of interest in sanitary work in the United States, which has been of great benefit already; and the obvious deduction is that the best thing that our States, cities, and towns can do, is to go on, and act precisely as if they expected that cholera will reach our shores next summer.

HEALING UNDER BLOOD-CLOT.

ONE of the most interesting papers read at the last Congress of German Surgeons was by Schede, of Hamburg, in which he gave the results of his experience with a plan for securing the healing of wounds, which is diametrically opposed to the general idea in regard to the management of blood-clots. It is usual to regard these as among the most inauspicious of foreign bodies, and to regard their removal as indispensable to prompt and successful healing. Since the general use of antiseptics, it has been frequently observed that the presence of a clot may not do any harm; that, in fact, the clot may become organized. Observing this fact, Schede has boldly made use of the blood poured out into a variety of surgical wounds to secure a protecting covering, which has the advantage of doing away with the necessity for drainage or compression. In the operation of Phelps for club-foot—open division of all the contracted soft parts, down to and including the astragalo-scaphoid ligament—he found that if he simply covered the gaping wound with a bridge of protective silk, placed over this a good antiseptic dressing, and secured fixation with plaster bandages, he could leave the wound to itself without concern; and that, after three or four weeks, there would be solid cicatrization, or only a short, narrow strip of granulation, or a little strip of leather-colored clot, still attached along the middle, as the sole remains of the large mass of blood which filled the wound immediately after the operation. In this way not only does the skin unite, but all the soft parts—muscles, tendons, and ligaments—assume their normal functions. In manner similar to this, Schede found a very large number of operations to heal without mishap. Of these he gives a list comprising 241 operations, including 40 resections of joints, with 37 typical recoveries; one resection of a piece of the wall of the thorax as large as the palm of the hand, with typical healing; 18 operations in which he chiselled out tuberculous foci in bone, with free opening of the joint, all with typical healing; 29 cases of removal of necrosed bone, with 27 typical recoveries; 20 open operations for club-foot, all with typical healing; 10 operations of scraping off of fungous granulations of the sheaths of tendons, with suppuration in only 2 cases; 24 cases of removal of tumors, with slight suppuration in only two. In one case he saw a large blood-clot become organized in the lacerated brain, after a severe complicated fracture of the skull; and once, in a fracture of the elbow-joint, in which he had to make a deep incision into the joint, to relieve tension, the wound being about nine inches long and three inches wide, the blood-clot remained in place for over three weeks, until the fracture was consolidated.

The method pursued in securing these extraordinary results was, where possible, to employ Esmarch's bandage, to observe the most scrupulous asepsis, and to remove every portion of diseased tissue. Large wounds were closed with sutures, placed at such intervals as to leave only one or two openings about half an inch long, to permit the escape of superfluous blood into the dressing. In some cases a counter-opening was made for this purpose. Schede found that the skin united well over considerable cavities, such, for example, as are left after an operation for necrosis, and that unsutured wounds, like that after Phelps's operation for club-foot, healed equally well. No drainage tube was used. The wound was covered with a piece of protective for two purposes: first, to secure complete filling of the wound with the blood-clot, and second, to keep this moist by preventing

its absorption by the dressings, which were only intended to absorb the excess of blood. Over all was placed a thick antiseptic dressing of sublimate gauze and cotton, and sublimate moss bags. It is important, in order to secure the filling of the wound with blood, that when a counter-opening is made, it shall be at the highest point, instead of, as usual, at the lowest. In regard to the control of hemorrhage, when no large vessels were wounded, and the bleeding was not profuse, no account was taken of it. Arteries of any size were ligated, of course, and the filling of the wound was left to the parenchymatous bleeding.

Perfect asepsis is indispensable to Schede's method. If any doubt exists in regard to having secured it, he advises filling the wound with antiseptic material, such as iodoform gauze, or sublimate gauze, or bismuth, and leaving it till granulation is established, after which the filling of the wound with blood can be secured by shaving off the granulations, and the cure will be hastened materially.

Schede is convinced that this method will soon secure many friends, because of its great convenience, and because it secures the safest, quickest, and most perfect healing, and often the most perfect functional results. The knowledge of his success will go far to fulfil this expectation, which will be aided by reflection upon facts which must have been observed by many a surgeon who has been already compelled to act as he has done without any well-defined purpose, such as prompted Schede to adopt and recommend this as a general method; for which reason it may well be called by the just and convenient name of "Schede's method."

PERLÈCHE.

Under this term Lemaistre, in *Le Progrès Médicale*, describes a parasitic disease of children, characterized by an affection of the lips, appearing first at the angles of the mouth and gradually involving the epithelium of both mucous and cutaneous surfaces. The heat and irritation cause the children to lick the lips, hence the name *perlèche—lècher* or *perlècher*, to lick—given by the people of the district in which it prevails. The lesion seems confined to the epithelial layers, and resembles closely a mucous patch. Small fissures may form, particularly at the angles of the mouth, and may bleed and cause great pain. The disease is not severe, lasts from two weeks to a month, relapses are common, and attacks may recur yearly. It is highly contagious and is probably communicated in the schools by the drinking cups. The statistics of the affection are interesting. In Limoges, of 5500 children attending the schools 312 were attacked. In the winter, when these figures were collected, the disease is not very prevalent, but in the spring and summer months the cases become very numerous. A microbe was readily discovered in the exudation—a streptococcus—and it is claimed that one similar in general character was found in the water adjacent to the infected schools, but the evidence of the identity of the two and of the actual dependence of the disease upon it, is not well sustained.

Possibly this affection is the same as certain forms of sore lips in children, which we see here at times, but never, so far as we know, in epidemic form. It may be allied to aphthous stomatitis, which is unquestionably contagious, and which in Holland, and occasionally in this country, has been epidemic during very moist seasons, or after inundations. Very good evidence of the spread of the disease in families is given in the *Gazette Médicale de Paris*, for August 21st.

Charleston experienced, last Tuesday, three more earthquake shocks, resulting in still further injury to her buildings. We particularly regret to learn that additional damage was done to her Medical College building, of which a large part of the walls fell in, so that it is now a gaping ruin, and apparently the remaining walls are so badly cracked that they will have to be pulled down to the basement.

The misfortunes which have overtaken our medical brothers of Charleston appeal silently but eloquently to the profession in other parts of the Union for liberal aid. The individual losses of the physicians of Charleston are so great that they are at present entirely unable to contribute to the rebuilding of their Medical College, which, although a time-honored institution, is without endowment. In this crisis pecuniary assistance should be forthcoming—promptly, liberally, and from all parts of the country. Aid now given will enable the Faculty to continue their labors, and, by holding their students in Charleston, to do their share toward promoting the revival of business in the earthquake-stricken city.

The Medical News will be happy to facilitate contributions by acknowledging in its columns the receipt of all sums sent to its care, and will forward the same to the Medical Faculty.

As a supplement to our editorials on the method of Antyllus for the treatment of aneurism in The Medical News of May 1st and 29th, of this year, we would call attention to a recent communication by Köhler, in the *Charité Annalen*, in which he reports its successful employment in a case of aneurism of the popliteal artery, rapidly developed, in a man twenty-seven years old. Instrumental and digital compression had proved useless, and Köhler excised the sac, which was four inches long by three inches wide, with about two and a half inches of the popliteal vein, and ligated the artery above and the tibiales

anticus and posticus below. The opening made was as large as two fists. It was closed with sutures and a drainage tube inserted. Healing occurred by first intention and no functional disturbance resulted from the operation. Köhler has collected the records of fourteen such operations since 1875, all successful.

Another volume of the *Index Catalogue of the Library of the Surgeon-General's Office* has just been issued. It comprises 959 pages and extends from "Insignarès" to "Leghorn." Like its predecessors, it has been compiled under the supervision of Surgeon J. S. Billings. An idea of the magnitude of the work which Dr. Billings has undertaken may be formed from the statement, that this seventh volume of the Catalogue includes 14,688 author-titles, representing 5,987 volumes, and 12,372 pamphlets, and 6,371 subject-titles of separate books and pamphlets, and 34,903 titles of articles in periodicals. As evidence of its comprehensiveness, and of its value as a guide to study, we may note that under the heading of "intestines," there are sixty double-column pages of references, under "labor" we find fifty pages, and the "larynx" furnishes over forty.

We find in this volume the same intelligent treatment of details and freedom from error in proof-reading which have characterized the previous volumes of this great work.

Hysteria in soldiers is a condition which, until a comparatively recent date, has been entirely unrecognized. Its existence, however, may now be regarded as established, especially convincing evidence having been lately adduced by Duponchel, who, in the *Revue de Médecine*, 1886, No. 6, records *in extenso* the clinical histories of numerous soldiers in the French army who suffered unequivocally from hysteria, and in some cases from the so-called *grande hysterie*. Ignorance of the facts here presented has undoubtedly caused those actually suffering from hysterical convulsions to be regarded either as malingerers or epileptics.

REVIEWS.

Die Intoxikationsamblyopien. Von Dr. Otto Bergmeister, Docent der Augenheilkunde an der Wiener Universität. 8vo. pp. 21. Wien: Urban & Schwarzentry.

Toxic Amblyopias. By Dr. Otto Bergmeister.

Dr. Bergmeister arranges these, according to their causation, in four groups. First, those due mainly to working with certain substances, such as the amblyopia and amaurosis to which workers with lead, bisulphide of carbon, etc., are liable. Second, chronic poisoning through the abuse of narcotics, as alcohol, tobacco, opium, and haschisch. Third, acute poisoning by certain medicinal substances, as quinine, salicylic acid, bromide of potassium, etc. Fourth, poisoning by snake-bite with subsequent loss of sight.

Cases of alcohol and tobacco amblyopia are the most frequent. To alcohol is assigned the greater influence in this direction, though chronic alcoholism, in which it occurs, is usually associated with the excessive use of tobacco. The comparative infrequency of the affection also indicates that individual predisposition plays an important *rôle* in its causation. The diagnosis does not rest upon the ophthalmoscopic appearances; but on the acuity of vision, the condition of the light-sense and the color sense, and especially on the oval central scotoma for red and green. Central visual acuteness may be greatly diminished, but the light-sense is unimpaired, the patient actually seeing better by a weak light. The ophthalmoscope shows early a slight hyperæmia of the disk with indistinctness of its margins, and later atrophy of the temporal portion of the nerve. The affection is one of the optic nerve, an axial neuritis near the apex of the orbit. Under treatment the prognosis is good except in advanced atrophy. Treatment consists in enforcing abstinence and the management of digestive derangements. Carlsbad salt in warm water, hydrotherapy with free diaphoresis, and injections of strychnia are recommended.

Of amblyopia due to lead-poisoning four forms are recognized, as by Leber: 1. Sudden binocular blindness; vision rapidly reduced to mere quantitative perception of light. Pupils dilated and fixed. Ophthalmoscopic appearances negative, or slight hyperæmia of the retinal vessels with blurring of the margins of the disk. Some of these cases are looked upon as analogous to sudden amaurosis caused by uræmia. These are to be treated by pilocarpine and the use of alkaline waters. Others are regarded as retrobulbar neuritis, which may also end in recovery, or in atrophy with impairment of vision. 2. Gradually increasing amblyopia, usually with central scotoma or concentric narrowing of the field of vision; sometimes color scotoma; impairment of the light-sense; and the same ophthalmoscopic appearances as the first form. These are also regarded as instances of retrobulbar neuritis. 3. Violent optic neuritis tending to pass quickly into atrophy. These cases may begin with sudden blindness or pass gradually to amaurosis. The prognosis is usually unfavorable. There are apt to be associated lesions of other cranial nerves, or of the brain. The urine is free from albumen. 4. Albuminuric retinitis occurring where albuminuria has been caused by lead-poisoning.

Amblyopia due to exposure to the fumes of bisulphide of carbon and chloride of sulphur occurs among workmen engaged in vulcanizing India-rubber. Usually it is preceded by other marked evidences of chronic poisoning. Subjective colors are noticed; there is paresis of accommodation, the visual acuity is lowered, and a central color scotoma occurs. The ophthalmoscope reveals evidence of an optic neuritis or perineuritis succeeded by atrophy. The prognosis seems favorable when further exposure to the cause can be avoided.

In quinine amaurosis the blindness comes on very rapidly and is often absolute, not a trace of the power of light-perception remaining. The pupils are dilated and fixed, the retinal vessels greatly contracted or entirely invisible, the optic disk chalky-white. The

prognosis is, however, quite favorable. The ophthalmoscopic appearances become normal. Sight returns and the acuity of central vision generally becomes perfect, but the field of vision enlarges slowly or remains permanently contracted in the form of an ellipse with the long axis horizontal. The dose causing these symptoms varies from three to eighty grammes, the latter taken in the course of two days. The inhalation of nitrite of amyl is recommended to relieve the retinal anæmia.

Cases of amaurosis, apparently similar to that produced by quinine, have been caused by salicylic acid, salicylate of sodium, and bromide of potassium. Cases of amblyopia have been reported due to poisoning by various other agents, as santonin, carbolic, osmic and hydrocyanic acids, opium, haschisch, mercury, and nitrate of silver.

Clinical Therapeutics. Lectures in Practical Medicine, delivered in the Hospital St. Antoine, Paris, France. By Prof. Dujardin-Beaumetz. The Treatment of Nervous Diseases, of General Diseases, and of Fevers. Translated by E. P. Hurd, M.D. Detroit, Mich.: George S. Davis, 1885.

Diseases of the Stomach and Intestines. A Manual of Clinical Therapeutics for the Student and Practitioner. By Prof. Dujardin-Beaumetz. Translated from the fourth French edition by E. P. Hurd, M.D. New York: Wm. Wood & Co., 1886.

These two volumes are taken from a series by Prof. Dujardin-Beaumetz, entitled *Leçons de Clinique Thérapeutique*, of which the work *Clinical Therapeutics* is the third and last volume and *Diseases of the Stomach and Intestines* is the first. But from the latter is omitted the first part of the French volume, including diseases of the heart and aorta. The second volume of the French series on the treatment of diseases of the liver, kidneys, lungs, pleura, larynx, and pharynx passed through its fourth edition in 1885. This, with the first part of the first volume above alluded to, we have not as yet in English, but it is to be hoped that ere long both will be added to the series.

Clinical Therapeutics, after a short discussion of the general subject from which the volume takes its name, is divided into three parts. The first part embraces short sections on the nervous system from a therapeutic standpoint, hydrotherapeutics, medical electricity, and chapters upon the treatment of neuralgia, hysteria, epilepsy, chorea, meningitis, apoplexy, and chronic myelitis. Part second takes up general diseases, discussing the blood, with instructive sections on bloodletting, the treatment of anæmia, acute rheumatism and gout, diabetes, and syphilis. Part third, after an introductory treatise on fever, deals minutely with the treatment of typhoid fever, intermittent fever, and the exanthemata. Not the least interesting of the contents of this volume is a short biography of Prof. Dujardin-Beaumetz, with a bibliography of his published works, contained in the translator's preface.

Diseases of the Stomach and Intestines are discussed in twenty-five lectures, and the subjects included are alimentation, regimen, and lavage and gavage of the stomach, dyspepsia, vomiting, neuroses of the stomach, buccal and intestinal dyspepsia, secondary dyspepsia and that of newborn infants, ulcers and cancers of the stomach, the intestine from a therapeutic standpoint, the treatment of constipation by hygiene and purgatives, and the treatment of intestinal occlusion, diarrhœa, dysentery, hemorrhoids, and intestinal worms. The titles show how comprehensive is a work which does not even pretend to be a handbook.

A large place is given in this volume to the hygienic treatment of disease; the necessity of pure air, of suitable exercise, of a proper dietary regimen, etc., is everywhere insisted on. Both volumes are enriched with copious annotations, giving concise summaries of the fruits of Continental research, and with valuable bibliographies suggestive of the immense amount of reading and clinical experience which have fitted the author to speak authoritatively to the medical public; and it is hardly possible to estimate the debt which the English-speaking branch of the profession owes to Dr. Hurd for placing these volumes in their hands.

SOCIETY PROCEEDINGS.

RHODE ISLAND MEDICAL SOCIETY.

Quarterly Meeting, held at Providence, Sept. 16, 1886.

The President, Dr. Horace G. Miller, called the Society to order.

Dr. F. C. Clark reported a case of *Abscess of the Mastoid Region*.

Dr. Anita E. Tyng, of Philadelphia, read a detailed report of two cases of

ABDOMINAL SECTION FOR OVARIAN DISEASE,

both ending in recovery from the operation. In one case both ovaries were found to be enlarged, but so adherent that it was impossible to remove them. In the second case, a cyst and contents, weighing 36½ pounds, were removed. The operations were performed at the Woman's Hospital, Philadelphia.

Dr. F. C. Clark read a paper on the

RELATION OF THE APOTHECARY TO THE PHYSICIAN,

and at its conclusion submitted the following resolutions:

Whereas, The introduction by apothecaries of certain remedies has had an injurious effect upon the profession of medicine, and tends to the usurpation of its functions:

Resolved, That the members of the profession use every means at hand to discountenance and discourage the employment in their prescriptions of any and every remedy put up and sold by any druggist, apothecary, chemist, or pharmacist, which compound comprises two or more medical substances, and has upon its label, wrapper, or both, the ailment or ailments for which it is to be employed, with or without the dose, and appended thereto some name or title to attract attention to it, whether of physicians or others, and thus contribute to the injury and dishonor of the medical practitioner; and, furthermore:

Resolved, That all such remedies, with or without the name and character of their ingredients, be interpreted in the same manner and spirit as are those nostrums coming under Article 1, Section IV., page 37, of the Code of Medical Ethics.

After some discussion, it was voted that the resolutions lie over until the next regular meeting.

The Chair announced that at the last annual meeting a proposition was made to appoint

A BUILDING COMMITTEE,

and that the objection was then raised that it would be unconstitutional to use the funds of the Society for the erection of a building. On examining the Constitution, he had found that the Society could hold real estate that should yield an income to the amount of only $500 per annum. He had, therefore, withheld his appointment of the committee, and recommended that the Legislature be petitioned to make the necessary changes in the Society's charter.

On motion of Dr. White, the Chair was authorized to apply for such an amendment.

The Chair announced the deaths of two Fellows—Dr. Charles F. Fabyan, of Providence, and Dr. Aldrich, of Wyoming, R. I.

Dr. O'Leary spoke of a very severe type of

ACUTE DYSENTERY

that is now prevalent in Providence, and reported three fatal cases that he had seen.

Dr. L. F. C. Garvin, of Lincoln, R. I., reported on the

PREVALENCE OF MALARIAL DISEASE

in Rhode Island, and said that he had seen no less than twelve fatal cases during the past five years. He regarded malaria as a very severe and dangerous disease, and one that should be brought under control as promptly as possible. In the fatal cases he had seen, death was preceded by coma, and had not resulted from the so-called congestive chill. He had heard of only one case in Rhode Island of the latter type.

The Society then adjourned, and took steamer to Silver Spring, where a shore dinner was enjoyed.

CORRESPONDENCE.

EXCISION OF VARICOSE VEINS.

To the Editor of The Medical News,

Sir: With reference to your editorial on "Excision of Varicose Veins," in the issue of The Medical News for September 11th, p. 291, allow me to say that on my recent visit to Europe I saw Mr. Clutton, one of the assistant surgeons to the St. Thomas Hospital, London, operate for the cure of varicose veins by excision, and also for varicocele by the same method.

He made, under chloroform-anæsthesia, a longitudinal incision four or five inches long along the course of the most prominent veins, isolated the vein by a neat dissection with the handle of the scalpel, tied it at each extremity of the incision, and cut out the intervening portion. He made three such incisions, parallel, about an inch or so apart, and removed an equal portion of the vein in each.

The operation for varicocele was done in a similar way in the case of a young man about nineteen years of age, who desired to enlist in the British army—the trouble being considered a defect, and cause for rejection both in the British army and also in the United States army. The incision, like that for varicose veins, was made along the course of the enlarged veins, the most prominent one separated, two ligatures applied, one above and one below, an inch and a half to two inches apart, the portion between removed by scissors, and exhibited to the students, which showed great thickening of its coat, being nearly patulous throughout. The incisions were closed by sutures, iodoform powder dusted over, and the usual antiseptic lint and gauze bandage applied.

I did not see the result of these particular cases, but was told that other similar cases operated on uniformly did well. No mention was made by the operator to the students or others, of any apprehension of danger from the operation, and as it proceeded and ended without the usual antiseptic precautions one might suppose was demanded in such cases, the inference was that it was looked upon as one of the usually necessary operations unattended by any particular risk or danger, and causing no uneasiness as to the result. The operation in both cases was smoothly, evenly, and quickly performed, and has much in it to recommend it in this field of surgery.

S. J. Radcliffe, M.D.

1523 K Street N. W., Washington, D. C.

DILATATION OF STRICTURE OF THE ŒSOPHAGUS AFTER GASTROSTOMY.

To the Editor of The Medical News,

Sir: In an interesting editorial article in The Medical News, upon "Dilatation of Stricture of the Œsophagus after Gastrostomy," the statement is made in regard to the method advocated by Dr. Victor von Hacker, of Vienna, that "it does not appear that this plan has ever been put into practice." Dr. von Hacker states, in his monograph "Ueber die Magen-operationen, etc., that he recommends the method, because he had obtained a good result in a cicatricial stricture of the œsophagus, by the introduction of a Nélaton catheter stretched over a whalebone guide. In a letter to me, dated July 27th, 1886, he mentions two cases in which the operation of dilatation by the use of drainage tubes attached to filiform guides had been performed; in one of which he states that the operation had already been successful; the other had been but recently performed at the time of writing.

Yours respectfully,

Randolph Winslow.

1 Mount Royal Terrace, Baltimore,

(*From our Special Correspondent.*)

Pseudo-insensibility Treated by Massage.—A paper recently read before the Academy of Sciences dwelt at length on pseudo-anæsthetic conditions masking actual sensibility which is aroused by prolonged stimulation. In locomotor ataxia, hysteria, and hemiplegia resulting from brain lesion, this pseudo-stimulation anæsthesia is often present and extends over a limb or one-half of the body.

No effect is produced on these patients by rubbing for a short time, however thoroughly it may be done;

but long-continued friction produces an impression more and more vivid as it goes on. More than this, the revival of sensibility does not only last for the moment, the effect obtained may persist and even increase from day to day. For example, it might be supposed that in people suffering from apoplexy, that after the occurrence of the accident which interrupted the communication between the brain centre and a certain part of the contiguous nerve centres, a prolonged effort must be necessary in order that the impression produced be transmitted and thus reëstablish the connection. Whatever the explanation may be, the fact exists and had already been noticed by M. Legroux. At the present time M. Ball and M. Courtade are making experiments relating to this subject. In the same way that there exists often a latent sensibility only requiring to be aroused, so in other patients the motor power may be dormant, and to reinduce action all that is necessary is to produce excitement by direct stimulation of the muscles. This can be done by electricity, but, when properly managed, massage is quite as good. M. Courtade groups his patients in different classes. There are in the first class persons paralyzed after brain apoplexy. Massage has produced effects on them which are truly surprising; in some instances the condition was recent, in others of long standing, and paralysis was in some accompanied with contracture. A man aged sixty-two, attacked with apoplexy three months ago, walked with difficulty. The left hand was quite useless. After one treatment by massage, lasting half an hour, he was so much better that he could energetically move his left hand and almost walk without a stick.

Another case is that of a sculptor who was attacked with apoplexy five years ago, and remained paralyzed on the left side. After eighteen months in the hospital he left, though walking with difficulty, but was obliged to return, as the upper limb of the left side being useless he could do no work. There was also contraction of the biceps. At first M. Courtade commenced by treating the upper limb with massage; the treatment was applied on four or five different occasions spreading over a month and a half. At the present time the paralysis of five years' standing and the resulting contracture have almost entirely disappeared in the upper limb. As to the lower limb, after massage being applied once it appeared more contracted the next morning, but afterward became much freer.

In a second class are patients who have been paralyzed after an attack of typhoid fever. For instance, a man aged twenty-one had typhoid fever last year and has been paraplegic ever since. He has undergone treatment by massage combined with electricity, and the results, though not yet complete, are still very good. At the present time he can walk with crutches.

M. Courtade has already obtained an almost complete recovery in the case of a young woman paralyzed after an attack of typhoid fever. Another woman, who had had typhoid fever when nineteen years of age, was not attacked with paralysis until eighteen months later, when she was suddenly seized with apoplexy, lost consciousness, and on recovering was found to be speechless and paralyzed in both legs and the right arm. Aphasia lasted six weeks and paralysis of the right arm two years. Later on, the lower limbs suddenly regained the faculty of executing movement. Three years ago the patient recovered the power of walking, but she accidentally fell and the two lower limbs again became paralyzed. She was from that time subject to attacks of hysteria, and presented the general aspect of a hysterical person. It is possible that hysteria being an etiological factor in the paralysis, trophic disturbance occurred. The lower limbs became swollen to an abnormal size; no muscles were distinguishable. The feet were bent and a painful feeling of cramp disturbed the patient's sleep. After the first treatment by massage there was a distinct improvement, which increased on each occasion. M. Courtade was careful that after gradually drawing out the feet they should be kept extended by an immovable apparatus. The pseudo-fat was rapidly absorbed. The legs, which had remained motionless for a long time, can now be raised more than a foot above the bed, and she can get up and dress herself.

The London Hospital Sunday Fund amounts this year to over $180,000, being $25,000 more than it was last year.

Poisoning by Potassium Chlorate.—A workman in Vienna, suffering from inflammation of the throat, was given two ounces of chlorate of potassium, with verbal instruction to use it for a gargle; the only instruction upon the prescription was, however, "a coffeespoonful in a glass of water." The patient's wife gave her husband a spoonful at one o'clock, and another at two, in a medium size tumbler of water, and half a spoonful about five, and another about six. Abdominal pains and diarrhœa set in shortly after taking the first dose. At 7.30 profuse perspiration came on, and, about nine, sleep. At ten the patient became unconscious, and at one in the morning death took place.

A Novel Obstetrical Expedient.—Dr. Shustoff writes in *Russkaya Meditsina* of April, 1886, that he was called to see a woman who had been in labor five days. The pains had begun well, but had since ceased. Upon examination, he saw something black protruding from the anus, and a little pulling brought to light a sausage over seventeen inches long and fourteen inches in circumference. The pains now began again, and the woman was soon delivered of a dead child. Dr. Shustoff found on inquiry that the sausage had been introduced on the recommendation of an old woman of the neighborhood in order to insure the birth of the child by the normal passage. This was probably the old wife's best attempt at supporting the perineum.

Death from Chloroform.—Lady Flora Wilmot died at Swansea, England, after taking chloroform in a dentist's chair for the extraction of a tooth. The anæsthetic was administered by a physician. The patient had taken chloroform twice before without any bad effects. In all, but two drachms were used. All attempts to restore the patient by the use of nitrite of amyl and artificial respiration were of no avail. The physician remarked, immediately after the extraction of the tooth, "I hate giving chloroform for you dentists because you will have your patients sitting up." Both the dentist and the physician were exonerated by the jury which

was called to hold an inquest. *Science* comments on this case as follows: "The evidences of the danger in the administration of chloroform are so overwhelming, except in a few cases, that no one is justified, at the present day, in using it in so simple an operation as the extraction of a tooth; and a jury would be doing its full duty in holding responsible for the death of the patient any physician or dentist who administered it in such a case with a fatal result."

A Fellowship in Pathology yielding five hundred dollars in addition to free tuition, will be granted by the Johns Hopkins University in October, 1886, if a suitable candidate applies.

The application must be made prior to October 1. The candidate must give evidence of a liberal education (including especially physics, chemistry, biology, and modern languages) and of special aptitude for pathological study, such as that afforded by some previous scientific work. The holder of the fellowship will be expected to devote his time to some special line of investigation (not strictly professional) under the direction of the Professor of Pathology. Further information concerning the purposes and the regulations of University fellowships is contained in the Annual Register.

A Fortunate University.—Since 1879 the University of Sidney has received donations exceeding a million of dollars. One bequest, known as the Challis bequest, is expected to realize £200,000. The Macleay Natural History collection, another recent gift, is valued at £25,000, and a sum of £6000 has been promised for the endowment of a curatorship in connection with it. For the purpose of founding a library, a donation of £30,000 was made.

Bombay Hospital for Women.—The *Times*, of India, gives an account of the opening of the Cama Hospital (officered entirely by women) by his Excellency Lord Reay, Governor of Bombay, in the presence of a very large assembly of friends, on July 30. The foundation stone of the hospital had been laid in November, 1883, by his Royal Highness the Duke of Connaught. In opening the hospital, Lord Reay remarked that there was no movement in India in which Her Majesty felt greater personal interest.

French Vital Statistics.—It was stated by M. Bertillon, in a lecture recently delivered at the Hygienic Exhibition in Paris, that the movement of the population for the past year throughout France had been very unsatisfactory, the total number of births being 922,361, or, upon the average, 30,000 fewer than for the last fifteen years. Moreover, out of this total, 74,118 were illegitimate, or rather more than eight per cent. of the whole, this being the largest number of illegitimate births ever recorded. Upon the other hand, there had been a slight reduction in the number of deaths, the total for 1885 being 836,897; but still, the excess of births over deaths was only 85,464.

Smallpox and Vaccination in New York.—The following is an extract from the Fifth Annual Report of the State Board of Health of New York (p. 454, April, 1885): "The objections and occasional resistance to vaccination which are met with among immigrant passengers, indicate a considerable scepticism in European communities, more particularly among the English people, as to the protection afforded by it, or else a fear that constitutional disease will be introduced by that means. The groundless character of the fear that disease will be communicated by vaccication, when proper care is used in the selection of the vaccine virus, has been too often demonstrated to require any argument in this place. The result of the teachings and influence of the anti-vaccinationists is well illustrated by the fact, that in the hospitals of the city of New York not a single case of smallpox exists at this time, while in the city of London the reports have shown for months past an average of upwards of eleven hundred cases in hospital. In New York city, where a 'from house-to-house' inspection and search among the tenement population for the unvaccinated is practised every year, smallpox is not met with, except as it was imported and developed by persons from other localities; in London, the weekly average of new cases, as indicated by bills of health and the number in hospital, has been from four to five hundred. The number of cases of smallpox on vessels that entered that port in 1883 and 1884, was twenty-five."

Ice in the Sick-room.—A saucerful of shaved ice may be preserved for twenty-four hours, with the thermometer in the room at 90° F., if the following precautions are observed. Put the saucer containing the ice in a soup-plate and cover it with another. Place the soup-plates thus arranged on a good heavy pillow, and cover with another pillow, pressing the pillows so that the plates are completely embedded in them. An old "jack-plane," set deep, is a most excellent thing with which to shave ice. It should be turned bottom upward and the ice shoved backward and forward over the cutter.

Doctoring an African King.—The following extract is from the correspondence of the *Scottish Geographical Magazine*: "It is no joke to be doctor to the King of Uganda, for whenever I took him a new supply of medicine I had always to take a dose myself, and to administer one to seven of the persons who might happen to be present. Should one of the seven unfortunates die within a week, it would be considered that I had attempted to poison the king. If the king had to take a pill, I had always to hold two in my hand; he chose one, and I had to swallow the other, unless I had a friend with me who kindly undertook the office. I soon noticed, however, that Mtesa also chose the smaller, so I arranged accordingly. One day Mtesa played me a nice trick. I had been to the palace to take him a lotion, and had warned him particularly not to drink it. After I had left he sent a page after me with a gourd of mwengi, asking me to taste it, and say if he might have some. I did so, and said, "Yes." It being a very hot afternoon, my friend drank the remainder; but it soon became evident that the king had doctored the wine, for my friend became violently sick. It turned out afterward that Mtesa wished to see what effect the lotion would have upon me."

American Rhinological Association.—The fourth annual meeting of this Association will be held at St. Louis, Mo., on October 5, 6, and 7, 1886.

PATENT MEDICINES IN AMERICA. — The *Western Druggist* informs us that recently published statistics state there are 5000 proprietary articles of home manufacture on the American market; 500 of these are of commercial importance, and 50 are run as an independent business. The patent medicine trade of the United States is $22,000,000 annually; of this $10,000,000 is annually expended in advertisements, and the net profit amounts to $5,000,000.

The traffic is the work of the past half century, most of the patent medicines having sprung up since 1830. Not one in a thousand patent medicine men have succeeded. There are five firms which have made $1,000,000 each; twenty others will aggregate $5,000,000, and the net savings of all the rest will not reach another $5,000,000. More patent medicines proportionately are sold in the United States than elsewhere. The great middle class buys most of them. The profits from and expenditures on established patent medicines run about as follows:

Expenses.	Per cent.
Cost of material, labor, and expenses	24
Advertising	12½
Jobbers' expenses	3½
Retailers' expenses	21
Total expenses	61
Profits.	
Manufacturers' profit	12½
Jobbers' profit	5½
Retailers' profit	21
Total profits	39

The smaller country newspapers subsist largely upon advertisements of these "remedies," and at least $100,000,000 have been paid newspapers during the last two decades, while upward of $5,000,000 have been expended in rock and fence advertisements.

The field for new patent medicines is narrowed every day. Cathartic pills and sarsaparillas do not succeed readily, because so many well established specimens occupy the field. Until the stamp tax was abolished, patent medicines yielded the government $1,800,000 annually. The census of 1880 shows that there were then 563 establishments in this line in the United States, employing 4015 operatives; that the capital invested was $10,620,000, and that the value of the annual output was $14,682,000. New York stood first in the amount of capital invested ($3,512,430), and in annual output (nearly $4,500,000); Pennsylvania second in capital invested, $2,000,000, and third in annual output, $1,000,000; Missouri third in capital, $1,500,000, and fourth in annual output, $750,000; Ohio fourth in capital, $570,000, and fifth in annual output, $450,000; Massachusetts fifth in capital, $521,000, and second in annual output, $1,500,000.

PASTEUR'S WORK.—Professor Virchow is reported to have said, in a recent lecture in Berlin, that Pasteur had done the world a great service if he had succeeded only in allaying the fear consequent upon the bite of a mad dog.

HYDROPHOBIA does not exist in Lapland; but two dogs brought from that country having been inoculated by M. Pasteur, contracted rabies, proving that Lapland dogs are not refractory to the disease.

WOMEN STUDENTS IN PRUSSIA.—In virtue of a recent decision of the Prussian Minister of Public Instruction, no women are permitted to attend any of the Prussian universities, either as students or auditors.

SCIENTIFIC EXPERTS AS WITNESSES.—Let us look at this question as it presents itself to men of science, alike to the chemist, the physicist, the mechanician, the geologist, the physician, and the microscopist, though certainly not to the astronomer, who is in no danger of being called, as such, to give his testimony. The expert occupies a totally anomalous position in court. Technically he is a mere witness; practically he is something between a witness and an advocate, sharing the responsibilities of both, but without the privileges of the latter. He has to instruct counsel before the trial and to prompt him during its course. But in cross-examination he is the more open to insult because the court does not see clearly how he arrives at his conclusions, and suspects whatever it does not understand. The late Dr. R. Angus Smith complained of being "contemptuously compelled to herd with thieves and scoundrels in a witness-box." He adds: "I have seen barristers speaking to a scientific witness in such a way as to show that to them a witness was always an inferior person." Surely, every person who has been present at a technical trial, or has had to appear as an expert in a poisoning, a patent, or an adulteration case, will be able to confirm this from his own observation and experience.

Now it may, perhaps, be cynically hinted that men of science should be willing to bear all this annoyance for the public good. But is it for the public good? In the first place, not a few of the most eminent men in every department of science distinctly and peremptorily refuse to be mixed up in any affair which may expose them to cross-examination. "I will investigate the matter, if you wish it, and will give you a report for your guidance, but only on the distinct understanding that I am not to enter the witness-box." Such in substance is the decision of not a few men of the highest reputation and the most sterling integrity. Certainly it is not for the interests of justice to render it impossible for such men to give the court the benefit of their knowledge.

Further, the spectacle of two men standing contradicting or seeming to contradict each other in the interest of their respective clients is a grave scandal. Men of the world are tempted to say that "science can lay but little claim to certainty, and is rather a mass of doubtful speculations than a body of demonstrable truth." To us, at least, there is nothing more saddening than to read the trial of a notorious poisoner, or the report of a great patent case, especially if taken along with the comments of the press and of society on these occasions.

Here, then, we see that our present mode of dealing with scientific evidence is found on all hands unsatisfactory. The outside public is scandalized; experts are indignant; the bench and the bar share this feeling, but unfortunately are disposed to blame the individual rather than condemn the system.

But we fear that this unanimity of dissatisfaction will vanish as soon as a remedy is seriously proposed. To that, however, we must come unless we are willing to dispense with scientific evidence altogether.

As it seems to us, the expert should be the adviser of the court, no longer acting in the interest of either party. Above all things, he must be exempt from cross-examination. His evidence, or rather his conclusions, should be given in writing, and accepted just as are the decisions of the bench on points of law.—*Chemical News.*

An English View of American Medical Schools.—H. W. Jones, M.A., M.D. (U. S. A.), writes as follows to the editor of *Lancet:* "It is by no means uninteresting to a medical man 'abroad' to observe his own country and its institutions through the eyes of foreign authorities. And while we must confess to much that was questionable in the past, it appears at present that the case of medical education in the United States is hardly put with fulness—if, indeed, with fairness. As the effete doctrines of the early Church yet serve as the sceptic's best weapons, so now do the allegations which I here rehearse rise against the 'American system.' We are charged with 'inadequate preparation,' opening the schools to crude and undisciplined minds; with a 'too short and narrow curriculum,' giving insufficient and unbalanced foundation for so serious and important a superstructure; with 'poverty of clinical advantages,' committing students to an unpractical, and, therefore, untrue, view of their future duties; with 'the full degree conferred by any of the too numerous colleges after such a course.' Truly a sad catalogue of errors, if applicable now and generally to the institutions of any country. But a knowledge of all the circumstances will insure material alteration in the scope of these charges and a much closer approximation to the truth. Though I write without statistics at hand, and only from a general acquaintance with the facts acquired by long professional observation, I venture to state that more than half the American graduates have for many years gone out from the three great medical centres, New York, Philadelphia, and Boston, whither have gravitated for the same period the greater lights of the profession as practitioners, teachers, etc. These men, many of them of humble birth, self-taught, having elevated themselves to a great and noble success, do not forget their own origins, and are slow to place impediments in the way of those who have the same aspirations, the same difficult ascent to make. Hence, the moderate requirements of the preliminary examination to be followed in these schools by instruction not easily surpassed in breadth and accuracy, I am bold to say, whether it be didactic or clinical. Here hospitals are numerous and abounding in every variety of material. At Yale and the Cincinnati, Chicago, Michigan, St. Louis, and New Orleans schools the same is true, excepting the restrictions arising from moderate hospital accommodation, which will always vary with population. Here at least a third of the whole number of annual graduates receive their diplomas, and in most of these schools the final or 'pass' examination covers the entire field of study, determining the solid acquirements of the student, rather than what he may have 'crammed' during the weeks previous. In some cases the 'State Medical Society' exercises a wholesome supervision, its delegates taking active part in the oral tests applied to scholarship. Post-graduate courses are often open to the more ambitious student, and to such practitioners of long standing as may desire henceforth to restrict their work to special lines. To 'graduate into a specialty' is not with us *en règle*. It is the 'mushroom school' which gives rise to offences as rank in the nostrils of American as in those of foreign physicians. These spring up in the growing towns of the vast West, partly the offspring of local ambitions and rivalries, partly from a local demand for a not too costly medical instruction, made by the pupils and assistants of neighboring practitioners, or by youths who labor two-thirds of the year to earn the means of defraying the cost of a winter's tutelage in medicine. Few of these ever graduate, and, if they do, few fail to seek their diplomas at a more legitimate fountain-head. The schools themselves meet with early graves, though their example and warning are not long heeded. It is true that all who graduate from these State-chartered schools receive the degree of M.D., and are styled 'doctors,' but in no country in the world does a man so soon find his proper level, whatever his profession or diplomas. It is the absence of social caste, the subordination of influence to real merit, the general indifference to titles, the knowledge that, after all, success must be fought for, which make the American physician so oblivious of the initialed distinctions that obtain in England and elsewhere.

"After all is said, in these days, when science is of common birth and acknowledges no single foster-mother, we may safely claim to be known by our fruits, and one may proudly point to the just and able criticisms of your own columns upon works of American origin for highest testimony to the value and volume of American professional attainment and culture."

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 14 to September 20, 1886.

Wales, Philip G., *First Lieutenant and Assistant Surgeon.*—Resignation accepted by the President, to take effect November 5, 1886.—*S. O. 212, A. G. O.*, September 11, 1886.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending September 18, 1886.

Simons, M. H., *Passed Assistant Surgeon.*—Detached from the "Alert," and placed on waiting orders.

Norfleet, E., *Passed Assistant Surgeon.*—Detached from the "Alert," and placed on waiting orders.

Bogert, E. S., *Medical Inspector.*—Ordered to Navy Yard, New York, September 28, 1886.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Two Weeks Ending September 18, 1886.

Austin, H. W., *Surgeon.*—Granted leave of absence for thirty days, September 16, 1886.

Goldsborough, C. B., *Surgeon.*—Promoted, and appointed Surgeon, from October 1, 1886. September 9, 1886.

Yemans, H. W., *Passed Assistant Surgeon.*—Granted leave of absence for ten days, September 16, 1886.

Bevan, A. D., *Passed Assistant Surgeon.*—Promoted, and appointed Passed Assistant Surgeon from September 1, 1886, September 7, 1886. Granted leave of absence for thirty days, September 7, 1886.

Glennan, A. H., *Passed Assistant Surgeon.*—Promoted, and appointed Passed Assistant Surgeon from September 1, 1886, September 7, 1886.

Norman, Seaton, *Assistant Surgeon.*—To proceed to Vineyard Haven, Massachusetts, for temporary duty, September 9, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIX. SATURDAY, OCTOBER 2, 1886. No. 14.

AMERICAN GYNECOLOGICAL SOCIETY.

ELEVENTH ANNUAL MEETING, BALTIMORE, 1886.

THE PRESIDENT'S ADDRESS.

Delivered September 22, 1886.

BY THADDEUS A. REAMY, M.D.,
OF CINCINNATI.

FELLOWS OF THE AMERICAN GYNECOLOGICAL SOCIETY:

The "lex non scripta" of this Society not only demands an annual address from its President, but the same authority, as precedented in former addresses, makes it customary for these inaugural words to be to some extent retrospective and advisory.

At this, the beginning of the second decade of this Society, I can but congratulate its Fellows upon the valuable and enduring monument they have erected to Gynecology in its ten volumes of *Transactions*. Further congratulation is warranted from the fact that an examination of current literature in obstetrics and gynecology, together with new books and ably rewritten editions of old ones, will show that much of the best work in the science and practice of these departments has been wrought by Fellows of this Society.

Valuable additions to the departments of science represented in this Society are contributed from all quarters in such rapid succession, as to require unremitting diligence of all who would keep pace with the tide of progress.

The epoch, therefore, is propitious, and since our yearly growth of members is secured largely by the election of comparatively young men of unusual capacity and promise, to fellowship, the belief is warranted that the work of the next ten years, as it shall be recorded in our *Transactions*, will be superior to that of the past.

I have spoken of our growth and flattering prospects, and it is but proper now to speak of our great loss.

We must for a moment turn aside in sorrow.

DR. ALBERT HOLMES SMITH

is dead, the sad event occurring at his residence in Philadelphia, December 14, 1885, since our last meeting. He was a man of high physical and intellectual endowments, and an obstetrician of the very highest skill; a writer of great clearness and force, always practical and instructive. Professionally he had an international reputation. He was an ex-president of this Society. He fell in the prime of his manhood, just as he was steadily and certainly approaching the zenith of a most successful career. He died triumphantly in the full confidence of Christian faith. A Fellow who knew Dr. Smith intimately, Dr. Parvin, whose pen can touch with eloquence and poetry even a subject so sad as death, has agreed to furnish for our *Transactions* an obituary sketch.

I now beg your indulgence while calling your attention to several current topics, some of which seem to me of special importance at the present time. No profound scientific discussion of any will be attempted, for such an effort, in a brief address like this, would be out of place; but such plain and humble criticism or commendation as may give expression to my convictions will be offered.

It may be said that the time during which our Society has been in existence is the abdominal epoch of the surgical age in Gynecology. It has seen abdominal section so developed and perfected that the brilliant achievements of skilful operators have far exceeded the most sanguine expectations of ten years ago. This is not only true of all fields of abdominal section, but especially so of ovariotomy, the pioneer operation in this realm.

It would seem that nothing further is to be desired in

OVARIOTOMY,

when we hear the astonishing report of 139 successive operations without a death. Such success as this challenges our admiration, and stimulates our emulation. It brightens the lustre of the star that stands over Danville, where ovariotomy was cradled. It makes Birmingham the Mecca for ambitious gynecological pilgrims from all the surgical world.

Phenomenal success, however, is not confined to Birmingham, Edinburgh, or London. Skilful hands are busy everywhere, and remarkable results are reported from all quarters. The statistics of American operators are constantly improving, in some instances reaching a high standard, although they have not yet reached the high mark attained abroad. The exact reasons for this discrepancy await demonstration. It is probable that the explanation will be found largely in climatic influences and constitutional conditions.

Again, it is unquestionably true that, in our own country, the operation is essayed by a relatively larger number of operators than abroad. In England and Scotland especially, it is done chiefly by a few of exceptional skill, and so far as practicable this practice should be the rule everywhere. These facts must have important bearing upon the statistics of an operation which, perhaps above all others, demands in those who perform it that coolness of judgment and especial intelligence which can only come from a large practical experience.

We have already seen that surgical results are eminently satisfactory so far as relates to cystic disease of the ovary which imperils life. But is the operation of removing the ovaries for supposed beginning "cystic degeneration," "cirrhosis," "catarrhal salpingitis," "chronic catarrh of the tubes," "stenosis," "congestion," "enlargement," always justifiable? I trow not. Have not the glowing reports of such cases, and the cures wrought, together with the facility of the operation and its comparative immunity from danger to life, led to the extirpation of many a sinless ovary? How often

in our experience have we met cases with the constant pelvic pain and its various reflexes, with a tender ovary slightly displaced, or some tortuous body about the uterine fundus, which we thought was the "congested," "hypertrophied," or dilated tubes; in short, having a clinical history, and physical aspect, incapable of differentiation from those cases from which we hear of ovaries being removed, and yet we have seen them cured by a patient recourse to diet, massage, electricity, vaginal irrigations, medication of the vaginal vault and cervix, rest of body and mind, postural treatment, etc.

Such occurrences are so very frequent in our everyday practice as to be painfully suggestive of too much freedom with the ovary, considering our want of familiarity with its minor pathological changes. The truth of this remark is in no way invalidated because of recent attempts in high quarters to settle this whole question on clinical testimony exclusively.

Dr. Coe has recently written an exhaustive paper on the slight pathological provocations which have been deemed sufficient cause to warrant the extirpation of ovaries. His conclusions, supported as they are by abundant, able, and intelligent investigation, are not of a nature restful to the consciences of any who may have been over-zealous in performing spaying, without due discrimination. It has been our wont to congratulate ourselves upon the great benefits which have accrued to humanity by the perfection and practice of ovariotomy, and justly so. Numerous and ingenious statisticians have delighted us with computations of the sum total added to human life by this single operation. To these gratifying statistics of alleviated suffering and respited death we have ever pointed with pride. We have so often adduced these figures to demonstrate the wondrous progress of our art, and offered them in expiation for what we considered the blunders of our drugging, dosing, and bleeding forefathers. I greatly fear, however, that somebody will one of these days show the other side of the picture, that some ingenious statistical cynic will compute the years of human life lost to the race by this destruction of ovaries of which the functional activity is yet unabated, and the structure of which yet bears many possibilities for population.

There has been entirely too much constructive pathology written upon the ovary. Much of the pathology has, I fear, been created in order to justify the removal of functionally active ovaries after they have been extirpated. We need the "fiat lux" of a practical pathology, sustained by the most extensive comparative investigations upon healthy and unhealthy ovaries. A humane and economic conservatism should keep our fingers off these organs until we know whether they are yet capable of discharging their function, or whether they are physiologically dead, or whether their possessor can be cured without their sacrifice.

The recent praiseworthy practice of Schröder in leaving the healthy portion of the ovary when possible, in the extirpation of ovarian cysts, is a movement in the right direction, and in every case of removal of the ovary or tubes for minor disease, if the operation must be done, but one ovary should be extirpated unless positive disease of both be detected on exposure.

If pathological processes destroy the ovaries or occlude the tubes, the patient is unsexed by disease, and then we may consider the propriety of removing these appendages only when we are convinced that such is unquestionably the case, and that their removal will probably cure the suffering. Again, many of the remarkable cures reported after this operation must be taken "cum grano salis" until such time has passed as will preclude the possibility of a relapse, or at least render it improbable. Time will, I fear, much change the aspect of some reported cures; this opinion is not wholly speculative.

Let us as a society and as individuals do our duty toward women by proclaiming and practising against this unsexing enthusiasm. Can we not take some steps toward the establishment of some hard and fast lines for the government of this practice?

In all the foregoing let not one word be so interpreted as to detract one iota from the boon conferred upon suffering women by the performance of spaying in properly selected cases. Abdominal surgery has conferred no greater blessing, nor shone with brighter lustre, than in the rescue by these operations of certain subjects curable by no other means, from death or a life worse than death.

The triumphs of ovariotomy have led to a broad field of possibility in abdominal surgery, both for the gynecologist and the general surgeon. It has demonstrated the fallacy of the old ideas of peritoneal intolerance. Peritoneal tolerance is now so well established that we are hardly astonished at the maxim "when in doubt open the abdomen." The success of ovariotomy and the development of its technique, have opened the way for many brilliant achievements at the hands of general surgeons. Notable among these are gastrotomy, nephrectomy, enterotomy, hepatotomy, and section for intestinal wounds.

One of the recent innovations of abdominal section, is its employment in

SUPPURATIVE PERITONITIS,

and the reports from this practice in England are highly satisfactory. It is fortunate that a procedure so rational as opening the abdominal cavity and free washing of its interior, as a treatment for suppuration, has met with such success in its very inception. It is, in my opinion, destined soon to become the established practice. The programme promises a paper on this subject from the pen of an able Fellow.

ALEXANDER'S OPERATION

may be said to be just entering upon its trial, since it has been performed in all countries combined less than 150 times. Anatomically and mechanically considered, it unquestionably rests upon sound principles, and it seems probable that it will have a future. It must be confessed, however, that since its mortality is variously stated at from one to six per cent., its utility should be tested with great caution and conservatism. Especially so, as when it is successful it can only relieve retroversion and prolapsus, conditions generally remediable by other means absolutely safe.

Moreover, even in the hands of experts, the operation has in quite a number of instances signally failed. It may be further stated, I think justly, that the subsequent clinical history of many of the subjects who have been apparently relieved by the operation will show relapses, for it is very doubtful whether in many instances the

uterine deviation was primarily due to abnormal length of the round ligaments. It is more likely that the lengthening of the ligaments is generally a result of uterine displacement, and will recur as a result of the cause which originally produced the malposition.

SIGNS OF PREGNANCY.

Since the formation of this Society nothing of importance has been added to our ability to diagnosticate early pregnancy. Hegar's sign, a slight relative change in the form of the uterus, has been offered, but it is no more decisive than many others of a similar character. Moreover, this sign is not new. Our manifest inability to detect early pregnancy is the opprobrium of obstetrics. Is it not probable that nature hangs out somewhere an unequivocal sign of this most important event in the animal economy, early in its career, and that we may cherish the hope that the near future will read its disclosure to the profession? As the programme pledges a contribution to this subject by an able Fellow, we shall await its revelations with interest.

During the period under consideration the attention of gynecologists has been so riveted upon surgery, and especially abdominal surgery, that they have neglected the subject of diagnosis. This important feature as a preliminary to rational treatment has made almost no progress since the beginning of the present surgical era.

ABDOMINAL SECTION AS A MEANS OF DIAGNOSIS

in doubtful cases is most valuable, but its character as a piece of surgery in itself, its danger and the time required for its employment, and the necessity for special skill, all preclude a very general utility. Again, the recourse to this practice for differentiation has made us less reliant upon the old-established methods. We should develop and perfect our methods of diagnosis by clearer directions and conceptions concerning the information to be gained by inspection, palpation, percussion, auscultation, and by a keener appreciation and analysis of subjective symptoms, and a more judicial interpretation of each history. There is a large field of promise here offering a rich harvest for patient and intelligent investigation. We seem to have lost sight of the importance of diagnosis as expressed by the adage, "qui sufficit ad cognoscendum sufficit ad curandum." High diagnostic skill is the first essential in successful practice, and the foundation stone without which rational therapeutics is impossible.

Partly as a result of deficient ability in detecting disease, and partly from the extraordinary attractions afforded by surgery in the treatment of the diseases of women, we have suffered a dearth in

THERAPEUTICS.

The scarcity of literature and investigation upon this subject is greatly to be deprecated. We should expect from this source a powerful adjuvant, in combating the surgical tendency of the times. The discovery of some remedy with a special action on the ovary might in many instances prove an ovarian saviour. In all the *Transactions* of this Society you have contributed but five papers on medicinal therapeutics. This neglect of medicine is not confined to this Society; it is one of the derelictions of all countries in this field.

Dr. Meadows, in his address in obstetrics before the last meeting of the British Medical Association, speaking of our sins of omission toward medicines, said; "It may be an Utopian idea on my part, but I confess I do not see why we should not possess a group of remedies whose action on the ovary or the uterus should be as well known and understood, and as certain in their results as are the actions of diurectics on the kidneys, purgatives on the bowels, and cholagogues on the liver." However Utopian such an idea may be, it is at least suggestive of our want in this direction, and promise to labor in the field.

ELECTRICITY

as a therapeutic agent in gynecology, has been swaying in and out of general favor. It has run the gauntlet of extravagant enthusiasm on the part of its over-zealous advocates on the one hand, and the condemnation of faint praise from those lukewarm in its advocacy on the other. Its utility as one of the most extraordinary agents in our power is at last well established, and from many quarters we are receiving clearer directions for its employment, and more rational explanations of its *modus operandi*. It has, however, not yet received the general and intelligent trial at the hands of the profession which it deserves. This agent has fought its way to the front through a most obstinate scepticism, bred largely of ignorance of the indications for its use, and methods of employment. In this country no one has done more to popularize electricity in gynecology than a distinguished Fellow of this Society in the pages of his own journal.

As an index of the favor and appreciation which this subject is receiving, I take pleasure in referring to our present programme, which promises three contributions upon the therapeutic value of electricity. I am sure, when we bear in mind the accomplishments and character of these contributors, we are justified in expecting classical additions of high merit to our knowledge in this direction.

Its use in extrauterine pregnancy is at last getting the attention it merits. Its value in this field has been especially pointed out in the *Transactions* of this Society. Dr. Aveling, the first to employ this treatment successfully in England, has just read an interesting paper, with cases, before the British Medical Association. Even the limited trial it has received, has demonstrated beyond doubt that it is the safest and most effective treatment yet proposed in this perplexing "lapsus naturæ." It is worthy of note that this treatment was first employed, and its value demonstrated in this country, by Dr. J. G. Allen, of Philadelphia.

The treatment for extensive fibroid disease of the uterus occupies no small chapter in the gynecological annals of the past few years. Medicinal treatment for these growths has been tried faithfully and abundantly, and in the main unsatisfactorily; though, in some instances, good results have followed the use of ergot and electricity. The latter agent has been employed with commendable enthusiasm and patience, especially by Apostoli, with results very encouraging. It probably has a more general value than any other therapeutic treatment yet applied to this condition, and its employment is becoming more and more popular. I have myself had some admirable results with the agent in arresting growth in these cases.

HYSTERECTOMY FOR UTERINE FIBROIDS

has been swaying to and fro in professional favor. Recently it has received a most wonderful impetus in the remarkable results obtained by Keith and others, particularly in Scotland and England. From a previous general mortality, varying from fifty to seventy-five per cent., Keith reports a series of cases with a mortality of only eight per cent. Schröder, whose statistics are probably the most favorable offered by any large operator in Continental Europe, has had a mortality of about twenty-nine per cent.

The question was asked by Keith, the most brilliant operator in this field: "Does a mortality of eight per cent. justify an operation for a disease that, as a rule, has only a limited active life, and that only for a time, though of itself it rarely kills?" It certainly suggested a negative answer to his mind, and in view of the much greater fatality generally following the operation, should inspire a similar reply from all.

Spaying in the treatment of extreme cases of uterine fibroids has met with more general favor and success than any other surgical procedure. It is attended with far less danger and is usually much more easily performed. The objection that it unsexes the patient is here not pertinent, since a fibroid of the uterus sufficient to justify the operation is in itself an unsurmountable barrier to fertility. It is in this operation for inducing an artificial menopause that we find our safest refuge in these tormenting cases, although there are a few where life is manifestly imperilled and the very large size of the tumor with complications renders the removal of the uterine appendages impossible, that recourse to the grave operation of hysterectomy may be justifiable. It is also probably true that in all fibrocystic tumors of the uterus, as well as in all suppurating ones, hysterectomy offers the only hope. Of course, nothing here applies to intrauterine tumors or such submucous ones as may be safely removed *per vaginam*.

The past decade has been especially fruitful in measures for preventing, and methods for overcoming those cases of more

SEVERE DYSTOCIA,

the difficulties and perplexities of which have hitherto required the grave operation of craniotomy. Improved hygiene, wiser sanitation, and such legislation as the Factory Act in England, are acting in happy combination to prevent those frightful pelvic deformities which have been such barriers to maternity and have compelled obstetric ingenuity to devise the various implements for infant destruction. Relief is also coming through the development and perfection of the Porro and Porro-Müller operations and laparo-elytrotomy each in its proper sphere. In the lesser degrees of pelvic deformity, premature labor, turning, improved forceps and their more skilful use.

The emancipation of the Cæsarean section from the ban under which it had been placed by Baudon in France, and Spaeth in Germany, has been conducive to the same end. This result has been largely due to the indefatigable labors of Dr. Harris, who, by persistently calling the attention of the profession to the possibilities of Cæsarean section as shown by a careful examination of all the literature on this subject, has demonstrated its past successes and future promises as an obstetric procedure.

Our chief reliance as an alternative to craniotomy, at least in cases of pelvic deformity where the conjugata vera is below two and one-half inches, is to be placed in the Sänger-Leopold operation, and what more convincing assurance need we offer than the fact that during the year ending with June, 1886, there were twenty Sänger operations in Europe with a loss of only two women?

Notwithstanding these remarkable results, the same confession must be made regarding this operation in this country, as regarding ovariotomy, although in this case the discrepancy against us is infinitely greater. For out of a total of thirty-eight Sänger operations reported up to date, with twenty-six successful, five were done in the United States, all of which were fatal. There can be little doubt that a strong element in this unfortunate showing for us is the failure to realize the importance of early interference. It is insisted upon by Dr. Harris, that, other things being equal, the danger to the mother is much increased when the operation is done after the death of the child.

Circumstances have environed this operation in this country that have existed nowhere else, at least to the same degree. With us the operation is almost never done until long waiting and protracted efforts at delivery by other methods, together with death of the child, have brought the patient to death's door. Indeed in many cases she is not only exhausted but septic. When the operation is done here as abroad, deliberately, early in the labor, as a primary and only measure, our results will be satisfactory. And this practice will soon be the rule.

It seems to me probable that the practice of deliberate destruction of the infant is being gradually encompassed about by a constantly narrowing circle of limitations, and it requires neither a seer's vision nor the spirit of prophecy to see in the near future this circle reduced to a vanishing point, to see a full fruition to the hope that craniotomy shall be abolished and the instruments devised for its perpetration relegated as curiosities to museum shelves.

THE TOTAL EXTIRPATION OF THE UTERUS FOR CANCER

has enjoyed a remarkable renaissance since the organization of this Society. It was already constantly gaining favor in Germany, in view of the good results obtained notably by Schröder, Martin, Sänger, and Fehling. But the recent extraordinary report by Leopold of thirty-eight operations with but two deaths must assure its acceptance as an approved measure. It is somewhat noteworthy that by all odds the largest number of successful operators in this field are Germans. It is true, also, that the most rational method of performing the operation is the one devised by Dr. S. C. Lane, of California.

The merits and demerits of the operation have been discussed in this country with signal ability by two members of this Society. The operation is not extensively practised in this country, but there is now a growing disposition to give it a fair trial. It may seem presumptuous to offer objections to an operation which stands approved by such strong clinical evidence, more especially when the disease for the cure of which the

operation is done is one that is necessarily fatal. Nevertheless I must confess that so far as I have been able to examine the clinical proof offered, it is not convincing. The patients have survived the operation, and have been in some instances improved, but have they been cured? As to total aggregate results, has life been prolonged? I must reaffirm, what I have already expressed in the *Transactions* of this Society, my own belief that it is not yet proven that the operation is justifiable except in rare instances where the disease is confined to the body of the uterus, the cervix and vagina remaining comparatively free.

The operation is also undoubtedly justifiable in all cases of spindle-celled sarcoma of the body. In such cases there is little or no danger of involvement of adjacent connective tissue lymphatics. Nor is it usual under such circumstances for metastasis to other organs to occur. Removal of the uterus, therefore, if timely accomplished, offers prospect of cure.

Current opinion with clinicians of largest experience, recognizes the probable truth that

EPITHELIOMA OF THE UTERINE CERVIX

is primarily a local disease, and that ordinarily the cells do not invade the surrounding tissues for a long time after its manifestation. The view that in a large proportion of these cases the development of this disease is related to the traumata of parturition, is not so universally held. A most distinguished Fellow of this Society has very recently expressed his dissent from this view, as follows: "I have yet to witness any evidence that chronic inflammation, congestion, or laceration of the uterus, predisposes to malignant disease of any kind." (Byford, Pepper's *System of Medicine*, vol. iv. p. 275.) *Per contra*, an equally distinguished Fellow in the British Medical Association, held at Brighton in August, uttered the following language: "Referring to the effect of fissure of the cervix he was convinced that one point had been brought clearly and certainly home to his mind, namely, that epithelioma of the cervix was commonly secondary to, and the direct result of, a previous fissuring of the neck of the womb." (Emmet, *New York Medical Record*, Sept. 11, 1886.)

After a careful clinical study of this subject, in a large number of cases, I unequivocally commit myself to the belief that the cervical traumata of parturition strongly predispose to the development of epithelioma. It has been shown by Veit that the so-called cicatricial plug left after laceration is simply indurated connective tissue. It is also well established that epithelioma commences, as already stated, in the mucous membrane. In six cases, within the past three years, I have removed the neoplasm while it was yet confined to the mucous membrane immediately covering the indurated connective tissue resulting from laceration. Why this should be so is, of course, not known, but that it is due to impaired nutrition of the overlying epithelium is certainly probable.

It is significant, in this connection, that such a large proportion of the subjects of this disease are women who have borne children, or had abortions. In an experience of thirty years, embracing many hundreds of cases, I have seen but three instances of cervical epithelioma in the virgin.

Emmet's operation for restoration of the cervix to normal conditions in cases where a manifest fissure exists, is, in my opinion, warranted upon the sole ground of prophylaxis against malignant disease, if upon no other. Clinical experience on all hands warrants the early and thorough removal of the cervix when malignant disease is developed, and has not extended too far for its complete eradication. The number of cases thus cured is now so large as to justify the brightest hopes for the future; radical cure in a considerable proportion of cases is no longer a question for discussion. My own clinical experience in this field is in perfect agreement with others. The method of operating, so it be thorough, is by no means so important as time.

THE CURETTE.

I shall now conclude these remarks with some observations on the uterine curette; and lest this seem to you a trite and trivial subject for occupying your time, let me preface with the statement that during the past few years in my own practice, alarming symptoms have followed its use in several instances, and in one case the result was fatal.

To speak of these experiences in this public way is the more imperatively my duty, because in a brief paper upon the use of this instrument, read by me before the Ohio State Medical Society, in 1878, the following language occurs: "Indeed, as to safety, I do not remember, nor have I the notes of, a single case where any serious consequence followed the employment, or were in any way whatever traceable to its use."

With a very much larger experience, I am bound now to say that dangers which cannot be foreseen, sometimes attend its employment. Nevertheless, I employ it almost daily, and fully concur in the general belief that it is the most efficient means we possess for controlling intractable pathological uterine hemorrhage. Of course, no one thinks of its employment, or, indeed, of any kind of intrauterine medication, in any case where periuterine inflammation exists, but it is frequently employed immediately upon the removal of tents where dilatation seemed necessary.

Against such practice I wish to enter an emphatic protest. Within the past year I removed with the blunt wire curette, small portions of retained and organized placental tissue from a patient who had given birth to a child ten months previously, and who had suffered from menorrhagia for the past four months. The character of the substance removed was verified by microscopic examination. The curetting was done immediately upon the removal of three small tupelo tents which had been inserted twelve hours previously. This patient died on the sixth day, of septicæmia.

Within the past few years I have rarely employed any form of curetting immediately upon the removal of tents without suspicious rise of temperature or pulse, or both, and in eight cases peritonitis has been well marked; in three of them the attack was severe and dangerous, although recovery occurred in each. Within the same period, although I have used the curette in hundreds of cases, peritonitis has not been developed in a single case where dilatation had not immediately preceded it.

It is, perhaps, also worthy of note, that in many of these cases where I have used the curette without unpleasant symptoms following, it was done at the same sitting with trachelorrhaphy, perineorrhaphy, or both.

I will further state that I believe the danger in these cases to be just as great after the tupelo tent as after the laminaria. Indeed, I must say I regard the high claims of superiority for the tupelo tent over the laminaria, as expressed on all hands, to be unfounded. As a matter of fact, the surface of the tupelo tent, on removal, is rougher than the laminaria, therefore inflicting greater injury to the tissues.

It is perhaps useless to state that I have not for several months, and shall not hereafter, immediately follow the removal of tents by the curette.

Rapid dilatation, which has recently been so popularized by the writings of a distinguished Fellow (Goodell), is alleged to be comparatively free from the dangers attendant upon the dilatation with tents. This view commends itself as rational. Certainly there could not be the same danger, *cæteris paribus*, in immediately following this method of dilatation by the curette. Time and further clinical experience, however, must determine more fully this question. In my own practice I am now employing this method of dilatation in all suitable cases. In one case peritonitis followed this method, the patient recovering.

I close by reference to the following somewhat peculiar case:

In July, 1881, I was consulted by a woman residing in Greene County, Ohio. She was thirty-four years of age, the mother of two children, the youngest four years old. An abortion had occurred one year subsequent to the birth of this child. The woman was below medium stature, a blonde, of decidedly nervous temperament, with the scrofulous type of fibre although there was no evidence of this taint. She was anæmic and feeble; she reported rather profuse menorrhagia for the past year, and during the intermenstrual period rather copious leucorrhœa, the discharge at times somewhat cheesy, at others tinged with blood. An examination showed an old laceration of the perineum, extending to the sphincter ani but not dividing it. No laceration of cervix. The vaginal walls were very flabby and relaxed. The injury to the pelvic floor was so great, and had existed so long, as to be followed by uterine descent and retroversion. The uterus was enlarged, measuring three and one-fourth inches, freely movable and not tender. No pelvic tenderness could be detected. She was placed upon iron, liberal diet, cold sponging of surface every morning, with friction. Under this treatment her anæmic condition was improved and the menorrhagia decreased.

The following September, in the presence of Dr. Wm. H. Wenning, now Secretary of the Cincinnati Obstetric Society, and my assistants, the patient being etherized, I proposed to curette the uterus, and at the same sitting to restore the perineum. The instrument employed was the blunt copper-wire curette very similar to but not the exact pattern of Thomas's, the patient being in the lithotomy position. No dilatation was necessary as the os was quite patulous, the curette entering the cavity with ease. The instrument was swept over the posterior and lateral uterine walls and a large amount of fungous tissue removed, showing under the microscope enlarged and distended glands, with the bloodvessels increased both in number and size, and embedded in a gelatinous mass. It was now carried over the anterior wall from the fundus with like results. During the manipulation no violence whatever being practised, as indeed none could be with an instrument so flexible, the curette suddenly passed in to a depth which brought the handle to the vulvar opening, to which I called the attention of Dr. Wenning, stating at the same time that I believed it had penetrated the anterior uterine wall, which opinion was at once verified.

Withdrawing the curette, Simpson's sound was carried in, the concave looking upward, and passed at once to its full length, nearly twelve inches, without resistance. Through the very thin and flaccid abdominal wall the point of the sound could be so very distinctly felt on a level with the umbilicus as to give the impression that nothing but the skin intervened between the sound and the fingers. I now moved the point of the sound right and left through a distance of three or four inches. The position of the distal end of the sound could be easily seen as it lifted up the abdominal wall. It is needless to say that further curetting was not done, and the perineorrhaphy was postponed. Before the patient had recovered from the ether an ice-bag was placed upon the abdomen, and when she had rallied forty drops of tincture of opium were given by enema.

She was not informed then, or subsequently, of what had occurred. On the morning of the following day the temperature was 99.5°, the pulse 80; no tympanites or abdominal pain. The temperature and pulse remained about the same until 2 P. M., when both gradually returned to the normal, where they remained throughout. The ice-bag was kept on continuously for five days. No pain and no symptoms at any time, and the patient left her bed in ten days. At the expiration of six weeks, in the presence of Dr. Wenning, the perineum was repaired and a perfect result obtained.

This woman is still living, with no return of menorrhagia, although she is still in rather feeble health. The extremely fragile condition of the uterine wall in this case, in view of the woman's subsequent history of fair though not robust health, is to my mind more mysterious than the fact that peritonitis was not lighted up by the rude manner in which the peritoneal cavity was invaded.

At the conclusion of his address, Dr. Reamy endorsed in strong terms the proposition which had been made to the Society to join with the Surgical and other special societies in a Congress.

ORIGINAL ARTICLES.

THE "PIG-BACKED" OR ALCOHOLIC KIDNEY OF DRUNKARDS.

A CONTRIBUTION TO THE POST-MORTEM DIAGNOSIS OF ALCOHOLISM.[1]

BY H. F. FORMAD, M.D.,

LECTURER ON EXPERIMENTAL PATHOLOGY AND DEMONSTRATOR OF MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA, ETC.

I WISH to invite attention to a certain peculiarity of the kidneys of drunkards. It concerns the gross anatomy and appearance of these organs, and chiefly their shape. A certain constant naked-eye appear-

[1] Read at the meeting of the Association of American Physicians, Washington, June 28, 1886.

ance of the kidneys of hard drinkers on the autopsy table appears to me diagnostic of alcoholism. It is due to a chronic, venous, or passive congestion, leading to a cyanosis and sometimes to œdema of the kidneys, giving to these organs a peculiar swollen, rounded shape, which I am in the habit of designating as the "pig-backed" kidney. It differs essentially from the renal cyanosis of cardiac disease. It differs also from Bright's disease, and I believe it to represent an independent kidney affection.

While I have been pointing out this "pig-backed" kidney for some time in my laboratory demonstrations, and lately have repeatedly shown specimens of it in connection with other lesions of alcoholism before the Philadelphia Pathological Society, I have not as yet published a detailed account of this peculiar and fatal kidney affection. I am not aware that any of the authorities on renal diseases have studied or described this kidney lesion of drunkards, which I believe to be a quite interesting and significant one.

A word of comment upon the character of the material that has been under observation is necessary. I do not intend here to consider the general morbid anatomy of the kidneys of the universal "moderate" drinkers, since these individuals eventually die of any kind of ailments and with any kind of kidneys, often dying from exposure, carelessness, and irregularities in diet and life incident to the state of drunkenness, and perhaps not at all from the direct effects of alcohol.

The class of cases which I shall chiefly consider in this communication is one to which the coroner is more often called than the practising physician. I have selected only those cases where the person died more or less suddenly, where the history and general appearance clearly showed that death was due directly to alcoholism, and where all other factors in causing death had been carefully excluded as far as possible. I have particularly excluded such cases in which the persons had primary heart disease and other affections known to produce renal cyanosis. Most of the subjects had been in good general physical health, but having been inveterate drunkards and nearly always intoxicated, died while on a debauch, or, in rare instances, after a brief illness following it.

Through the kindness of the Coroner of Philadelphia who, of necessity, is called upon to issue death certificates in such cases, I have had, during the last two years, the opportunity of making observations which some time ago numbered *two hundred and fifty cases*, belonging strictly to the category above referred to, and mainly from my own autopsies. In this city with a population of about one million, there are annually nearly two thousand cases of sudden death subject to legal inquiry. The proportion of cases of alcoholism appears thus remarkably large. I am indebted to my colleague, Coroner's Physician Stewart, for some of his autopsy material and his corroboration of the "pig-backed" kidney, and to Drs. George H. Chambers and A. Smith for valuable assistance in these observations.

A. Anatomical Considerations. I have met with two varieties of the kidney lesion now to be described:

First, a hard cyanotic form of the "pig-backed" or alcoholic kidney, in cases of sudden death; and

Second, a soft œdematous form of the same, in cases where death had been delayed.

First form: In nearly all persons who died more or less suddenly from the direct effects of alcohol, I found the kidneys to present the following appearances: The kidneys are always above the normal size; they are often from one-third to one-half larger, and are sometimes even double their usual size and weight. They are longer and thicker than normal, while their width is diminished, so that the natural, characteristic flat kidney, or bean-shaped form, is changed to a swollen, rounded, sausage-like or "pig backed" appearance or form. They are bluish-red or livid in color from being engorged to their utmost capacity with venous blood, reminding one of the rounded enlarged appearance of animal kidneys when overfilled by some artificial injection mass. In most cases these "pig-backed" kidneys are elastic, but quite hard when freshly removed from the body; but unlike the cyanotic induration from heart disease, they gradually become softer, unless the renal vessels are at once tied to prevent escape of blood from them.

On section the cut surface presents the same dark red or livid appearance as seen in the cardiac form of renal cyanotic induration. While in the latter, however, the pyramids of the medullary substance are especially congested, in the alcoholic cyanosis the whole kidney substance is almost uniformly dark red. Dark blood oozes from the cut surface and blood extravasations can be often seen by the naked eye, principally below the capsules.

Second form: The other form of the alcoholic kidney referred to, was met with in persons who had died some time after a debauch (suffering from a few hours to a few days from delirium tremens previous to death). The kidneys of such subjects are found to be soft and flabby from œdema, and they are less red; otherwise presenting the same appearance as the hard variety of alcoholic renal cyanosis, including the "pig-back" shape of the kidneys.

In either form of this kidney lesion the capsule strips off easily, the surface is smooth, but often lobulated, not unlike the lobulation seen in congential conditions. If the alcoholic lesion is not complicated by heart disease, the "pig-backed" kidney is less heavy in proportion to size, and less firm and tough and also less dry than the kidneys of the pure cardiac renal cyanosis. This is probably due to the greater amount of blood present and to the accompanying œdema, which I have not seen in the cardiac variety.

In the purely cardiac affection, however enlarged, the kidneys retain their natural flat shape. This may be explained by the fact that in the latter case the morbid change is slow, gradual, and uninterrupted, and the resulting change (the induration from the connective tissue overgrowth) is a permanent one—whereas in the alcoholic cyanosis the process is rapid and intermittent, the effects of the alcohol being paroxysmal with each debauch and the mere resulting congestion receding more or less during

the intervals of sobriety. It is probable that in the latter case the kidneys may return temporarily to their normal condition and shape.

A transverse section through the middle of the kidney from a case of alcoholic cyanosis is sometimes nearly circular, while a similar transverse section through a normal kidney or one of a cardiac renal cyanosis is oval or wedge-shaped and at least twice as long as broad.

Both kidneys are equally affected, sometimes the upper ends are found to be flattened or compressed anteriorly from pressure exerted by the enlarged liver on the right, and an enlarged spleen on the left side; the left kidney, as a rule, was more often found to be of a typical "pig-backed" shape than the right, and more frequently compressed at its upper end.

One hundred specimens of these kidneys were weighed and revealed the average weight of 250 grammes or a little over seven ounces—about two ounces over the normal average weight. The average variation in size and weight between the right and left kidney was insignificant.

A certain proportion of the 250 cases included in my records showed, besides the alcoholic renal lesion, appearances of Bright's disease. It is difficult to draw in all instances a definite line between these two lesions, but I would say that in about 10 per cent. (or in 25) of the cases Bright's disease was evident. In 16 of these cases chronic catarrhal nephritis with formation of small cysts was noted; and in 9 cases chronic interstitial nephitis or a tendency to the granular contracted kidney was apparent. But, however affected otherwise, the "pig-back" shape of the kidneys was always a conspicuous feature in these cases. It appears that this chronic venous congestion (and œdema, when present) of alcoholism affects structurally diseased and normal kidneys in the same manner and manifests itself alike in both.

B. The cause of the "pig-backed" shape in the alcoholic renal cyanosis. The reason why the alcoholic kidney presents the roundish swollen shape is because the organs are over-distended with blood and serum, the kidneys acquiring the properties of, and in extreme cases may be compared with, true erectile or cavernous organs.

A "pig-backed" shape of kidneys can easily be induced experimentally in animals when the renal veins are tied or when kidneys removed from the body are artificially injected with a liquid.

Experiments have also shown that a hypertrophy of one kidney follows the removal of the other kidney, and under these circumstances I have seen the remaining kidney enlarge to double its natural size and acquire a typical "pig-backed" shape from being overfilled with blood.

A nearly similar appearance of hyperæmia of the kidneys may be seen in cases of acute fever, particularly, in cases of infective fevers of children when death occurs during the height of the attack.

The loss of the flat kidney shape may be compared also with the loss of the biconcavity of red blood disks or corpuscles which when immersed in any liquid which they absorb become spherical bodies.

C. Microscopy. Sections were made from a number of specimens of the alcoholic kidneys, care being taken to examine microscopically all the different structural parts of these organs. For brevity's sake, only the essential changes will be referred to.

The cortical and medullary portions of the kidney appear to be similarly affected, but, as a rule, the latter less so than the former.

In the hard, cyanotic form of the alcoholic renal cyanosis the Malpighian glomeruli of the cortical portion are highly congested, and extravasated blood is seen within many of the Malpighian capsules; some are enlarged to double their normal size, but the majority appear rather compressed by the surrounding swollen uriniferous tubules and by the over-distended blood-vessels. The latter (both arteries and veins) show thickened walls and are deeply congested nearly everywhere throughout the organ. The stellate veins in particular are enormously distended and plugged up by blood corpuscles as if thrombosed. The lymph spaces beneath the capsules as well as around the tubules are also dilated and distended, and are either seen empty or they contain extravasated blood. In some sections the kidney structure gives the appearance of a cavernous change.

The epithelium of the convoluted tubules is cloudy, swollen, opaque, and the nuclei obscured by granules, which, however, become cleared up upon the addition of a solution of sodium hydrate. The epithelial cells appear to be double their normal size and although no visible desquamation or proliferation of the cells could be noted in any one of the typical specimens examined, it appears that the lumena of the tubules are obliterated completely, as seen in transverse sections of the tubules.

In the straight tubules of the medullary portion the same changes have been noted, but are less marked.

The connective tissue elements of the pure alcoholic kidney show no pronounced hyperplasia. In the sections of most of the kidneys it is hardly perceptible. Sections in which the epithelial lining was forcibly removed by means of a camel's-hair brush showed the connective tissue to be dense, stiff, often pigmented, but only moderately increased in a few places around the bloodvessels.

The connective tissue increase was notably prominent only in sections derived from occasional specimens which showed at the same time other evidences of inflammatory changes (Bright's disease), and in cases complicated with heart disease. I do not remember having seen in one of the sections of the pure alcoholic affection tube-casts or blood within the uriniferous tubules.

In sections from the soft, œdematous form of the alcoholic kidney, the minute changes were essentially the same, but not so marked as those described above. Extravasations of blood were less frequently seen, while the connective tissue elements appeared occasionally more or less proliferated. In sections from some cases, however, no other change could be observed than the very prominent cloudy swelling of the epithelium peculiar to all the specimens of the alcoholic kidney.

I do not think it necessary to describe the sections

from the few cases in which Bright's disease and the alcoholic renal cyanosis coexisted.

D. Pathology. From the above studies it appears that the exact position of the "pig-backed" or alcoholic kidney in morbid anatomy is as follows: there are, as stated before, two forms or perhaps stages of this lesion. *First*, a *chronic or venous congestion with cloudy swelling*, or a renal cyanosis with hypertrophy represented by the *hard, red, "pig-backed" kidney* (the earlier and more active lesion); and *second*, a *hypertrophy with œdema* of the kidneys, represented by the *soft "pig-backed" kidney* (the more latent and less rapidly fatal lesion). The latter I met less frequently than the former, and believe it to be the later stage of the alcoholic kidney. Whether the lesion described eventually develops into Bright's disease, if the victim survives, I am unable to tell from my purely post-mortem observations.

I met with only twenty-five cases of established Bright's disease among two hundred and fifty cases of confirmed drunkards, from which it appears that Bright's disease is not more frequent in drunkards than in any other class of patients. Some of the foremost clinicians and authorities on kidney diseases (Bartels, Rosenstein, Tyson, etc.) are disinclined to give a prominent place to alcohol as a causative factor of Bright's disease, which appears to be in accord with the above observations.

That either form of the alcoholic renal cyanosis may be fatal in itself, without terminating in Bright's disease, I have satisfied myself, and hence I *believe that it deserves a place as a separate and independent kidney affection.*

The true mechanism of the *death* of drunkards from this alcoholic renal cyanosis is a matter of conjecture. If causes such as heart failure and œdema of the brain (which probably were the ultimate, immediate causes of death in some of my cases) are eliminated, a fatal uræmia is then the only plausible explanation. The empty urinary bladder in some cases, the high specific gravity of the urine, when found at all, post-mortem, in the bladder, and the histories which I had obtained in a few of the cases, favor such a view. In many cases of sudden death of drunkards it appears that death must have ensued under conditions similar to those of asphyxiation, because the blood in these cases was found dark and liquid throughout the system. A like condition of the blood, however, I have seen in certain other forms of poisoning, such as chloral, hydrocyanic acid, and carbolic acid. This subject requires further study.

But, while I have seen hundreds of drunkards dead of alcoholism, thousands of equally hard drinkers are at large and well. It appears that under favorable conditions the alcoholic renal cyanosis is capable of returning to the normal state of the kidneys, and that in its early stages it may be only a temporary lesion, paroxysmal, like the excessive drinking. Quite significant seems to me the experience of the drunkards themselves. One of them, a brewer, who had been a number of times prostrated from alcoholic excesses, and whom I treated about ten years ago for delirium tremens, told me that of late years he keeps himself well, because he stops drinking beer at once for a day as soon as he fails to urinate about every hour or two. I examined his urine lately and found no traces of renal disease.

E. Pathogenesis. The ordinary cyanotic induration of the kidneys, the result of long-continued permanent passive congestion of these organs, caused principally and directly by organic heart disease and indirectly by aortic and pulmonary affections, has been recognized as a separate kidney affection since the time of Traube. Tumors pressing upon the vena cava or upon the renal veins, or thrombosis of the latter also produce renal cyanosis. So I should think any causes interfering with the return of blood from the kidneys will produce renal cyanosis, even if the cause resides in the kidneys themselves. The kidneys are organs especially predisposed to congestion, on account of their close and direct vascular communications with the large abdominal blood channels, and the renal veins, as Tyson well puts it, "are without valves and are the first, therefore, to receive the brunt of stagnation."

The alcoholic or "pig-backed" kidney we have seen to be essentially a renal cyanosis also, only differing, as pointed out above, in some anatomical features from the known cardiac renal cyanosis. The essential etiological factor, however, is in both the same, namely, the chronic venous congestion. The question is only as to the mechanism of the production of the alcoholic cyanosis. In alcoholism we must look to the kidney substance itself for the cause of the obstruction to the renal circulation, because there is, as a rule, no cause for it outside of the kidney: no disease of the thoracic viscera and no thrombosis of the veins. Of the latter fact I have satisfied myself from the examination, in a number of cases, of the vena cava and the renal veins. Besides, in most of my rapidly fatal cases of alcoholic cyanosis I found the blood to be non-coagulable as stated before. It is possible that the large, fatty liver, which sometimes reaches an enormous size, may be held accountable for the pressure upon the large abdominal venous trunks; but I have often seen "pig-backed" kidneys in drunkards with but moderate hepatic enlargement.

I have heard Virchow say that "beer drinkers have *hypertrophied* kidneys." This view is also expressed by other pathologists, but no explanation is offered, nor have the anatomical peculiarities of the kidneys of drunkards been described. In relation to the pathogenesis of the alcoholic renal cyanosis the following explanation suggests itself:

It is well known that in persons who ingest great quantities of fluid, particularly alcoholic beverages in dilute form, the kidneys are strained to overwork. The quantity of urine normally passed by such persons is enormous so long as the kidneys act at all, and can at times be favorably compared with the quantity of urine passed in diabetes. It is evident that such overwork must invite a constant active (arterial) hyperæmia which of necessity produces a hypertrophy, due to a cloudy swelling of the epithelium and an overgrowth of all the structural constituents of the kidneys. A long continuance or a constant repetition of these conditions

leads eventually to a passive (venous) congestion, which persists or increases or subsides according to the repetition and the duration of the debauches of the drunkard. The renal circulation of the blood is retarded by the pressure of the swollen epithelium of the uriniferous tubules as exerted upon the vessels —a pressure which the thicker walls of the intertubular arteries and arterioles can resist more readily than the soft and thin walls of the corresponding veins. There appears to be also thrombosis of the stellate veins. The exit of blood is thus retarded while the arterial pressure continues unabated and keeps the kidneys constantly overfilled with blood. Eventually the kidneys are filled to their utmost capacity with blood overcharged with carbonic acid, and in consequence also with serum, which, leaking out of the obstructed veins into the renal lymph spaces, makes the kidney tissue œdematous; blood extravasates also, and adds to the firmness, redness, and roundness of the organ. Finally, the renal circulation comes to an entire standstill, coincident probably with a suppression of the urinary secretion.

This seems quite evident from the post-mortem appearances and from the swollen, cyanotic, and sometimes œdematous "pig-backed" kidney of drunkards, and is suggested also from the observation derived from the microscopicial examination of sections of these kidneys.

I will return to these studies in a future paper.

F. Statistical Remarks. Of the 250 cases of sudden death from alcoholism so far analyzed, 176 were men and 74 women. The hard, red form of the "pig-backed" kidney was found in men, principally in the younger and middle aged; while the softer œdematous form was more common in men of advanced age and in the women. The kidneys in which Bright's disease was coincident with the alcoholic lesion were mostly those of persons in advanced life.

The alcoholic renal lesion was nearly equally divided between persons of Anglo-Saxon and German descent, and, so far as I could perceive, equally between whiskey and beer and ale drinkers. I cannot speak about wine drinkers who in this country belong to the higher classes of society, and are seldom reached by the scapel of the pathologist.

It is interesting to note in connection with this point that the large, fatty liver (occasionally more or less indurated, but not contracted) which I met with indiscriminately in nine-tenths of all cases of death from alcoholism was equally distributed between all the denominations stated above, including imbibers of strong and of dilute alcoholic beverages.

The following order in the occurrence of the important and more frequent lesions may be roughly given from my autopsy records of 250 persons who died from alcoholism strictly:

The "pig-backed" or alcoholic kidneys	248 times.
Fatty, infiltrated, enlarged liver	220 "
Cystitis, acute and chronic	170 "
Mammillated stomach (or chronic thickening of walls)	150 "
Congestion and œdema of brain (meningeal and ventricular)	150 "
Simple cardiac hypertrophy	90 times.
Atheroma of vessels and valvular heart disease	50 "
Acute gastritis	50 "
Bright's disease (various forms)	25 "
Phthisis	20 "
Cerebral apoplexy	10 "
Cirrhosis of liver, with contraction below normal	6 "

I will make no comments upon the above figures in the present communication. The lesions of alcoholism other than the "*pig-backed*" kidney, I will consider on another occasion. Of great interest are the changes in the stomach, liver, and brain. Brief communications by myself upon some of the lesions of alcoholism may be found in the proceedings of the Philadelphia Pathological Society, 1885–86, when published.

The brains of confirmed drunkards should be studied by psychologists. The claim that chronic drunkenness is a form of insanity may perhaps be found to have some foundation.

G. The Medico-legal Aspect. A thorough knowledge and correct interpretation of the post-mortem appearances of alcoholism is perhaps to no end more important than when the life or welfare of a fellow-creature is at stake. There is a great deal to learn in this direction generally, and in no department of medical science are text-books more indefinite and "behind the times," and more rich in errors, than in the subject of medical jurisprudence.

I have myself once testified in court in an insurance case—and I know of other physicians who have done so—that "a certain person who had a large, fatty liver, to our best knowledge and belief was not likely to have been a hard drinker during life, chiefly because at the autopsy no cirrhosis of liver was found!" This was fully in accord with the teachings of our masters in medicine and with text-books. Yet, I am sorry to say, it is entirely wrong; and the jury decided against the insurance company on account of such erroneous medical testimony.

My experience has since taught me that cirrhosis with contraction of the liver is at least as rare an affection in drunkards as it is in "teetotalers," and that the traditional "hobnail" or "gin-drinker's" liver is not diagnostic at all, while the large, fatty liver is one of the most prominent signs of alcoholism. The facts are that in 250 drunkards I found the enlarged, fatty liver 220 times, and the contracted, cirrhotic liver but 6 times.

Often when a drunkard falls dead on any occasion, a cry of murder is raised, especially when bruises are found upon the body. It is here that a familiarity with the post-mortem appearances of *fatal* alcoholism is particularly necessary and nowhere can ignorance on the part of the examiner do more harm than here.

The constant occurrence of the "*pig-backed*" or *alcoholic* kidney in hard drinkers who perished from their drinking, and the rarity of kidneys of such character in those who are not confirmed drunkards, induced me to regard the kidneys as a valuable sign in post-mortem diagnosis; and next to the presence

of alcohol in the stomach, they are, together with the large, fatty liver, the most valuable proof that alcohol was operative or had contributed in producing death.

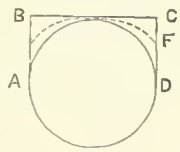
The "pig-backed" or alcoholic kidney, while a valuable diagnostic sign of the *effects* of the prolonged abuse of alcohol, may not show itself in persons who had been but moderately addicted to the use of alcohol, and in such case alcoholism should not be given as *the* cause of death.

REPORT OF TWO HUNDRED AND TWENTY-ONE CASES OF CATARACT EXTRACTION.[1]

By GEORGE STRAWBRIDGE, M.D., of Philadelphia.

Since the publication of my report of forty operations, which appeared in the *Philadelphia Medical Times* for February 19, 1876, I have performed two hundred and twenty-one operations, and all by the upward modified corneal flap method, which may be described as follows:

Incision.—Erect two perpendiculars, AB, CD (*vide* woodcut), tangents to the cornea at its horizontal diameter, join these above by a line tangent to the cornea at its upper border BC. Select two half-way points on these vertical lines as points of puncture,



and counter-puncture, with the centre of the incision a tangent to the upper corneal border. This will give an incision of about 11 mm. in extent, and in the corneal tissue, with the exception of the small scleral flaps at the points of puncture and counter-puncture, and the height of the flap CF being about 2.75 mm., makes this a compromise between the corneal flap and the Gräfe linear operation, and thus lessens the risks incident to either.

The iridectomy and opening of the lens capsule do not differ from the Gräfe operation, the lid speculum being often removed at the completion of the corneal incision, if the patient shows great anxiety, the lids being then kept open by the finger of the assistant.

The lens removal in many of these operations was accomplished by upward inward pressure with a Daniel spoon on the cornea at the puncture of the middle and lower thirds; but, latterly, I have preferred, after removal of the speculum, to exert a similar pressure by the index finger on the lower lid, thus avoiding rubbing of the corneal epithelium.

On completion of the operation, both eyes were closed by a compress and bandage, and the patient placed in bed.

[1] Read before the American Ophthalmological Society at New London, July, 1886.

After-treatment.—If the patient rests quietly without pain, the eye is not disturbed for twenty-four hours, at which time the compresses are changed. The eye is washed out (latterly with a two per cent. solution of boracic acid), a drop of a four grain solution of atropia sulphate is applied and bandages replaced. This proceeding is repeated once or twice a day as circumstances indicate.

My practice formerly was to insist upon perfect quiet, in a horizontal position, in a darkened room. Further experience would lead me to believe that this was a mistake, and at the present time I make it a rule that the patient shall be *absolutely comfortable*, change of position (with the nurse's aid) is freely allowed, the room in many cases is not even darkened (particularly has this been the case with hospital patients), except at the time of dressing the eye, and I am sure that this has been a great advantage to the health and good humor of both patient and nurse. As cataract operations generally concern the aged and infirm, I am careful to make the food as nutritious as possible. Whiskey and quinine are often given, and a large choice of food allowed.

During the past year, acting on the plan that the course of life of the aged should be changed as little as possible, I have frequently allowed the patient, with assistance, to sit up in bed twenty-four hours after the operation, and on the second day to be moved to a chair, and on the third day a gentle walk about the room is allowed. I am inclined to believe that any risk that may be run by this plan is much less than the debilitating effects of a recumbent position in bed, continued for a number of days.

In regard to antiseptic dressings, three-fourths of these cases had no such treatment; with the remainder, a two per cent. solution of boracic acid was used as a wash at the time of dressing of the eye. I cannot say that I place much importance on its use.

The use of cocaine as a local anæsthetic.—Method of application: drop one drop of a two per cent. solution of hydrochlorate of cocaine in the eye, wait one minute, then apply a second drop to the eye. This drug has been used in forty-eight cases, with great relief of pain to the patient. The first case in which it was used suffered, a few hours later, from a violent purulent inflammation, totally destroying the eyeball. This case occurred at Wills Hospital, and was quickly followed by two similar cases in the same hospital, which led to the belief at that time that the cocaine was acting as the exciting cause. Further experience has not confirmed this view, and, therefore, its use is continued.

Ether as a anæsthetic was used in four cases because of the impossibility of controlling the patient without its use. I am decidedly of the opinion that the depressing sequelæ of ether are detrimental to these cases.

MEDICAL PROGRESS.

THE DESTRUCTIVE ENERGY OF THE TINCTURE OF THE CHLORIDE OF IRON ON THE TEETH.—A paper with the above title was recently read before the New York Odontological Society, by GEORGE W. WELD, M.D., D.D.S.

It was shown conclusively that the tincture of the chloride of iron of the official strength had but little, if any effect upon the enamel structure of a tooth when immersed in the same for a period of twelve hours, but that when immersed in a solution of the tincture and water in proportion of one ounce of water to one drachm of the tincture, the enamel was materially injured in five minutes.

Two specimens of teeth which had been immersed in the tincture and alcohol were shown, and compared with teeth which had been immersed in the tincture and water. It was observed that although the alcoholic solution used contained the same quantity of the tincture and possessed apparently the same relative strength, and the teeth were immersed for the same length of time, yet no injurious effect was produced on the lime-salts of the teeth. This was attributed to the fact that alcohol is a dehydrating compound and that the peroxide which is formed in the alcoholic solution is of the anhydrous form, and in character very compact, adhering closely to the surface of the tooth, thereby preventing immediate chemical action; whilst, on the other hand, in the presence of water the peroxide which is precipitated is the hydrated form and flocculent in character, does not so well adhere to the surface of the tooth, leaving the free hydrochloric acid in the solution to unite the lime-salts with greater facility.

The teeth immersed in an ounce of the elixir of the pyrophosphate of iron with one drachm of the tincture of the chloride added for a period of twenty-four hours, produced apparently no chemical effect on the enamel; but with the same quantity of water and the tincture the enamel was completely destroyed. The elixirs are composed of nearly twenty-five per cent. of alcohol, the presence of which, as observed in the strong solution of the tincture, and in the alcoholic solution, affords a protection to the enamel of the teeth in the manner described. But it is to be noted that when a tooth is immersed in a solution of the tincture and simple syrup, in the above proportions, the enamel is but little affected. This is due to a mechanical reason or a condition of fluidity of the solution—*i. e.*, the presence of the sugar in solution coats the surface of the enamel, preventing the chemical affinity between the acid, or perchloride of iron, and the lime-salts in the teeth.

The manner in which syrup modifies the destructive energy of the tincture on the enamel was beautifully illustrated by the effect produced on the specimens of teeth which had been immersed in a weak solution of phosphoric acid, viz., "Horsford's acid phosphate," "Phos-acid," and "Phospho-muriate of quinine compound." The first two of these proprietary medicines are watery solutions, and their effect is to destroy the enamel of a tooth in an hour, whilst the last one, which is a syrupy solution (each fluid-drachm containing two grains of free phosphoric acid), produces but little, if any, injurious effect on the enamel in twenty-four hours.

When a drachm of the tincture is added to an ounce of Vichy-water, a slight effervescence occurs, indicating that the sodium bicarbonate contained in the water has neutralized a part of the free acid contained in the tincture; in consequence, when a tooth is immersed in such a solution, the destructive energy of the iron is to a great extent modified. Unless the specific nature of the tincture of the chloride of iron is materially affected (and the peculiar odor of the tincture remains) there seems to be no reason why this preparation of iron, at least in all cases of anæmia, should not be administered in combination with Vichy-water.

There are then three menstrua which may be employed to modify the destructive energy of the tincture of the chloride of iron on the enamel of the human teeth. The first is alcohol in some form; the second is Vichy-water, which neutralizes to a slight extent the free acid contained in the iron; and the third is some form of an elixir or simple syrup.—*American Journal of Dental Science*, August, 1886.

RHEUMATIC HYPERPYREXIA.—DR. H. BARNES, in a paper read before the Carlisle Medical Society, urges that in all cases of acute rheumatism, as soon as there is any indication of nervous symptoms, and particularly in patients of a high degree of nervous susceptibility, a careful watch should be kept on the temperature. Dangerous symptoms may be sudden in their onset, and medicinal treatment seems entirely to fail to arrest them. He recommends the application of cold when the temperature reaches 105°. The graduated bath is the method he most approves, commencing it at 90° and gradually reducing it to 70°. As soon as the temperature is sufficiently lowered, the treatment should be suspended and the patient placed in warm blankets, otherwise dangerous symptoms of collapse may supervene.—*Edinburgh Med. Journ.*, June, 1886.

BENZOATE OF SODIUM IN ERYSIPELAS.—HABERKON records a series of fifty cases of erysipelas in which the internal administration of sodium benzoate in the aggregate daily dose of four to five drachms was attended with admirable results. The drug is given in suspension in mucilage or in some effervescent water. Under its influence the febrile temperature diminishes and in twenty-four hours attains the normal. At the same time there is noted a diminution of the other symp-

toms. No external applications were used. In only two cases was an augmentation of the dose necessary. —*L'Union Médicale*, September 2, 1886.

Spartein.—Until very recently, investigations into the properties of the two principles, scoparin and spartein, contained in the broom, have thrown but little light on the therapeutic power of the drug itself. Scoparin has not been shown to possess physiological activity, though it has been regarded by some as a diuretic; and Fick's careful experiments with spartein (*Arch. f. Exp. Path. u Pharm.*, 1873, i.) led him to the conclusion that it acts chiefly on the nervous system. He found, indeed, that it influenced the heart, but concluded that its effects resemble those of atropine; and though increased urination was observed, it only took place shortly before the death of the animals experimented on.

Fronmüller ("Memorabilien," Heilbronn, 1878) attributed a diuretic action to spartein, but Rymond's conclusions from his researches in Vulpian's laboratory in 1880 ("Étude expérimentale de la spartéin et de son sulphate"), though not in complete accord with the results obtained by Fick, agree with them in specifying the nervous system, not the kidney or heart, as the special seat of the physiological activity of spartein.

In 1883, spartein was mentioned by Sée as a cardiac medicament, and last year (*Compt. Rend.*, Nov. 25, 1885), he brought forward a series of cases of cardiac disease, in which the administration of sulphate of spartein had quickly, and in an enduring manner, strengthened and steadied the heart's action. Laborde, about the same time, pointed out the predominant action of spartein on the heart of the lower animals, and now, in conjunction with Legris, he gives an account of its physiological action and clinical use.

In some of the lower animals, according to these observers, spartein causes increased reflex excitability of the spinal cord; in all it strengthens the systolic impulse of the heart.

If three-fifths of a grain be given subcutaneously to a rabbit the heart's beat is strengthened and slowed, and the effect is still more marked if the injection be repeated; frequent and abundant urination likewise ensues.

A dog of from sixteen to eighteen pounds weight is not injuriously affected by one and a half grains of sulphate of spartein. Three times this dose causes a tetaniform condition, with convulsions apparently spinal. Death takes place from paralysis of respiration, whilst the heart continues to beat regularly.

A small dose (one-seventh of a grain) is sufficient to strengthen the pulsation markedly in both large and small vessels.

In the frog, the heart's beat is greatly strengthened and quickened by spartein, and the organ continues to beat for an unusual time after death.

Laborde and Legris have not definitely determined the exact cause of the cardiac stimulation produced by spartein. They are inclined to think it is in part due to the action of the drug on the heart muscle, in part to centric nervous stimulation.

Sée, in his paper above alluded to, states that in man spartein strengthens the heart's beat and the pulse as powerfully as digitalis or convallamarin, and that its tonic action is even more durable. He says, too, that it regulates cardiac rhythm better than any other known drug; that it quickens the heart's action in grave atonic conditions; that it acts in an hour or more after its administration; that its effects last three or four days after its exhibition has ceased.

Laborde and Legris agree almost altogether with these statements; they only find the pulse increased in frequency when it is unduly slow, but they at times noted slowing when the heart's action was unduly quick. They find, however, that the effects of spartein usually appear in half an hour. Seven cases of cardiac disease are recorded in which spartein was taken with advantage, and tracings are given to illustrate its influence. In five of the cases no valvular lesion was diagnosticated, but either indications of asystolism or hypertrophy with palpitation. In two, mitral stenosis was present. In all, the heart's action markedly improved under spartein, in doses of one and a half to two and a quarter grains. They recommend that the drug should be given in doses of one and a half to three and three-quarter grains daily:

1. In cases where the heart is weak from tissue alteration, or unable to overcome obstacles in the circulation.
2. Where the pulse is irregular, intermittent, or arhythmic.

It has the advantage of acting quicker than digitalis, and it is not cumulative.

As a diuretic, they recommend spartein to be given in an infusion of the flowers of the broom. In cardiac dyspnœa, sulphate of spartein may be combined with iodide of potassium, and associated with inhalations of pyridine.

The contradiction between the results of Laborde and Legris, and those obtained by Fick, Rymond, and other observers, is so marked that further investigations into the subject are required, but the diuretic influence of broom is easily comprehensible if spartein has the cardiac influence attributed to it by recent French observers.—*Manchester Medical Chronicle*, September, 1886.

On Cases of Sudden Death Resulting from Venous Thrombosis and Embolism after Fractures of Bones.—Prof. P. Bruns, of Tübingen, gives one case of his own and a tabular synopsis of thirty-five extant cases. Analysis of these shows that the fractures occurred most frequently in the lower extremity, and in persons of from forty to sixty years of age. The immediate cause of thrombosis of the veins consists in compression or injury of the veins at the seat of fracture; and some predisposition is usually present on the part of the patient, such as varicosities or circulatory impairment. Embolism may occur at any time between the fourth and seventy-second day after the fracture, and death may result immediately, from asphyxia or syncope, or after a longer period of time from infarction of the lung, or, finally, recovery may take place.—*Annals of Surgery*, September, 1886.

Hydrofluoric Acid in Phthisis.—In the Medical Section of the Congress of the French Association for the Advancement of Science, session of August 14, 1886, M. Seiler described his method of administering inhalations of hydrofluoric acid in cases of phthisis. With the aid of a jeweller's bellows air is passed through a solution of the acid in three times its weight of water, the mixture being kept, of course, in a gutta-percha vessel. The air, thus impregnated with the acid, is introduced into the apartment of the patient in the ap-

proximate proportion of ten litres for each cubic metre of air in the room.

Seiler states that such treatment has been maintained daily during twenty to thirty successive days in sessions of an hour each, in a number of cases, that the inhalations are entirely innocuous, and that they often effect great amelioration of the disease.—*Le Progrès Médical*, August 28, 1886.

NITRITE OF AMYL IN OPIUM NARCOSIS.—*L'Union Médicale* reports a case of opium poisoning, in which the inhalations of nitrite of amyl brought on a rapid cure, when belladonna had failed, and the patient was almost beyond help.

TARTAR EMETIC IN LABOR.—In a paper on "Neglected Remedies," which appears in the *Medical Times* of September 18, 1886, DR. CALEB GREEN writes as follows: It seems not to be very generally known that tartar emetic is one of our most efficient agents in promoting parturition. When the pulse is tense, the os rigid, the skin dry and hot, the advance of the head slow, I have seen, by the use of small doses of antimony, the most prompt and happy change for the better. The pulse softens, the skin becomes moist, the rigid os relaxes, the vagina becomes bathed in a plentiful supply of mucus, and the uterine contractions hasten on to a speedy termination of the labor.

It is not a substitute for ergot, but it has properties which makes it much oftener available as a means of hastening labor to a happy termination. If the dose can be so graduated as to produce its effect as a parturient just short of nausea, and especially short of vomiting, the effect seems to be better than where vomiting occurs.

THE TREATMENT OF FEVER BY ELECTRICITY.—PROF. E. DE RENZI, having by chance observed a case of quartan fever cured by the application of electricity, instituted a series of experiments in this direction, and has formulated as a result of these observations, the following conclusions:

1. Fevers of malarial origin resist the action of the electrical current much more than do those symptomatic of bronchitis, pulmonary phthisis, etc.

2. During the application of electricity the temperature remains elevated, or even rises to a fraction of a degree; but soon after, at the most within an hour or two, a fall of several degrees occurs.

3. The best effect is obtained by holding a moist electrode in the hand while a metallic brush attached to the other pole is swept over the surface of the body.

4. Arterial pressure is increased during the application, the skin becomes reddened, and often moistened with perspiration, and the pulse is increased in force. It is probable, therefore, that the antipyretic effect of electricity is due to the increased activity of the cutaneous capillary circulation, whereby caloric is rapidly lost.—*New York Medical Monthly*, September, 1886.

OIL OF TURPENTINE IN THE DIGESTIVE DISORDERS OF INFANTS.—DR. BEDFORD BROWN writes as follows in the *Journal of the American Medical Association* for September 25, 1886.

In the therapeutic management of the more painful and grave affections of the alimentary canal of infants, and in those of a harmless character attended with suffering, I have for some years past been testing the virtues of the oil of turpentine as a curative agent. The use of turpentine in this class of affections has given me much satisfaction.

All infants are liable to transient attacks of painful colic, arising from temporary distention from accumulation of gas in the stomach, or from the presence of acids. But artificially fed infants more particularly are occasionally subject to a violent, protracted, and intensely painful form of gastralgia in which appetite and digestion are suspended, accompanied with rapid reduction of flesh and strength, sufficiently to endanger life. Vomiting may or may not be present. There may be slight diarrhœa or constipation. The affection is invariably attended with wasting of the tissues and suspension of development, anxious and contracted facies, but no fever except in advanced stages, when gastritis or duodenitis may be developed. Pain is the great and absorbing feature of the disease, which is a never-ending source of suffering to the little patient, and a source of perplexity to friends.

The disease may appear at a very early age. It does not appear to be associated with any organic lesion. It does not partake of the intermittent character of ordinary colic. But the pain is almost constant and unceasing, without relief from opiates. The abdominal walls are usually retracted. The shrill, penetrating cry of these little sufferers may often be heard, to the dismay and distress of all, pervading the entire house, day and night, except when under the influence of opium. On one occasion a feeble, emaciated, little infant was brought to my office, suffering with this affection, for treatment. Such were the shrill and distressing screams of the little creature, the wasted and piteous expression, that all transient callers were compelled to leave the room. The mother was robust and apparently in a vigorous state of health, and afforded an abundant supply of nourishment.

I think that in this case the child was suffering from an aggravated form of acidulous dyspepsia, with simple irritation of the gastric and duodenal mucous membranes. In two or three months this wretched little sufferer, under the turpentine treatment, combined with a few simple anodyne and alkaline remedies, was converted into a rosy, fat, merry, healthy infant. I have found the following formula a useful remedy in this class of cases:

R.—Mucilag. acac.	ʒiss.
Sodæ bicarb.	grs. x.
Chloroformi	gtt. x.
Ol. terebinth.	ʒss.—M.

Sig.—A teaspoonful every two or three hours to an infant of six months.

ANTISEPTIC VASELINE.—DR. P. MÉNIÈRE advises when uterine dilators, of either metal or vegetable material, are to be introduced that they be previously lubricated with the following mixture, which is not only antiseptic but favors dilatation.

Vaseline	ʒij.
Extract of belladonna	ʒj.
Bichloride of mercury	gr. ¾.

This pomade is best kept in long, narrow bottles, into which the instrument may be plunged before it is used.—*Gazette de Gynécologie*, September 1, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 2, 1886.

CONTAGIOUS PLEURO-PNEUMONIA.

FOR the past two weeks the daily press has contained reports of the detection of pleuro-pneumonia in cattle at Chicago, and the statements of Dr. Salmon, the Government Veterinarian, leave no room for doubting the existence of the disease. We are not surprised to find realized in this way the worst fears of veterinarians and cattle breeders. It has been known for some years that the disease prevailed more or less extensively in New York, New Jersey, and Pennsylvania. The State and central governments have been repeatedly warned of the extreme danger of allowing this plague to exist, and half-hearted measures have been taken to eradicate it. Not a month has passed, however, without the intelligence of outbreaks, which plainly showed that the disease still lingered in our midst.

The limitation of the affection to the Eastern States, while gratefully recognized, was forcibly urged as the very best reason for its complete suppression. Once past the Alleghanies, where would it stop? Now the country is face to face with the most serious problem in animal pathology which it has had to encounter. The existence of the disease in Chicago—the great cattle centre of the West—threatens directly the herds on the ranches, and only extraordinary precautions can prevent their infection. The matter is one of grave public interest, as involving one of the great industries of the country, and should be dealt with by the central authorities at once. The spread of the disease in the Western herds means the loss, directly and indirectly, of many millions of dollars, and a damage to the cattle trade from which it would take years to recover.

To an American, nothing is more remarkable in Europe than the extreme anxiety displayed by the Governments in the investigating of every case of disease in cattle, the stringent quarantine of suspected localities, and the enforcement of sanitary regulations which we scarcely here think needful in our civil or municipal affairs. But they have bought their experience dearly enough, and it is the burnt child who dreads the fire. Our country has been remarkably free from devastating cattle plagues, and it is difficult to get people to realize the full danger until the mischief is irremediable. Those best acquainted with the condition of things have repeated their warning, but, too often, to deaf ears, and it really looks as if some great calamity, such as the cattle plague which overtook Great Britain in 1865, were needed to arouse public opinion to the point at which the question could be dealt with as its importance demands.

In the present crisis the indications are plain. The districts in which pleuro-pneumonia exists should be declared infected; a thorough examination should be made of all suspected animals; the immediate slaughtering and burning ordered of cattle found diseased; the isolation of cattle which have been in contact with diseased herds; and the systematic supervision of infected regions until such time as all danger of further trouble is over. To accomplish this the inspectors must be armed with arbitrary powers, and the Government must be prepared to spend large sums of money, but every thousand dollars now spent will mean one hundred thousand dollars saved, if pleuro-pneumonia can be kept out of the Western herds. There should be no trifling, and the action to be effective must be immediate. Only a few weeks ago, pleuro-pneumonia broke out in the cattle at quarantine at Quebec, where all animals coming from Europe are isolated for three months, on purpose to prevent the importation of this disease, the incubation of which may extend to ten or twelve weeks. Rather than risk the introduction of the disease, the Dominion authorities ordered the entire lot to be killed and burned, at a loss of over three hundred thousand dollars. Just such stringent measures are now called for at Chicago; nothing less than the destruction of the affected animals will give a reasonable prospect of checking now, and ultimately eradicating, the disease.

THE TREATMENT OF GRANULAR CONJUNCTIVITIS.

IN the treatment of granular conjunctivitis one of two objects is to be kept in view: either to subdue inflammation when this is already excessive; or, when it is deficient, to excite it to greater activity, so as to lead to the absorption of the morbid tissue which has been formed. For the latter purpose various chemical applications have been used, and even

inoculation with gonorrhœal pus; while attempts have also been made by scarification to lead to atrophy and absorption of the granulations.

One of the most recent methods proposed for the treatment of trachoma is that described by Dr. Cecchini Settimo, of Modena, in the *Gazetta degli Ospitali*, Nos. 100–103. 1885. It consists in destroying the granulations mechanically and chemically, by scraping and cauterization. All the cases Settimo has seen involved the upper lid, which he turns up, protects the eyeball with cotton soaked in a solution of boric acid or smeared with an inert ointment, and scrapes out with a Volkmann's spoon as many of the granulations as possible. He checks the hemorrhage with cotton dipped in cold water, and then practises a vigorous cauterization with pure nitrate of silver. Before doing this he pushes the lower lid against the reversed upper lid, and places between them a little cotton soaked in a solution of chloride of sodium, to protect the cornea. After the cauterization, the upper lid is well washed with the same solution, followed by a cold solution of boric acid. For the subsequent pain, he instils a solution of morphia and atropia, and applies light compresses, dipped in iced water. In some cases he applies a leech, or leeches, to the temple. The patient is ordered to keep the head elevated and the eye cool with applications of cold boiled rice, washing it out with boric acid solution.

The operation is contraindicated only when there is pronounced hyperæmia, in which case it is important to cure or to diminish this before scraping. Settimo prefers not to use an anæsthetic, as the contraction of the palpebral muscles helps the scraping process, although this is quite painful.

The operation may be done at one sitting if the granulations are soft and not very vascular, and the infiltration is not very great; but, if the granulations are hard and cartilaginous, it is advisable, but not necessary, to make the scraping in two or three sittings, at intervals of not less than three days. Chemosis is to be combated by taking blood from the temple, by incision of the external angle as in the method of Gräfe, and by deep incisions in the conjunctiva.

Settimo has used this method, combining it with the administration of iodide of potassium in twenty cases, with the most brilliant results, and naturally recommends it very warmly for general adoption.

More recently, Kramsztyk, in the *Gazeta Lekarski*, has called attention to a method of treating trachoma which was originally proposed by Wicherkiewicz, and which consists in crushing the granulations between the thumb-nails of the operator, or by means of a pair of forceps. The operation is very painful; and, although it has succeeded in a number of cases, it does not appear to have any advantages over the method of Settimo, especially if the granulations are very numerous.

Both of these methods are so heroic, that surgeons must be strongly convinced of their utility and of the necessity for having recourse to them before they are likely to be generally employed. Meanwhile, it is interesting to note, that Minor, in the *New York Medical Journal* for July 31, 1886, reports that he has had most excellent results with powdered boric acid dusted over the conjunctiva two or three times a day, or less frequently. The application causes pain lasting about thirty minutes, and a free serous discharge, which is soon followed by relief. The improvement in the conjunctiva and the clearing up of the cornea may not be very noticeable for a week, but after this time it will be apparent. Minor has found that boric acid ceases to be tolerated after three or four weeks, when some other drug must be substituted.

HYSTERICAL APOPLEXY.

At the meeting of the Société des Hôpitaux, August 13th, reported in the *Gazette Hebdomadaire*, No. 34, Debove communicated the facts of an extraordinary case of hysterical apoplexy in the male. The patient, a man aged thirty-one, formerly quartermaster in the marines, suddenly lost consciousness and remained insensible for twelve hours; but without convulsions and without involuntary evacuations. For two hours there was complete paralysis of the left side, which gradually disappeared, so that in the morning, on admission to the hospital, there was only an enfeeblement with hemianæsthesia. There was no history of any previous malady, and the patient was a vigorous man, but of an emotional temperament. The diagnosis of a hysterical condition was based on the character of the anæsthesia and its cure by suitable agents. The insensibility involved the skin, mucous membranes, muscles, and organs of sense of the left side. There was limitation of the field of vision, lack of preception of violet color, and monocular polyopia. The application of a magnet caused the return of sensibility in the left arm, and at the same time a disappearance of sensation in the corresponding right limb. It required several days' application of the magnet to restore completely the sensibility of the left side. The motor paralysis followed the anæsthesia in its transference from one side to the other, and disappeared with the restoration of sensibility. Only a hysterical condition could present such features, and be modified and cured by the application of magnets.

LUXATION OF THE ULNA IN COLLES'S FRACTURE.

It is now about fifteen years since Moore, of Rochester, called attention to the occurrence of dis-

location of the ulna and its separation from the triangular cartilage in Colles's fracture of the radius. He first observed these complications in the case of a woman, who, in a fit of mania, leaped from a third-story window, and broke her spinal column and both wrists. Four additional cases have been studied by him and have confirmed his convictions that, even when these fractures are the result of ordinary violence, they present the same features of a separation of the triangular ligament from the ulna, rupture of the lateral ligament, and tearing off of a portion of the styloid process of the ulna.

Moore's assertions have not so far secured the consideration they seem to deserve. Indeed, the credit of the discovery of the important relation of the dislocation of the ulna and fracture of the styloid process to Colles's fracture has lately been assigned to another investigator, Mr. Clement Lucas, whose observations were published in *Guy's Hospital Reports*, vol. xlii., for 1883 and 1884. These observations support the views so long ago expressed by Moore, although they differ from his in certain particulars.

There can be no doubt of the correctness of the statements of both Moore and Lucas. It is, moreover, certain that there is more or less displacement of the ulna from its connections at the wrist, with fracture of the styloid process, in many fractures at the lower end of the radius, in which these lesions are not discovered or even suspected. Moore estimates the frequency of these complications as about fifty per cent., and Lucas found them present in fifteen out of twenty-eight specimens in Queen's College Museum, which he subjected to a careful and critical examination.

THE NEGLECT OF VACCINATION.

We have noticed in the statistics of one of our large cities a recent marked falling-off in the number of operations performed by the public vaccinators, a fact which we fear portends evil in the near future. Although these data apply to a particular class, the smallness of the official returns of the past year or two, as compared with those of preceding years when smallpox was prevalent, may be taken as a fair index of a condition of the community in general, and is attributable to carelessness and neglect, so commonly observed during a season of immunity from the disease. When the incentive of fear is removed, people soon lapse into a condition of false security, and ignore the very measures which have procured for them a respite from epidemic visitation.

There are always in every community some people who reject vaccination under all circumstances. There are others who have their prejudices but are open to persuasion and conviction of their error. But the vast majority believe in the efficacy of the operation, though they are often negligent about its performance, especially after the abatement or disappearance of smallpox. The number of unprotected persons is thus constantly increasing during an interval of exemption from this disease, and is greatest before an outbreak occurs.

The remedy for this condition of things is compulsory vaccination; but so radical a measure is not received with favor. The alternatives are the imposition of disabilities and warnings and persuasion. In a period like the present, the importance of vaccination should be brought to the attention of the public in every possible way, and every facility should be afforded for gratuitous vaccination with thoroughly reliable virus. The public school boards should rigidly enforce the rule prohibiting unvaccinated children from participating in the advantages of free education. Physicians, as well as the local sanitary authorities, should be earnest in their endeavors to secure the widest possible results of this beneficent discovery.

Dr. Shakespeare returned to Philadelphia last week from Europe, after a year's absence, during which time he has been engaged as the representative of the United States in investigating, under the direction of the Secretary of State, the causes, progress, and proper prevention and cure of cholera. For this purpose he visited, and prosecuted his researches in, the cholera-infected districts of Spain, France, Italy, and in India. He is now engaged in preparing his report, which, we understand, will be forwarded by the President to Congress, and will be published as an official document.

Dr. Shakespeare's friends in the profession of Philadelphia gave him a reception on Wednesday evening at the Hotel Bellevue.

THE CHARLESTON MEDICAL COLLEGE.

We are in receipt from the Dean of the Charleston Medical College of the following statement of the extent of injury suffered by the college building:

"It is impossible to use any of the lecture rooms. $5000 would make the building tenantable for the purposes of lecturing. It will probably require between $8,000 and $10,000 to put the College in its former condition. The portico in front of the building is completely destroyed. The public inspectors of buildings have decided that the roof should come down, because it is badly supported by the upper portions of the wall. The annexed building used for dissecting purposes is also completely destroyed.

"The temporary repairs would, therefore, consist in strengthening the supports of the roof, in preventing leakage, removing cracked plastering, and building a dissecting room.

"We have secured for temporary use the old Marine Hospital building, which will have to be repaired at the expense of about $700. This will be done in time for the commencement of the lectures. The session will open as heretofore announced, on October 15th.

"To the above statement of the condition of the College it should be added that the institution has no mortgagable property, that is, has no funds, and, finally, that there is scarcely a probability of its participating in the general relief fund."

We have received for transmission the following contributions for the fund for the repair of the Charleston Medical College:

Philadelphia County Medical Society	$100.00
Lea Brothers & Co.	100.00
Dr. S. Weir Mitchell	100.00
Dr. J. M. DaCosta	25.00
Dr. Laurence Turnbull	10.00
Dr. Charles W. Dulles	5.00

SOCIETY PROCEEDINGS.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Eleventh Annual Meeting, held in the Hall of the Johns Hopkins University, Baltimore, Md., September 21, 22, and 23, 1886.

Tuesday, September 21.—First Day.

Morning Session.

The President, Dr. Thaddeus A. Reamy, of Cincinnati, called the Society to order.

Dr. H. P. C. Wilson, of Baltimore, delivered an

ADDRESS OF WELCOME.

In the name of the resident Fellows, of the general profession, and of the citizens of Baltimore, he extended to the Society a hearty welcome. "Were our hands as big as our hearts," he said, "we should kill you with kindness. Baltimore is ever ready and willing to welcome you whenever you are ready to come. I can assure you of the great interest which this community takes in the subjects of your deliberations."

Dr. H. P. C. Wilson then read the first paper; it was entitled

THE DIVISION OF THE CERVIX BACKWARD IN SOME FORMS OF ANTEFLEXION OF THE UTERUS WITH DYSMENORRHŒA AND STERILITY.

The operation, from want of a judicious selection of the cases, by being done by unskilled hands in proper cases, by being done in unsuitable cases, and from want of appropriate after-treatment, has been barren of good results in certain hands and followed by bad results in other hands. This operation has been substituted by the use of stems, sponge tents, and dilators, but the speaker had found no measure so safe and efficient in the classes of cases to which he shall call attention as the knife. The classes in which he would recommend the operation are:

First, those of anteflexion of the uterus, with a hard, indurated cervix, where the body is bent upon the neck, or the neck upon the body, forming a more or less acute angle.

Second, those cases of acute flexion where the cervix is hyperplastic and indurated and dense as cartilage.

Third, those cases where there is a hard, unyielding, internal os, through which the probe passes with difficulty, and in its passage gives the sensation of passing over rough, dense cartilage, while the finger in the sulcus between the body and the neck in front gives the feeling of a strong cord tied around the uterus. The third class is frequently combined with the first, and often with the second. In a typical case calling for the knife, all these lesions coexist. Nearly all these cases are sterile. In all of them the Nabothian and utricular glands are hypertrophied and indurated.

The different methods of operating were then reviewed. If the patient escapes the secondary results which are liable to follow the use of tents, they are the most efficient means of overcoming the difficulty, next to the use of the knife. The forcible dilatation does not restore the anteflexed uterus. For the purpose of rectifying the difficulty, the knife is the surest means in the cases which have been referred to. Where the posterior lip of the cervix is divided, and the internal os is divided anteriorly and posteriorly, the circular muscular fibres are paralyzed and the longitudinal fibres contract and tend to rectify the position.

The method of operation was then described. With the patient under an anæsthetic, the uterus is drawn downward by a tenaculum in the anterior lip; the posterior lip is then divided with scissors up to the vaginal junction. An uterotome is next passed, and the internal os divided anteriorly and posteriorly to an extent sufficient to permit the introduction of a large sound. The parts are allowed to bleed freely. A pledget of cotton soaked in a mixture of Monsel's solution, iodine, and glycerine, is then introduced into the cervix and over this pledgets treated with Monsel's solution and water and the vagina lightly tamponed. These are not removed until the third day. All manipulation of the uterus is avoided for at least two weeks. A sound is then carefully passed, and every second day the os is gently stretched with a steel dilator. The patient is allowed fully to recover from the operation, which usually requires one month. Local treatment is then suspended for one month, to allow the intrauterine mucous membrane to improve. The patient then returns, and applications of Churchill's tincture of iodine are made to the endometrium two or three times a week. The treatment, after the lapse of a month, is again suspended, to be resumed in the course of one or two months. If this after treatment is not carefully and properly carried out, the operation had better not be done. The speaker had performed the operation 400 times, and had never obtained as good results from any other method. In no case has he had a death which could be attributed directly to the operation. If the patient is not disturbed by meddlesome after-treatment for ten days subsequent to the operation, there is not much danger of inflammatory troubles. There are some cases of dysmenorrhœa and sterility where this operation is entirely unsuited. It was recommended only in the cases described in the beginning of the paper. Several illustrative cases showing the good

effects of the operation in overcoming dysmenorrhœa and sterility were related.

Dr. T. A. Emmet, of New York, said that he would have been willing, some years ago, to endorse all that had been said by the speaker. He thought that he had done as much harm as any one by this operation. We must separate dysmenorrhœa and sterility as being due to widely different causes. Mechanical dysmenorrhœa he considered a myth. We must also separate two conditions of flexion, one a flexure of the neck, a congenital defect, and the other a flexure of the body of the uterus, due to preceding inflammation outside of the uterus. Sterility resulting from this latter cause is not relieved by the operation, and its performance is attended with great risk to life. The congenital flexion is the only one in which he operates to relieve the sterility. There are a few cases of the inflammatory form of flexion where the operation benefits the reflex symptoms by its revulsive action. Where he has done the operation he has drawn the vaginal mucous membrane to the bottom of the wound and secured it with stitches. This does away with the necessity for plugging and the fear of hemorrhage. This operative procedure is not free from danger. He was aware of at least twenty deaths from it. If, as has been suggested by Dr. Wilson, all the effects of previous inflammation are removed, there is not the same danger, but he could not see that the operation will do any good.

Dr. James R. Chadwick, of Boston, remarked that he had not been successful with this operation in curing sterility or dysmenorrhœa. He considered flexion as always congenital, the result of the persistence of the infantile shape of the uterus. This, he was convinced, is not confined to the anatomy of the organ, but also involves its function. The defect probably extends to other portions of the genital tract. The only cases in which he had had any results from operation had been where there was flexion with a small external os. In a certain proportion of these cases, impregnation had followed the operation. He held that the operation should be restricted to those cases in which there is flexion with a small external os, but in which the uterus seems to be well developed in other respects.

Dr. W. H. Baker, of Boston, said that while the immediate results were very gratifying, in many cases they were not permanent. The question arises, If this operation, which was performed so frequently, was successful, would it not have lasted? It was found that in many cases less severe measures would give equally good results. This has led to a clearer discrimination of the cases. Of late years he had limited the operation to the class of cases in which there is a congenital malformation and those in which there was seen an inflammatory condition, the results of which had been removed. The good results which Dr. Wilson reports must be explained by the great care in the after-treatment which he practises.

Dr. Fordyce Barker, of New York, stated that some thirty years ago he had seen Simpson perform this operation a number of times. He performed it in his office, and did not seem to apprehend any danger from hemorrhage. He employed the operation in a few cases, but he soon gave it up. The only cases in which he employed it was where the narrowing was at the os externum.

Dr. J. Scott, of California, had practised the operation. But while the immediate results have been good, he had been disappointed in the ultimate results. He had gradually come to limit the operation to the cases described by previous speakers. After the operation, the patient should be confined to bed at perfect rest, and hot water injections be employed every two hours.

Dr. W. T. Howard, of Baltimore, remarked that he had given all the operations alluded to a fair and full trial. His experience has not shown him that any particular operation is the one for all cases. By the anteroposterior incision he had had some excellent results. With the precautions adopted in operating in other portions of the body an incision of this kind in the majority of cases should not be dangerous. Dr. Mundé, in a paper on this subject, reports over one thousand cases, with only nine deaths. He thinks, however, that forcible divulsion is attended with as much risk as incision. In his practice the method adopted has varied according to the case. In some he had employed the posterior incision, in others the bilateral incision; but in the majority of cases he dilates, using antiseptic precautions. He had never taken less than twenty to thirty minutes to complete the operation.

Dr. H. P. C. Wilson said that he had not heard any thing in the discussion to convince him that in properly selected cases division of the cervix is not the best thing to do. As he had already said, if the operation is not followed by proper after-treatment, it had better not be done. The danger is not from the operation itself, but from the improper after-treatment.

Dr. R. Stansbury Sutton, of Pittsburg, then read a paper on

Another Modification of Emmet's Cervix Operation, with a Case in Point.

A case of old-standing neglected double laceration of the cervix was reported. The cervix was composed of dense, hard, hyperplastic tissue, almost cartilaginous in character. An operation by the ordinary method was out of the question, for the sutures would not have held. In order to remove the greatest amount of cicatricial tissue and overcome the condition, the following procedure was resorted to: the lower lip of the laceration was denuded of its altered mucous membrane, leaving only a narrow strip corresponding to one-half of the strip usually left to serve for the future os; the upper lip was treated in the same way, leaving the opposite half of the strip of mucous membrane. When the flaps were brought together, the strips of mucous membrane lay side by side, with the undenuded surface of one flap in apposition with the denuded surface of the opposite flap. In this way union in the position of the future canal was prevented. Good union followed the operation and at the end of three weeks a Simpson sound was passed without difficulty. This operation may be of service in certain cases where the usual operation cannot be performed.

Dr. Emmet considered the modification to be an ingenious one, but its value can only be determined by future trial. In such cases, however, where there has been such cystic degeneration, it is often better surgery to amputate a portion of the cervix, so as to get into healthy tissue. In a certain number of cases, he had always performed amputation. He objected to ampu-

tation in so-called elongated cervix. If we remove the tissue to a depth below the follicles, the remaining dense tissue will gradually soften.

Dr. George J. Englemann, of St. Louis, said that he had found no difficulty in preventing union, and had paid very little attention to the strip of mucous membrane. In such cases as had been described, he had cut away nearly all the mucous membrane and inserted a short piece of fine catgut. This maintains as large an opening as is necessary. When, however, we come to such extreme cases, it is better not to attempt what has been termed Emmet's operation, but to resort to partial amputation, as is performed in Germany.

Dr. W. H. Baker held that if we can restore the healthy character of the strip of mucous membrane and retain it, that is the best surgery. In this class of cases he had removed a transverse wedge-shaped portion of each lip of the cervix and then brought the parts together. In this way the hyperplastic tissue preventing the apposition of the surfaces is removed. If proper preparatory treatment is employed, the saving of the strip of mucous membrane can usually be accomplished.

Dr. R. Stansbury Sutton, in closing the discussion, said that in the case described there was one of two things to be done, either to remove the cervix or devise some new method of operating. This modification gave complete satisfaction in this case and he purposed trying it in other similar cases.

Dr. Elwood Wilson, of Philadelphia, forwarded some

NOTES ON THE TREATMENT OF RECENT LACERATION OF THE CERVIX UTERI.

Occasionally a tear of the cervix can be recognized, he said, immediately after labor, but sometimes this can not be done. The patient should always be examined ten or twelve days later. If laceration be found immediately after labor, injections of corrosive sublimate solutions, one to five thousand, with the insertion of an iodoform suppository, should be resorted to. The vagina should be irrigated every other day and the suppository renewed. When the laceration is found within three weeks after delivery, the following treatment should be employed: After the surface has been carefully cleansed and dried, it should be painted with a solution of nitrate of silver, one drachm to the ounce of distilled water. From three to five applications at intervals of five days are usually required. In every case in which the author had tried this measure (six in number), the result was entirely satisfactory.

Dr. Fordyce Barker, of New York, thought that the practice recommended in the paper is better worthy of trial. It is much preferable to the *rôle* laid down within the past few years, that if there is a laceration it should be closed immediately after labor. If this method will effect union it should be tried.

Dr. Thomas A. Emmet supposed that a certain amount of laceration occurs in every labor, but it is wonderful what nature will do to restore the cervix where septic poisoning is not present. It seemed to him that in all cases where under favorable circumstances nature has failed to repair the damage, there have been symptoms indicating septic inflammation. In the cases reported, he believed that the same results would have been obtained even if nitrate of silver had not been employed.

Dr. J. Scott, of San Francisco, said that in only one case had he attempted to sew up the cervix shortly after labor. In this case there was an extensive tear of the cervix and of the perineum. There was considerable bleeding, and five hours after labor he thought it advisable to sew up the cervix. The tissues were so soft that it was with the greatest difficulty that he could get the sutures to hold. Union took place, however, both in the cervix and in the peritoneum.

Afternoon Session.

Dr. Thomas Addis Emmet read a paper on

PELVIC INFLAMMATIONS: CELLULITIS *vs.* PERITONITIS.

In this country the term cellulitis has come to signify pelvic inflammation without reference to the special form, but its origin is supposed to have been in the connective tissue. So close is the relation between the connective tissue and the peritoneum, that it seems impossible for inflammation to be present in one without affecting the other. There are situations, however, as between the uterus and bladder, and between the uterus and rectum, where cellulitis might exist without involving the peritoneum. Inflammation in these situations tends to resolution, and so the tissues soon regain their healthy condition if suppuration does not take place. After septic poisoning, the peritoneum rapidly becomes inflamed and adhesions occur, the circulation in the bloodvessels becomes more or less obstructed, and the action of the absorbents is greatly impeded. Finally, a condition is produced which remains long after the symptoms have subsided, and one not prone to change or amenable to treatment. In such cases a fresh attack is provoked by slight causes.

It has been objected that when the abdominal cavity is opened for the removal of the ovaries, very slight evidences of inflammation are found. In a recent case the speaker had expressed the opinion from the vaginal examination, that a thickened and shortened left broad ligament would be found; at the operation no broad ligament was found, but there was an enlarged tube lying against the side of the vagina. Similar cases have been noted. He would explain these cases in this way: If there is an inflammation between the folds of the broad ligament, it must involve the peritoneum. As a result of the inflammation, the connective tissue disappears and adhesion of the opposing surfaces takes place. The broad ligament is flattened out so that Douglas's cul-de-sac disappears on that side. The vaginal wall is raised up so that it and the tube lie in contact. This is the condition found by the surgeon when he operates for the removal of the diseased Fallopian tubes. In all these cases he felt satisfied that there has been inflammation of the connective tissue. He thinks that the inflammation has been secondary to the cellulitis in every instance except where the primary inflammation was the result of gonorrhœa. If his observations are correct they would prove that the connective tissue never regains its integrity after having been once inflamed. If the surrounding tissue has restored the loss the part will return to its normal condition. If the loss cannot be replaced, nature can only repair the injury by a process of adhesive inflammation of the parts involved.

He had used the term thickening of the broad ligament, but he had not meant to imply that there is a deposit of lymph between the layers of the broad ligament. The enlargement is, he thinks, due to the dilated state of the veins. The condition is one easily aroused to activity.

It is still a moot question as to the way in which the tube has become involved where gonorrhœa is not the cause of the inflammation. In septic poisoning after surgical injuries, he believes that the connective tissue of the veins and lymphatics first become involved and that the inflammation of the peritoneum is secondary. There is no evidence to prove that the inflammation passes into the uterine canal and thence to the tubes, except in such cases where the process is due to gonorrhœa.

The prognosis as to the result to be gained by local treatment is doubtful in those cases due to gonorrhœa, in those cases where the pelvic inflammation is of long standing without reference to the cause, and in those with a history of frequently recurring attacks. In cases which can secure every attention, a cure by local treatment can sometimes be effected, but a long time is required. In patients who have to gain their own living, we may seriously consider the advisability of an operation after having gained the consent of the patient after a true representation of the operation and its results. We should enter a protest, and the profession should demand a recognition of the responsibility of those who are immediately operating for the removal of tubes and ovaries. It requires an expert to determine when the operation is necessary, and still more experience and skill to do it with safety to the patient. It should only be done as a last resort after other measures have failed. In a number of cases, in private practice, he had succeeded in restoring the patient to health by local treatment, although the operation had been strongly urged. If we could get accurate statistics, he thinks that it would be shown that the average amount of benefit gained does not compensate for the amount of risk. He believes that the operation is done too often even by those who have the least death-rate. He predicted that five years will not pass before it will be almost necessary to offer an apology when this operation is proposed.

Dr. Robert Battey, of Georgia, said that from his experience it has seemed to him that the pelvic cellulitis which gives so much trouble was, in a large proportion of these cases, secondary. So far as disease affecting the tubes is concerned, he believes that if we throw out of consideration the gonorrhœal cases, the primary disease starts in the ovary. He regards most of these serious inflammations of the pelvic cellular tissue as dependent upon cystic or cirrhotic disease of the ovary. With reference to the frequency with which this operation is done, he said that he was largely in sympathy with the speaker. He thinks that the operation is done too often. He does not believe that every case of organic disease of the ovary requires operation.

In reply to a question of Dr. Fordyce Barker asking him to state the grounds on which he would advise removal of the tubes and ovaries, he said that every case must be determined for itself. If he had a poor, miserable patient, without the means of comfortable subsistence, suffering with ovarian or tubular disease, he would operate. If he could put such a patient under suitable surroundings, and under a prolonged course of treatment, he might not think of the knife, but we have to look at the cases as they exist. He does not require in his cases an absolute diagnosis of disease of the tubes or ovaries prior to operation. It is sufficient for him to know that the general health is broken down by reason of the perverted function of her ovaries, that she is utterly miserable, that there is no reasonable hope of restoration to health by other means, and that there is a reasonable prospect of restoration by the removal of the ovaries. Under such circumstances he unhesitatingly operates, and, contrary to his former views, he finds that the ovaries are diseased.

Dr. R. Stansbury Sutton, of Pittsburg, believed that when the ovary is diseased, and cannot be cured by ordinary means, when it is interfering with the health of the woman and her duties in life, it should be removed. If the ovary is diseased, and is a burden to the woman, it is as much the duty of the surgeon to remove that ovary as it is to remove a diseased eyeball. He agreed that the operation is being done too often, not, however, by competent men, but by incompetent men. The conditions which require the operation are not always clearly understood before the abdomen is opened. He did not believe that a man is compelled to be positively certain of what he is going to find before operating. The speaker then presented several specimens, and described the cases from which they were removed.

Dr. Busey, of Washington, thought that if pathologists will return to the histological basis, there will not be the difference of opinion which now exists. He believed that it is now held that the cellular tissue is really a vast lymphatic structure, and that the peritoneum is a large lymphatic sac. Instead of discussing nice distinctions between pelvic cellulitis and pelvic peritonitis, it would be better to classify as pelvic lymphangitis these different varieties.

Dr. J. Scott, of San Francisco, mentioned some of the cases bearing upon this point which he had seen. One was a patient supposed to have fibroid tumors. The abdomen was opened, and both ovaries found to contain pus. They were removed, and the patient recovered. In the second case the patient presented a tumor in the right side. The temperature record was kept for two months, during which time it did not vary half a degree. On opening the abdomen the ovary was found to contain ten ounces of pus. The right ovary was removed, but the left appeared to be healthy, and was left in position. During the operation the bladder was opened. This was sutured, and the patient made a good recovery. Five weeks later the patient complained of pain in the left side, and on examination he found an enlarged left ovary. This was removed, and the patient promptly recovered. In a somewhat similar case, one ovary was removed. In a short time the other enlarged, but the operation was postponed, and the woman died of rupture of the abscess.

Dr. Matthew D. Mann, of Buffalo, alluded to the possibility of one tube and ovary being diseased without involvement of the other. There is no reason why it should be so. He had, in several cases where the disease appeared to be limited to one side, removed but one ovary, and the result has been a perfect cure. This operation avoids some of the objections urged against the removal of both ovaries.

Dr. H. P. C. Wilson, of Baltimore, believed that where there is a general cellulitis there is more or less pelvic peritonitis. These two affections are often associated. In the early stages the inflammation is often controlled by active treatment. If it is not controlled, it may go on to the formation of abscess. The pus may be discharged and the patient recover. Occasionally the abscess occurs in the tube or ovary, and these are the cases in which laparotomy is often called for. He agreed that the operation is done too frequently. The point which Dr. Mann had raised, that it is not always necessary to remove both ovaries, is a very important one.

Dr. John C. Reeve, of Dayton, Ohio, reported

A CASE OF ABDOMINAL SECTION FOR CHRONIC SUPPURATIVE PERITONITIS.

A., aged nineteen, living as if married, was healthy until November last. She had never been pregnant. She was attended by a physician, who found abdominal inflammation. On January 18th, she was seen in consultation by the speaker, at which time she presented the evidences of chronic peritonitis, but no history of a gonorrhœal origin could be obtained. One month later she began to pass pus by the rectum. After other measures of relief had failed, laparotomy was offered in April, but declined. The patient was not again seen until June 20th, when she desired the operation. She had suffered with hectic, the menstruation had ceased since January, and examination of the urine showed no albumen. There was great tenderness and hardness all over the abdomen, pus being still passed with the stools. By vaginal examination no definite hardness could be detected. By the rectum there was ill-defined resonance high up on the left side. No opening into the rectum could be detected, although frequent examinations for this purpose were made. The patient was greatly emaciated, the weight having fallen from 125 to 70 pounds.

The operation was performed June 23d; there was great difficulty in the administration of the ether. On opening the peritoneum, all the parts were matted together. The abdomen was washed out by allowing water to run into it from a pipe, and then syringing out what remained. Finally a cavity was reached in the left lumbar region. It was impossible to attach the walls of this cavity to the abdominal wound, and as the condition of the patient was by this time alarming, a drainage tube was introduced and the abdominal incision closed with sutures. In the course of several hours, the patient gradually rallied from the operation. The temperature did not go above 100°. The cavity was washed out with a solution of iodine in tincture in water. The upper two-thirds of the abdominal wound failed to unite. On the fourteenth day a large quantity of fecal matter came through the wound. This has continued to recur. In July, evidences of Bright's disease were detected; since then there has been some improvement in the general health. He thought that if the patient had consented to the operation when first proposed, the result might have been different. One of the principal objects of the paper has been to ascertain whether, as has been stated, fecal fistula is an invariable consequence of laparotomy for abdominal inflammation in cases where pus has already escaped by the rectum.

Dr. J. Scott mentioned the following case. A patient was admitted to the hospital with prolapse, inflammation of the ovaries, and cellulitis. After three months' treatment without improvement, removal of the ovaries was recommended, but declined by the patient. The patient was kept under treatment for six months longer, when enlargement of the right ovary began. Later, pus discharged by the rectum, and subsequently the abscess opened into the bladder. The patient then consented to operation. The abdomen was opened, an opening made into the vagina, and a drainage tube introduced. The improvement was not marked, and in the course of two months the patient was as bad as ever. The removal of both ovaries and tubes was then performed. Four or five days after the operation, feces appeared in the wound. During the five months succeeding the operation, the fecal fistula has closed, the patient has gained ten pounds, and is able to walk about.

Dr. William Goodell, of Philadelphia, said that the only case which he had had at all similar to the one reported, was one of pelvic abscess opening into the rectum and bladder. He performed laparotomy with the intention of opening the abscess and stitching its walls to the abdominal wound. The abscess had been so constantly drained, that it was not larger than a pear. By compressing the abscess sac, he was able to make it prominent in the vagina, and force into it a closed pair of scissors, which were then opened, and the opening gradually enlarged and a drainage tube inserted. This case gradually recovered, both the rectal and vesical openings closing in the course of time.

Dr. C. C. Lee, of New York, thought that the rule will come to be established that in chronic suppurative peritonitis, laparotomy is not only justified, but the procedure to be adopted.

Dr. R. S. Sutton said that in a case of pelvic abscess as large as a cocoanut, he performed laparotomy, and then stitched the peritoneum at the edge of the incision to the peritoneum covering the abscess, which was then opened and a drainage tube introduced. The patient recovered.

Dr. Joseph T. Johnston, of Washington, suggested that in such cases as the one described by the author, in which time is a matter of importance, much can be gained by adopting the procedure employed by Drs. Bantock and Tait. In washing out the abdominal cavity they pour the water into the cavity with a pitcher, using gallons at a time. In this way the cleansing is rapidly accomplished.

Wednesday, September 22d.—Second Day.

Morning Session.

Dr. John Goodman, of Louisville, Ky., read a paper on

ERGOT AFTER LABOR.

The administration of a full dose of ergot immediately after the completion of labor has become a general practice. It is claimed that it promotes involution, prevents after-pains, and tends to prevent post-partum hemorrhage. Some years ago, the author administered a full dose of ergot after a perfectly normal labor. In fifteen minutes, severe pain appeared and increased. The tenderness in the uterus continued for a week.

There was no milk, and the patient, previously prolific, never again conceived. The trouble was attributed to inflammation of the muscular coat of the uterus, produced by the action of the ergot.

In a second case, treated in May, 1886, ergot was given after a forceps delivery. On the seventh day the patient had a chill, followed by a temperature of 104°. The next day a clot was washed out of the uterus, and the temperature fell to 99°. Well-marked septicæmia developed, and the patient died one week later. In this case the retention of the clot was attributed to the spasmodic contraction of the uterus preventing its escape. The author had seen other cases in which injurious effects were produced by the administration of ergot.

He claimed that ergot did not assist involution, which is a natural process, and requires a certain length of time for its completion. That we have in ergot a remedy capable of arresting after-pains, cannot be doubted, but it does so by exciting a mode of muscular action at variance with all physiological laws. After-pains are conservative, and it is better to wait until they become of abnormal severity before resorting to treatment. Ergot is capable of preventing hemorrhage, but its use is attended with such dangers that it should be employed only under exceptional circumstances. It should be an inviolable rule not to give ergot at the close of the third stage of labor, unless hemorrhage is imminent. It should then be used by hypodermatic injection.

Dr. Reamy had in process of preparation a paper in which he enters his protest against the routine practice of the administration of ergot after the third stage of labor. This conclusion is based upon his experience, and upon a study of the action which is claimed for the drug. The contractions produced by ergot are unlike those of nature. The contraction of ergot is persistent, while the normal contraction is intermittent. If the contraction is persistent, the circulation of the uterine wall cannot reach a healthy state, and thus the process not only retains what is in the uterine cavity, but it interferes with the process of involution, and lays the foundation for sepsis and inflammation. He thinks that in the course of the next five or ten years, the practice of obstetricians in this matter will be revolutionized.

Dr. William Goodell said that the author of the paper stated that it is only since last May that he has given up the use of ergot. He thinks that he has not had sufficient time to form such positive opinions. In the first case, he thinks that there must have been a fibroid tumor. The second case was a clear instance of septicæmia. He does not think that after-pains are conservative. As a rule, we do not see them in the primipara. These pains are, in great measure, the result of weaknesses induced by civilization. He does not believe that every woman who has given birth to a child needs ergot, but we do not know the cases which do require it. In twenty-five hundred cases of labor he has always given ergot after the completion of labor and he has never seen any harm from its use. He does not believe that one dose of ergot has much effect in favoring involution. Involution is the result of fatty degeneration, and the greater the contraction the greater the interference with circulation and the more rapidly should this change take place. He has used ergot for two purposes, one was to prevent hemorrhage and the other to prevent the absorption of septic matter. Since the introduction of antiseptics, which he thinks should be used in every case of labor whether public or private, the use of ergot to prevent septic infection is not so important. He thinks that it does not do the harm which has been mentioned.

Dr. George J. Englemann, of St. Louis, held in the main the views which the President had expressed. He used ergot much less than he did a few years ago. He believed that we have equally effective measures in the hot antiseptic douche and in the faradic current. After the contents of the uterus have been expelled ergot will in certain cases always be a useful and effective remedy. He would not venture to say that after labor ergot is out of place, but he thinks that he might say that before the contents of the uterus are expelled it should not be used at all.

Dr. Theophilus Parvin, of Philadelphia, believed that the effect of ergot varies with the dose. A small dose acts simply to increase the normal uterine contractions. He objected to the assertion that ergot should never be given before the completion of labor. Statistics show that those who are most successful in the treatment of placenta prævia are the men who use ergot. Again, in a multipara with the os dilated, where a sudden rupture of the membranes has taken place, with a cessation of labor, fifteen or twenty grains of ergot cause a rapid completion of the labor. After a protracted labor there is a weariness of the uterus and a failure to enter upon the normal retraction which is a preventive of hemorrhage and tends to promote involution, As long as in the third stage of labor we assist nature in the expulsion of the placenta, why should we not assist nature in securing normal retraction of the uterus after the completion of the third stage? In some experiments which he made at the Philadelphia Hospital, to determine the rapidity of involution of the uterus in women who had received ergot and in those who had not, it was found that in those who received ergot after delivery, uterine involution seemed to take place more rapidly.

Dr. Skene, of Brooklyn, had never seen such effects from ergot as have been described in the paper. He did not think that in the cases reported the ergot had anything to do with the production of the effects. All rational men use ergot as any other remedy, when it is necessary or may possibly become necessary; if there is any doubt whether or not it is needed, it is better to give the patient the benefit of the doubt.

Dr. P. C. Williams, of Baltimore, believed that ergot has its place in obstetrical medicine. He had never yet regretted its use in any case, but had regretted not using it. The great danger under the use of anæsthetics is hemorrhage. To avoid this the use of ergot seems to be the proper thing. He admitted that ergot is abused, but the abuse of ergot is no argument against its proper use.

Dr. Reamy, in concluding, said that the profession is not taught that ergot should be given in diseased conditions, but that it shall be given in all cases after labor as a routine practice, and it is only against this use of it that he raised his voice.

Dr. Reamy then delivered

THE PRESIDENT'S ADDRESS,

(See page 365.)

DR. FORDYCE BARKER, of New York, read a paper on

THE INFLUENCE OF MENTAL IMPRESSIONS ON THE FŒTUS.

The belief that maternal impressions may affect the nutrition and development of the fœtus *in utero* has existed from the earliest periods of which there are any records. Medical writers, with hardly an exception down to the beginning of the eighteenth century, express the belief, with more or less distinctness, that fœtal marks and deformities are due to the emotions, desires, or shocks of the pregnant mother. Reference was then made to numerous papers written within the past twenty years, in which this theory was strongly controverted. Those who disbelieve in this doctrine, base their scepticism on what they regard as physiological reasoning, and chiefly on the assertion that there is no direct nerve connection between the maternal and fœtal systems. Deformities, they urge, are due to arrest of development. But no one has brought forward sound physiological reasons why this arrest of development may not have been caused by mental impressions affecting the fœtal nutrition by their influence on the maternal blood. Extremely rare as is the occurrence of cases which prove the result of this influence, he considered the fact to be so well proved by sufficient authentic evidence as to make it as certain as any other fact which cannot be explained by science. The term "mental impressions" should include those which have a physical as well as a psychical origin.

Five cases coming under the author's observation were described.

Case I. was that of a young lady who, at the age of eighteen, had for the first time been taken to the theatre, and had seen Sothern, the actor, in the part of *Lord Dundreary*. From this time she spent her whole time in writing to Lord Dundreary, and thought and talked of nothing else. This continued several months, but under treatment and change of scene, gradually wore away. She subsequently married, and four years after her attack of insanity, her first child—a boy—was born. As the child became able to talk, he exhibited peculiarities resembling those of Lord Dundreary. He walked with a little skip, had a slight stammer in his speech, and his left brow was drawn down with the lids practically closed.

Case II. was that of a lady, a typical brunette, who was first married to a gentleman, a typical blonde. She was never pregnant by him. Subsequent to his death she married a gentleman as marked a brunette as herself. Her first child was a decided blonde. Both her own and her husband's relatives are all brunettes. The lady has since had three children—all brunettes.

Case III. was that of a lady who, during the first month of pregnancy, had been much worried over her oldest daughter, who had had her ears bored for rings. The ears became inflamed and caused much trouble. When the child was born, both ears presented the appearance of having been pierced for rings, and through at least one of the lobes a thread could be passed.

Case IV. was that of a lady who, at a very early period of pregnancy was much impressed by seeing three ladies, all of whom had harelips. When her child was born it had a double harelip.

Case V.—Mrs. X., married but a few weeks, was at the theatre with her husband. Something vexing him, he placed the point of his elbow on her hand and held it so firmly that she could not draw it away. Not wishing to make a scene, she bore it until she fainted. The fingers were much swollen and painful for several days. She never lived with her husband afterward. Thirty-five weeks and three days after the theatre incident, she gave birth to a son. On the left hand, the first and second phalanges of all the fingers and thumb were absent, looking as if they had been amputated.

Other reported cases were then referred to.

DR. GOODELL, of Philadelphia, related one case which seemed to bear out the theory. A physician was called upon to assist at the operation of circumcision. His wife, who was in the early months of pregnancy, was much interested in the operation and insisted upon having all the details. The operation occupied much of her thoughts. When her child was born, a boy, it was found that the glans was exposed, the prepuce well retracted with granulating edges, showing an appearance very similar to that of recent circumcision. He had recently seen an almost identical condition in a child, which could not be accounted for by any impression on the mind of the mother.

DR. SAMUEL C. BUSEY, of Washington, believed that there is some relation between mental impressions and fœtal deformities. Any prevalent and concurrent belief must be based upon an element of truth. This belief has prevailed since the time of Jacob. At the present time it is a fixed belief in the female mind. In the physical world there is no effect without a cause, and in the world of life the rule is the same. If we can demonstrate in any single instance a connection between the deformity and the mental impression, we must concede that such a thing can again occur. If there are any number of cases where we can show a precise correspondence between the impression and the deformity, the relation must be accepted as presumptively proven. Dr. Barker has cited some instances, and Dr. Goodell has given another case. In another case the mother, while pregnant, saw a man with an opening in his trachea from which a tracheotomy tube had been removed. The child, when born, exhibited a depression in the same position. Another case is reported where the mother received two distinct impressions, and the child was born with two distinct deformities corresponding to the separate impressions received. In another case the father had removed, in the presence of his mother, a metacarpal bone of one of the fingers. When the child was born it exhibited a corresponding deformity. A consideration of these cases can bring us to but one conclusion. The earlier in pregnancy the impression occurs the more frequently does the deformity follow and the greater is the correspondence between cause and effect.

The discussion was then postponed until the afternoon session.

AFTERNOON SESSION.

DR. JOHN S. BILLINGS, of Washington, said that there were many cases on record which cannot be explained by any knowledge which we now have. As to the influence of previous pregnancies on the characteristics of subsequent pregnancies, we have no scientific information. If we could obtain the statistics showing the char-

acters of children born of different fathers we should have some scientific data on which to form an opinion.

Dr. Barker remarked that in all the cases he had reported there was no evidence that the period since conception had been more than six weeks. He had rejected all cases in which conception occurred three or four months before the mental impression was produced.

Dr. John Byrne, of Brooklyn, presented a paper on

THE TREATMENT OF PROCIDENTIA UTERI BY GALVANOCAUTERY.

In regard to the relation of laceration of the perineum to prolapse of the uterus, the speaker held that laceration of the perineum, by interfering with the process of involution, may be a remote cause, but that laceration and prolapse can be associated in any other sense, cannot be admitted. Operations on the perineum can only influence the prolapse by offering an obstacle to vulvar protrusion. Only when a portion of, or the entire cervix is removed, can we look for permanent and satisfactory results after operation on the perineum.

In February, 1872, Mrs. H., the mother of four children, presented herself with the entire womb and vesico-vaginal wall protruding. She was thirty-five years of age. The cervix was ulcerated from the friction. She was treated by applications of glycerole of tannin and irrigation, for two months. The ulceration was healed, but no impression was made on the prolapse, or on the size of the uterus, which measured four and one-half inches. The cervix was then removed with the galvanocautery loop. The patient recovered without a symptom. Five weeks later there was no bulging of the vesico-vaginal septum, and the uterus could just be reached with the finger. No reasonable amount of force, by means of a volsella forceps, could draw it down. The patient was discharged cured, and has continued well.

The whole number of cases treated with the galvanocautery has been nine, but in only three has the cervix been removed. In six of the cases, linear cauterizations were required.

Case II. was a patient with procidentia, who had been treated with pessaries for a long time. The cervix appeared to be healthy. A double tenaculum was introduced into the cervical canal, and the whole mass pushed into the pelvic cavity, and lifted, to show the line of vaginal insertion. A groove sufficiently deep to admit the loop was then cut around the cervix, close to the vaginal vault. The hot loop was then adjusted, and the cervix cut through to the depth of one-fourth of an inch. The wire was then removed, and tampons of glycerole of tannin inserted. Two weeks after operation, the uterus resisted all reasonable efforts to depress it. Two years after operation no perceptible change was observed. The health had never been better, and menstruation was regular.

In *Case III.* the parts were returned, and the line of vaginal insertion marked in spots with the cautery knife. The entire mass was then drawn down, and a deep fissure, three-eighths of an inch in depth made around the circumference of the cervix. Then three incisions were made in the vagina, one central, and the others diverging, and the whole mass was then returned. The recovery was complete. In none of the cases has there been peritonitis of any severity.

The speaker highly recommended further trial of the galvanocautery in these cases.

Dr. George J. Englemann, of St. Louis, then spoke on

ELECTRICITY IN GYNECOLOGICAL PRACTICE.

After referring to the confusion which had surrounded this subject, he referred to the following points which should govern the use of electricity as a therapeutic agent: The formation of strict indications for the use of the galvanic and faradic currents; a differentiation between the varying forms and modifications of the galvanic and faradic currents; differentiation between the active and indifferent pole; the localization and concentration of the current; the precision of the dose; the use of stronger currents continued for a short time. He has used the galvanic or faradic current in the reduction of the size of neoplasms, fibrous polypi, cystic growths, and urethral caruncles; also, in chronic pelvic inflammation, and in chronic ovarian inflammation, in stenosis of the os, for the relief of the engorgement accompanying subinvolution, in prolapse when due to relaxation of the tissues. It is an aid in the correction of various forms of displacement; in metrorrhagia, when due to inflammation and relaxation; in certain forms of amenorrhœa, and for the relief of many annoying reflex symptoms. In obstetrics, it is useful in uterine inertia during or after labor; in cases of weak and irregular labor pains; in post-partum hemorrhage; in delayed involution; in paralysis of the urethra or bladder after labor, and in the interruption of extrauterine pregnancy.

The only contraindication to the use of electricity is the presence of severe acute inflammation. It may be used in subacute inflammation. In the more acute pelvic inflammations, care is required in its use.

A number of cases were then referred to, showing the beneficial effect of electricity in diminishing the size of fibroid tumors and in other conditions.

Evening Session

was devoted to

THE BUSINESS MEETING.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. A. J. C. Skene, of Brooklyn.

Vice-Presidents.—Dr. John C. Reeve, of Dayton, O., and Dr. Elwood Wilson, of Philadelphia.

Secretary.—Dr. Joseph Tabor Johnston, of Washington.

Treasurer.—Dr. Matthew D. Mann, of Buffalo.

Additional Members of Council.—Drs. W. H. Baker, of Boston; C. C. Lee, of New York; T. M. Drysdale, of Philadelphia; and A. Reeves Jackson, of Chicago.

The following were elected

NEW MEMBERS:

Drs. Charles M. Green, of Boston; A. F. A. King, of Washington; E. C. Dudley, of Chicago; A. W. Johnstone, of Danville, Ky.; J. E. Janvrin, of New York; H. Marion Sims, of New York; B. F. Baer, of Philadelphia; and W. Gil Wylie, of New York.

PLACE OF NEXT MEETING.

It was decided to hold the next meeting in New York, beginning September 15, 1887.

A communication was presented with reference to the organization of

A CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Dr. John C. Reeve, of Dayton, Ohio, offered the following:

Resolved, That this Society expresses an opinion favorable to the formation of the proposed Congress, but that the committee be instructed not to favor any plan looking toward a surrender of its distinctive title and character, or to interfere with the full and entire management of its own affairs in every respect.

The following amendments were offered and accepted:

1. That this Society does not favor meetings of the Congress oftener than biennially.

2. That the committee opposes, as far as possible, meetings in the month of June.

The resolution as amended was adopted.

The committee consists of Drs. Samuel C. Busey, of Washington; Fordyce Barker, of New York; T. A. Emmet, of New York; J. R. Chadwick, of Boston; and Joseph Tabor Johnston, of Washington.

NEWS ITEMS.

Meeting of the Committees of Conference of the various Special Associations requested to Participate in a Conjoint Session.—In response to the notice issued by the Secretary of the Committee of Conference of the American Surgical Association, the Committees of Conference met at the Army Medical Museum, Washington, D. C., at 12 o'clock noon, on Friday, September 24, 1886.

The meeting was organized by the election of Dr. S. C. Busey, of Washington, Chairman, and Dr. J. Ewing Mears, of Philadelphia, Secretary.

The Secretary reported that he had received notification of the appointment of committees by the following societies: American Ophthalmological Association, American Otological Association, American Gynecological Association, American Laryngological Association, American Dermatological Association, American Surgical Association, American Neurological Association, American Climatological Association, Association of American Physicians and Pathologists.

The following members of the Committees were present:

Ophthalmological Association: O. F. Wadsworth, M.D.; Samuel Theobald, M.D.; Wm. Thomson, M.D.

Otological Association: C. R. Agnew, M.D.; W. H. Carmalt, M.D.

Gynecological Association: S. C. Busey, M.D.; J. R. Chadwick, M.D.; J. Tabor Johnston, M.D.

Laryngological Association: J. F. Knight, M.D.; E. L. Shurley, M.D.

Dermatological Association: H. G. Piffard, M.D.; G. H. Tilden, M.D.

Surgical Association: C. H. Mastin, M.D.; J. Ford Thompson, M.D.; J. Ewing Mears, M.D.

Neurological Association: L. C. Gray, M.D.; J. Van Bibber, M.D.; J. Hendrie Lloyd.

Climatological Association: F. Donaldson, M.D.; W. W. Johnston, M.D.

Association of American Physicians: Wm. Pepper, M.D.

On motion, it was resolved that the Associations represented should vote by title, taken in chronological order, and as a unit.

Dr. Wm. Pepper offered the following resolutions, which, after careful consideration and discussion by those present, were adopted separately, and then as a whole:

1. That it is desirable that the American Surgical Association, the American Ophthalmological Association, the American Otological Association, the American Neurological Association, the American Laryngological Association, the American Gynecological Association, the American Dermatological Association, the American Climatological Association, and the Association of American Physicians and Pathologists, shall arrange for a conjoint meeting in the City of Washington, in the month of September, 1888, and subsequently at intervals of three years, at the same time and place.

2. That this arrangement shall not interfere in any way with the autonomy of each special Society; and that each Society shall retain the right to withdraw at any time from this conjoint scheme.

3. That the special feature of the meeting shall be the conjoint assemblage of the special Societies on two evenings during the session; on one of which there shall be an address delivered by the President of the conjoint meeting, and on the other there shall be communications by a referee and a co-referee on some subject of general professional interest.

4. That each special Society approving of this report is invited to appoint one representative (with an alternate), and that the representative so appointed shall constitute an executive committee to serve for one year, with power to elect such officers for the first conjoint meeting as may be deemed necessary; to prepare a programme for said meeting; to make all other necessary arrangements; and to prepare and submit a plan of organization for future meetings.

5. That all expenses connected with the conjoint sessions shall be apportioned equally by the executive committee among the special Societies participating.

Owing to the views entertained by the Committees of the Ophthalmological and Dermatological Associations, with regard to the intervals of time between the meetings, they abstained from voting upon the first resolution.

The Tenth Census.—The report of F. H. Wines, special agent of the tenth census, on the defective, dependent, and delinquent classes, is full of interesting details The number of males confined in prisons and workhouses in the United States in 1880 was 53,604, and of females, 5005. The number of prisoners to each million of the population was 1069; in 1870 it was but 853. There were 1833 insane persons, 1533 idiots, and 976 blind persons to each million inhabitants. There were 21,595 out-door paupers, and 66,203 inmates of almshouses, during the census year.

The Paris Academy of Medicine is reported to have announced the following remarkable subject for a prize essay: "Préciser par une série d'observations s'il existe un traitément abortif de la syphilis confirmée." To abort a confirmed syphilis appears to be as encouraging a task as the proverbial locking of the stable door after the steed is stolen.—*Boston Medical and Surgical Journal.*

Lead in Tinned Provisions.—Dr. Rabchevski, of St. Petersburg, has published the results of a series of investigations made on various kinds of tinned provisions, with the view of determining the suitability of food preserved in this way for the purposes of the army commissariat, especially when on active service. He first examined the tinned plates in the preserved provision manufactories, and found them in all cases quite free from lead. The case of the solder was, of course, different, the amount of lead contained in it varying from 60 to 70 per cent. The chemical examination of the contents of the tins was conducted by Pouchet's method, and showed that while some classes of food, such as roast meat, were quite free from lead, others, such as sour cabbage, which, to a Russian, is a very important article of diet, contained very appreciable quantities of lead, in one case as much as 0.327 per cent.; so that a man taking 200 grammes, or about a quarter of a pound, of this for his dinner would introduce into his system 0.654 gramme, or about eight grains, of lead—a quantity which, especially if taken frequently, can by no means be considered as harmless. The conclusion arrived at by the author is that these tinned provisions should only be used in the army in case of urgent need, and for a very short time. It would appear, too, that a choice might be made, only such classes of preserved food being accepted by the authorities as were shown to be least likely to become contaminated by the injurious substance contained in the solder.

The Bicycle and Prostatic Disease.—The *California Practitioner* says that horsemen, after the age of forty, begin to exhibit evidences of disease of the prostate gland. This being true, it is evident that the rider of the bicycle is much more likely to acquire such disease The genito-urinary specialist will rejoice in the prospective harvest afforded by the increasing use of the bicycle.

Farewell Dinner to Dr. R. T. Edes.—A farewell dinner was given to Dr. R. T. Edes, at Young's Hotel, Boston, Friday evening, September 17th, prior to his departure for Washington, where he intends to make his home and practise his profession.

About thirty of Dr. Edes's medical colleagues sat down at the table with him, the staff of the City Hospital, the Harvard Medical School, and the Dorchester Medical Club being especially represented. Dr. Francis Minot presided, and addressed the guest of the evening on behalf of the Harvard Medical School.

New York State Board of Health.—In the matter of food and drugs work has been vigorously pushed, and excellent monthly reports made, by the three chemists employed. The cream of tartar of the State has been thoroughly overhauled, and found to be, with few exceptions, adulterated. In two instances, at Brockport and Albany, a poisonous adulterant, oxalic acid, has been found. The entire stock in each case has been taken, its sale stopped, and efforts are being made to reach the manufacturers.—*Sanitary Era.*

New Lenses for Microscopical Work.—Professor Abbé, of Jena, has made an invention in microscopic lenses, which, if correctly reported, will work a new era in microscopical work. After five years' experimenting (rendered possible by a subsidy of $15,000 from the German government) Professor Abbé perfected a new combination, which, it is claimed, more perfectly corrects both spherical and chromatic aberration than any previous one. Some of the lenses composing the objective are of silicious glass, the remainder being compounds in which borax and phosphorus are leading constituents. These compounds were worked out by Dr. Scott in conjunction with Abbé, and the objectives have been made by Zeiss. Dr. Van Heurck describes them as follows in the *Journal de Micrographie:* The objective is homogeneous immersion, of a focal distance of three millimetres, or about one-eighth English measurement. It is not arranged for cover-glass correction, as this is not necessary, that function being obtained by means of the sliding tube of the body. It contains five lenses, and has a numerical aperture of 1.4, which is a trifle less than has been obtained in England and America (1.5); but so far as its optical qualities are concerned it is far superior to anything ever before made, the new glass permitting the absolute correction of all aberrations. The field is perfectly flat, the minutest object in the extreme edge of the field showing as sharply and clearly as though it were in the centre. With the vertical illuminator an amphipleura (silvered) is resolved into pearls—not merely in spots, but over the entire frustule, and with such clearness that these pearls can be counted. In the study of other diatoms I have found details which have hitherto escaped notice. As to the bacteria, details of structure are shown that have never before been seen—details that will without doubt serve to differentiate them by ocular means. Accompanying the objective are three eye-pieces, two for direct use, and one for photography. They are also made of the new glass and by entirely new optical formulæ.

Life Insurance.—A recent interesting case in the English Court of Appeal brings up some new points. It appeared that a person applied to a company for insurance, and answered in his application a large number of questions as to his habits, health, etc. In addition to this, as is the usual custom, he was examined by a physician, and upon his report the risk was accepted by the company, but only on the terms that there should be no insurance until the premium was paid. The gentleman was prepared to pay the premium whenever the papers were ready, but before they were ready a change had come in his health, making the risk a poor one, and the company refused to issue the policy. The premium was tendered, but refused by the company, and a suit was brought to compel the issuing of the policy. The court declined to take this action, and held that there was no binding contract until the premium was paid. If it had been tendered at the time of the acceptance of the application, instead of waiting for the preparation of the policy, the company would have been obliged to issue the policy.

A District Nurse Society has been formed in Philadelphia for the care of the sick poor in the Third District (Fifth, Seventh, and Eighth Wards) who cannot be sent to the hospital. A trained nurse is provided by

the Society to visit those who are ill and give them such care as is needed. The office is at No. 1030 Race Street.

The Society will also furnish bed linen and other comforts for the sick. For these services a charge of five cents a day is made, except in case of extreme poverty. The members of the medical profession are requested to send notice to the Society of those who require a nurse's aid, and with this notice there should be directions for the nurse in case any special treatment is required.

Testing House-drains.—At a conference in connection with the Building Exhibition held in London under the auspices of the Society of Architects, Mr. R. K. Burton described methods used by himself in testing the soundness and arrangement of house-drains. Three questions, he said, were to be decided: (1) Is the drain water- and gas-tight? (2) Is it self-cleansing? (3) Is it disconnected from the sewer? The first point is best decided by a test; but it is well to observe the appearance of the joints before taking the trouble to apply any test, as such may at once reveal the fact that the drain is leaking. In more cases than those who have not made many inspections would imagine, it will be found that there is absolutely nothing in the joints of a tile-drain. In others it will be found that there is clay only, and he had never known a clay-jointed drain to be water-tight. In still other cases it may appear, from looking at the tops of joints, that they are carefully made with cement; but when a rod of iron or a chisel is plunged into the earth underneath them, it comes up wet and black with sewage. It is only when none of the appearances described are to be seen that it is worth while applying a test. The best undoubtedly is the water-test. In this the drain is opened by the removal of a pipe, and is plugged.

It will be found impossible to fill more than perhaps about one out of three drains, except in houses which have been very recently remodelled, and that it is necessary to avoid pouring too much water into a leaky drain. If the drain does fill up the running water is stopped, and it is observed whether the water in the gullies or surface-traps remains at a constant level. The test next in efficiency to that by water is the smoke-test. The next question is as to whether the drains are self-cleansing or not. As in the case of the water test, an opening must be made; but it is not needful to remove a whole pipe. It is sufficient to chip a round hole in the top of one. If no deposit appears just under the opening, water is allowed to run into the drain at the upper end, and the flow is observed at the opening. If the water runs briskly and clear past the opening all is right. If, however, it comes tardily, and carrying deposit with it, it is a question of ascertaining the cause. A drain, if well laid, should, with a fall of one in sixty, clear itself. A house-drain should seldom or never be larger than six inches; four inches is large enough for very small houses, and if five inches were the size generally made, it would probably be better than either four inches or six inches for the majority of houses. Now as to whether the drain is disconnected from the sewer or not. To make absolutely sure whether or not there is a concealed trap on the drain, if the opening does not reveal this, the only plan is to pass rods down the drain. One may, however, have evidence approaching to certainty by burning a match in the drain, and observing whether or not there is any current of air through it. If there is, it may be assumed that there is no trap on the drain. It is necessary to test each branch for self-cleansing properties. The material for soil-pipes should be ascertained by removing the wooden casings which generally cover them. If an internal soil-pipe is made up of light cast-iron pipes (rain-water pipes), and lead junction-pieces for the closets, it may be condemned without any further investigation. The best test for a whole-drainage system is undoubtedly the smoke-test. This test consists essentially in filling the drainage system with smoke at some pressure, and observing whether or not it issues at any place other than the openings intended for ventilation.

Smoke-rockets are now largely used by those who have to make inspection of sanitary arrangements. These consist of paper cases filled with a composition which gives off a vast quantity of smoke at a considerable pressure. The smoke-test can never be taken—when it gives negative results—as an absolute test for drains. The peppermint-test is inferior to the smoke-test when the latter is properly applied, in the speaker's opinion. The next thing of most importance to do is to trace the overflow-pipes of the cistern to see whether these are connected with the drain or not. A connection of any kind between a cistern and the drain is a thing to be condemned. The baths, sinks, basins, etc., come next under examination. The discharge-pipe—and overflow, if there be one—of each of these must be traced to discover whether or not it is connected with the drain. The closets must be very carefully examined, although they are not nearly so often the points of ingress of sewer-gas to the house as in any other appliances, such as sinks. They are often, however—especially when of the old pan form—themselves generators of foul gases, and as such objectionable.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM SEPTEMBER 21 TO SEPTEMBER 27, 1886.

Fisher, W. W. A., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, to take effect September 10, with permission to apply for one month's extension.—*F. O. 88, Department of Arizona*, September 1, 1886.

Gandy, Charles M., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Concho, Texas.—*S. O. 131, Department of Texas*, September 18, 1886.

Bache, Dallas, *Major and Surgeon.*—Granted leave of absence for twenty-five days, to take effect on or about October 2, 1886.—*S. O. 143, Division of the Atlantic*, September 24, 1886.

Appel, Daniel M., *Captain and Assistant Surgeon.*—Assigned to duty at Fort Davis, Texas.—*S. O. 133, Department of Texas*, September 22, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING SEPTEMBER 25, 1886.

Bailhache, P. H., *Surgeon.*—Granted leave of absence for thirty days, September 25, 1886.

Vansant, John, *Surgeon.*—Granted leave of absence for thirty days, September 24, 1886.

Bratton, W. D., *Assistant Surgeon.*—Relieved from duty on Revenue Steamer "Corwin," and ordered to duty at Marine Hospital, San Francisco, California, September 20, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIX. SATURDAY, OCTOBER 9, 1886. No. 15.

ORIGINAL ARTICLES.

THE SUBIODIDE OF BISMUTH IN THE TREATMENT OF ULCERATIONS.

BY A. SIDNEY REYNOLDS, M.D.,
OF PHILADELPHIA.

IN 1876, while resident physician in the Presbyterian Hospital of Philadelphia, I devoted considerable time and attention to the study and treatment of wounds and ulcerations, and to experiments directed to the modification of the tegumental tissues in repair, to obtain, if possible, more rapid and more normal cutification or cicatrization than was common.

Having been granted unusual facilities to pursue these studies during my service, I was enabled to have constantly under my care and observation a great variety of chronic ulcerations.

Skin grafting was then fashionable, iodoform was the popular dry dressing, and subnitrate of bismuth was in common use.

Among a number of new preparations sent to the Hospital for trial, with no claims for therapeutic value, was the "subiodide of bismuth," made by R. A. Fairthorn, an experimental chemist of Philadelphia at that time.

The chemical affinities of the new salt with the subnitrate and iodoform suggested its use for its supposed alterative and sedative properties. It was at once seen that it not only met my expectations, but that its action in some unexplained way was simply marvellous. Ulcers which had previously defied all treatment, seemed to yield at once to its influence.

In the face of my evident successes, it was said that either my cases were "easy ones," or that the coincident treatment and favorable surroundings were the secret of success.

As a test case, an inmate of the Philadelphia Hospital who had an ulcer that had resisted all treatment for over ten years, and who had finally been pronounced incurable, was, by permission, transferred to the Presbyterian Hospital for treatment. His was the worst case of atrophic ulcer I have ever seen; the leg was little but skin and bone, and looked as if a few hours might make it an elegant dry specimen for the museum. Under the use of the subiodide of bismuth alone, he was returned cured in three weeks.

The subiodide was then introduced into the Philadelphia Hospital, and received the highest praise; but its use was discontinued shortly afterward because it was "too expensive."

The new preparation never became popular; no therapeutic claims were ever made for it so far as I know; it was not generally introduced, and its manufacture was stopped soon after.

Personally I have continued its use for chronic ulcerations during the past ten years, and of late have discovered such additional properties as will make it a valuable addition to the materia medica, and the armamentarium of the surgeon. It will control inflammation, allay irritation, suppress suppuration, promote granulation, and induce cicatrization. It has been found to be almost a specific in gonorrhœa, in various septic and specific mucous inflammations, oral and nasal catarrhs, ophthalmias, etc., in chancroids, rectal ulcers, etc., and in the various cachectic and dyscrasic ulcerations.

Internally it is strongly recommended in gastric ulcer, gastritis, and in typhoid fever.

Its therapeutic and physical properties may be summarized as follows:

a. It subdues the inflammatory process.

b. It substitutes the inflammatory regeneration of tissue with a neoplastic force, which closely simulates normal embryonic histogenesis.

c. It is, by its action, *a vital aseptic*.

d. It prevents the formation of pus.

e. It lessens direct and reflex irritability.

f. It is so bland and unirritating that it can be used on any surface.

The subiodide of bismuth, by virtue of these properties, is almost a specific for ulceration.

There are certain kinds and conditions of acute and chronic ulceration which may require special treatment, preliminary to or coincident with the use of the subiodide of bismuth.

The asthenic or œdematous ulcer; the congested, the inflamed, the irritable, and the readily bleeding ulcer; the ulcer with exuberant or fungous granulations; the cachectic, the varicose, the phagedenic, and sloughing ulcer: the ulcer with callous edges; the eczematous, syphilitic, scorbutic, scrofulous, lupoid, and cancerous ulcerations: all may require some radical or specific treatment to convert them to a simple form of ulcer, or to remove pathological elements which would retard or impair healthy tissue formation.

Particularly should attention be directed toward restoring a normal condition of the cutis and its accessories. Varices may be compressed or obliterated by other means; œdema, congestion, or inflammation controlled by position and rest; nodules of specific character, as in lupus, rodent ulcer, etc., ablated with caustic potassa; the irritable ulcer allayed with chloral; the errhytic or readily bleeding ulcer blanched with a five per cent. powder of salicylic acid; exuberant granulations resolved with bromide of potassium; the callous edges cut down with salicylic acid or the knife; phagedena and slough controlled with caustics or chlorine; the atonic bases of syphilitic ulcers stimulated with nascent iodide of mercury, etc. These or other

accessories may be required, but in a great majority of cases the subiodide of bismuth alone will prove sufficient.

The action of subiodide of bismuth on an ulcerating surface is presumably as follows: Iodine acts upon granulation tissues, inducing an increase of all normal physiological processes (Schede, *Arch. f. klin. Chir.*, 1882, xv. p. 14); it produces a protoplasmic energy ordinarily obtained only by congestion, hyperæmia, or inflammation, and induces a reversion of the tissues to an embryonic state. It imparts a formative impulse or force to the cellular elements of the three germinal or blastodermic layers and their derivatives, which closely approximates to the laws of normal development. Its specific action as an alterative in certain dyscrasiæ is also a valuable factor. Iodine ranks high as an antiseptic agent, having power to inhibit germ development, being efficient in the proportion (minimum) of 1 to 4000.[1]

The bismuth unites with the albumen, forming an albuminate, which acts as a sedative, aseptic, impermeable coating on the granulations; retarding evaporation of the cellular moisture; modifying the formation of striated connective tissue from the gelatinous intercellular substance, and preventing the retrograde metamorphosis of the white blood-corpuscles. Its oxygen may play some chemico-vital part in the process, possibly in its nascent state as an aseptic.

They simply oxidize the deoxidized pus, rendering it an unfit soil for septic germs, and possibly feed the struggling tissues enough oxygen to promote granulation.

Under the use of the subiodide of bismuth ulcers, which usually heal by cicatrization at the rate of one-half to one line per day, have been seen to dermatize at the rate of three to five lines per day. The cicatrix is fleshy and firm, and is but little disposed to destructive inflammations or subsequent alterations, even over syphilitic sores.

The shape of the ulcer seems to be no obstacle to the process of cutification, circular healing as rapidly as linear or oval ulcers.

The formative force does not seem to diminish as the centre is approached, thus differing from common healing, and indicating that the process is not one especially of stimulation, but a truly regenerative force imparted to the tissue elements. Surfaces denuded by gaping after division of cicatrices will rapidly heal under its use.

Its utility, in my observation, has in no instances been more forcibly shown than in cases of indolent ulcers, where, to save time, I have used it only on the centre of the sore while the edges were undergoing some preparatory treatment; active germination of the peripheral cutis having been observed to commence before the morbid epiderm began to show any improvement. The same phenomenon has been observed with skin grafts.

Subiodide of bismuth then, in ulceration, appears to be, if not a true specific, at least a decided chemico-vital adjunct to tissue repair. By its manifest virtues and properties, and its entire freedom from any objectionable features, it will bear comparison with any therapeutic agent or system.

Subnitrate of bismuth, iodoform, oxide of zinc, burnt alum, clay, "mineral earth," etc., have been lauded as perfect dry dressings. Each has its virtues, and each its faults.

Subnitrate of bismuth, from liberation of nitrous acid or from contamination with arsenic, is to some degree aseptic, but it is not free from danger by absorption, having been known to cause enteritis, nephritis, and gangrenous stomatitis.

Iodoform also is credited with numerous toxic sequences from absorption, and is objectionable on account of its odor.

In the subiodide of bismuth, we have a perfect dry dressing; it is bland, unirritating, and, if absorbed at all, has never yet proved injurious; it supports life, promotes nutrition, and maintains the integrity of the tissues—hence it is a *vital aseptic*. It is probably an "inhibitory antiseptic,"[1] being potent in holding in check the development of pathogenic germs by sterilization of the tissues and their discharges. It gives physiological rest by restoring the functional relations of cell life, and it makes the work of repair a passive process.

In the following description of its use I have followed the treatment of a bad case. In many cases I have known a single application entirely to heal ulcers that had long resisted treatment by other means.

My usual proceeding in a case of chronic leg ulcer is as follows: I first thoroughly wash and cleanse the face of the ulcer, removing all slough, shreds of tissue, foreign matter, etc. I then disinfect it well, generally with solution of acetate of aluminium, *q. v.*, and then dry the surface of the ulcer and the surrounding parts. The granulations are then dusted with, or the ulcer packed with the subiodide of bismuth, alone or in combination, or with whatever powder may be indicated by the exigencies of the case. Calomel, salicylic acid, and bromide of potassium, I have found very useful. I then, while holding the limb vertically to drain it (the patient on his back), firmly strap it with adhesive plaster from below upward. The straps should be about one inch wide, and are applied as a spica, nearly surrounding the leg, and extending an inch or more above and below any œdematous or congested part. A firm bandage is then applied, including the foot, and the patient is allowed to go about as usual. This dressing, according to circumstances, may be allowed to remain from one to four days, and it may or may not need renewal.

When in proper condition—that is, when the ulcer has assumed a healthy aspect—the remainder of the treatment is simply to dust the granulations with the subiodide, protect with a Maltese cross or perforated square of plaster, cover with a thin layer of absorbent cotton, and again apply the bandage firmly.

These dressings should be renewed in from two to five days, when the limb may be gently rubbed to stimulate the circulation, or the patient may be al-

[1] Sternberg, table, American Journal of the Medical Sciences, April, 1883.

[1] Lister, British Medical Journal, October 25, 1884, p. 804.

lowed to stand or walk about for a few minutes without the bandage.

In removing the dressings I use no force to dislodge any of the powder which may have dried on the surface or about the edges; but I generally douche the granulations with diluted alcohol or the solution of acetate of aluminium.[1] In some cases the ulcer is not washed at all from the beginning to the end of treatment, any moisture or discharge being lightly sopped off with absorbent cotton.

If the surrounding skin shows any irritation from the plaster or from pressure, I dust the part with the subiodide and smear the surface with Goulard's cerate.

Strapping and bandaging, as used by me, are simply valuable adjuncts to secure physical rest to the parts; on other parts of the body pressure is seldom required.

In gaping wounds with no loss of tissue, after drying and dusting with the subiodide, I use the extraneous ligature; that is, the parts are approximated and held in position by lacing together the free edges of parallel strips of perforated or porous plaster. The edges of such wounds are generally covered with a strip of lint saturated with the compound tincture of benzoin. It is surprising how often by these means such wounds will heal by first intention.

In recent wounds and acute ulcerations, the dressings should be less frequent than in chronic cases.

Proper diagnosis of the individual characteristics of ulcers and specific therapeutics of special indications, will certainly influence the results; and these must depend upon the judgment of the surgeon.

If the subiodide of bismuth is used properly, the prognosis in every case may be "certain cure in half the time, and with far better results than can be obtained by any other treatment."

The prescription price of the subiodide of bismuth is from twenty to twenty-five cents per drachm, and as it is dusted on or used freely, it will require from a drachm to an ounce to effect a cure in an ordinary case of leg ulcer; so it is comparatively inexpensive.

Subiodide of bismuth has been used in the treatment of gonorrhœa with the greatest success. (Bis. subiod. gr. xx: glycerin et. aq. āā ℥iv, as an injection.) I would suggest that it would do better used dry, if the urethra could be rendered patulous; or it may be used in the form of a soluble bougie.

It has been used successfully in rectal ulcerations (bis. subiod. ℥j, unguent, ℥j), applied with an ointment syringe.

It is highly recommended for internal use (gr. v–x ad. glycerin ℥j, t. i. d. or p. r. n.) in gastric ulcer, intestinal irritations, and in typhoid fever; for gastric ulcers or intestinal irritations it should precede food at least an hour.

Many other local and general uses of the new drug might be suggested: it has properties which deserve therapeutic investigation and application, and which should appeal to the profession for extended use.

I would be pleased to answer any inquiries regarding it, or to hear from any one of its use and results.

[1] Sol. acetate of aluminium: ℞. Alum. sulph., gr. 198; plumbi acet., gr. 446; aq. ℥xvj=sol. aluminii acet., gr. x ad. ℥j—the proper strength for use.

Until recently, the subiodide of bismuth has practically been out of the market. It is at present manufactured by Dr. Charles G. Frowert, Twelfth and Vine Streets. The original preparation was variable in color and not entirely free from some irritating foreign substance in crystalline form.

The subiodide or oxyiodide of bismuth is produced, as an insoluble precipitate, in the reaction between KI and BiO,NO_3 in the presence of HCl. It is a heavy, amorphous, impalpable powder, of a bright red color, odorless and almost tasteless; it is neutral in reaction, and perfectly insoluble in water, alcohol, or ether. Sp. gr. 6.73. It contains, as its formula indicates, BiOI: Bi 208, O 16, I 127 parts in every 351, or an equivalent of nearly one grain of iodine in every three grains of the subiodide.

No. 1217 Vine St., Philadelphia.

ARTHRITIS DEFORMANS.[1]

By JAMES M. FRENCH, A.M., M.D.,
ASSISTANT TO THE CHAIR OF THEORY AND PRACTICE OF MEDICINE, AT THE MEDICAL COLLEGE OF OHIO; MICROSCOPIST AND PATHOLOGIST TO ST. MARY'S HOSPITAL.

Arthritis deformans was not recognized as a distinct disease by the ancients, but was confounded with chronic articular rheumatism and gout. We find, for instance, in the "Satyres and Epistles" of Horace, in the works of Martialus, Celsus, and other writers, references to the disease chiragra (finger gout), which there is every reason to believe was arthritis deformans. Aretæus, in fact, faithfully describes the affection under this title. But any uncertainty that might now remain of its existence at the time of these writings, or even before it, has been removed by the exhumation of bones, bearing the characteristic deformities, in the ruins of Pompeii, in the catacombs of Paris, and in an ancient monastery at Pomerania. Sydenham, in 1766, wrote the first accurate description of the disease, but failed to identify it as an independent malady, considering it a variety of rheumatism. Landre-Bouvais, of France, in 1800, and Heberden and Haygarth, of England, a few years later, described, under the title "nodosities of the joints," the polyarticular variety, distinguishing it from both gout and rheumatism. Brodie, Chomel, Aston-Key, and others mentioned the monarticular form of the disease, but Adams, Colles, and R. W. Smith, of Ireland, were the first to describe it minutely, especially as it occurs in the hip (morbus coxæ senilis). It remained, however, for German investigators (Rokitansky, Förster, Virchow, Volkmann) to study the morbid histology of the affection, and to demonstrate that the lesions attending the two varieties of the affection are identical. We are indebted to Charcot for the best classification of the disease, namely: 1. The polyarticular or general form. 2. The monarticular or partial. 3. Heberden's nodosities.

Symptoms.—Arthritis deformans is an essentially chronic affection, advancing slowly, and continuing indefinitely. Yet the most chronic cases are frequently attended by an occasional acute paroxysm,

[1] Read before the Cincinnati Academy of Medicine, September 6, 1886.

and in a certain, rather small proportion of cases, the onset is sudden and violent. In either instance, the symptoms may closely resemble those of a mild attack of acute articular rheumatism.

The general and partial varieties of the disease have few features in common. The former is usually symmetrical, invades by preference the smaller joints (fingers and toes), and appears coincidently in corresponding joints of the opposite limbs. The monarticular or oligarticular variety is generally confined to one or a few of the larger joints (hip, knee, shoulder, elbow, spine). The former is a disease of early or middle life, much more frequent in the female sex; the latter is observed for the most part in the aged and decrepit of both sexes.

The variety described by Heberden is probably the same disease modified by constitutional peculiarities, natural or acquired. The disease presents most of the features of arthritis deformans, both in its choice of subjects and in the appearance of the affected joints, but is peculiar in that it seldom leaves the articulation first affected, and that it seldom or never develops in any but gouty individuals.

The individual who is about to become the victim of arthritis deformans usually first observes a numbness and stiffness of the joints, most frequently of the metacarpo-phalangeal articulations of the index and middle fingers. These then become slightly swollen, painful, and hot. The pain is often intense, is generally spasmodic and worst at night, is aggravated by pressure and still more so by motion of the affected joint, and becomes almost unbearable during the acute paroxysms of the disease. The attack lasts but a few days, however, and subsides often without treatment, or under home remedies. Several attacks of this character usually occur at intervals of from a week to a month or more, one or several additional articulations becoming at each time involved, and the enlargement and deformity of the previously affected joints becoming with each paroxysm more permanent, until immobility and apparent dislocation result. The disease when situated in the upper extremities advances, as a rule, in a centripetal direction, from the fingers to the shoulders; but in the lower extremities it frequently pursues a reverse course, beginning at the knees. The disease has its remissions, but no regression. With its advance the progressive deformity and immobility of the joints increase, and the individual becomes more and more disabled, his muscles atrophy from disuse, his general strength fails from want of exercise, until he becomes, in the worst cases, utterly helpless—helpless on account of his deformities, however, more than from actual suffering, although it is seldom that pain is long absent from the affected members. Motion of the joint is frequently attended by a creaking or a grating crepitus that is both heard and felt. These are the individuals too, whose bones do barometric service in foretelling changes of the weather. The pain to which I have referred is not always confined to the affected joint, but frequently invades the muscles and nerves of the entire limb, especially when the disease is located in the lower extremities. Last winter I treated a case of arthritis of the shoulder of five months duration, in a woman about fifty, who was confined to her bed and had to rest her arm on a pillow, the limb being so exceedingly sensitive and painful that morphia had to be administered at regular intervals until the more severe symptoms had subsided. Such myalgic and neuralgic pains frequently precede for a variable time the articular inflammation, and sometimes persist for a long time after the disease has apparently subsided. A case that recently came under my observation had suffered for two years from a violent sciatica before the arthritis of the hip was recognized by the characteristic crepitus. A consequent rigidity of the affected muscles is further an important factor in the production of deformity. Notwithstanding the suffering that is often endured by these individuals, the nutritive functions are usually well performed, and in mild cases the general health is maintained.

The deformity which results from arthritis deformans is best studied in the hand. Sydenham said the joints of the fingers appeared to be turned over. Such is usually the appearance of at least the first phalangeal articulation, and this with the moderate flexing of the metacarpo-phalangeal and second phalangeal joints, the epiphyseal enlargement, and the wasting of the interosseous muscles, gives the fingers a peculiar conical, or in some cases a claw-like appearance. Fortunately the thumb often escapes, and when attacked is usually flexed toward the palm. The deformity of other joints need not detain us. The spinal column becomes distorted at a time when compensatory curvature does not take place. The shoulder, hip, knee, and elbow, from long resting in the position which secures for them the greatest immunity from pain, become fixed and render the limb useless and a burden. But probably the most lamentable case is that in which the temporo-maxillary articulation becomes immobile.

Complications seldom arise in the course of this disease, but asthma, pericarditis, endocarditis, pleurisy, hemicrania, such cutaneous diseases as psoriasis and lichen, and various cerebral and spinal affections have been reported in connection with it. They are as a rule, I think, merely coincident, although their occurrence is undoubtedly due, in many cases, to the attendant impoverished state of the system. Pericarditis and endocarditis, when they occur, can usually be traced to a precedent or an intercurrent attack of acute articular rheumatism. The affection has little or no influence on the duration of life, and the patient generally lives to die of cerebral hemorrhage, pneumonia, or other disease incident to old age.

Etiology.—The causes of arthritis deformans are obscure, and such must of necessity be the case until we shall have acquired more definite knowledge of the nature of the disease. To say that it occurs spontaneously or without a definite cause is merely to evade the point at issue, and contrary to all analogy. The polyarticular form of the affection occurs most frequently in females between twenty and thirty years of age. The occurrence of frequent pregnancies or of menstrual disorders and prolonged lactation have been observed as frequent antecedents of the disease, and have, therefore, been considered important

etiological factors. The belief in such relationship is strengthened by Fuller's eleven cases in girls under eighteen, ten of whom had suffered from various menstrual disorders, and probably also by its frequency about the time of the menopause. That these influences are only predisponent, and in no way essential, is abundantly demonstrated by the occurrence of the disease in males and in females not the subjects of disease.

Gout was once supposed to be closely related to the disease, but at present there are none who hold that it bears more than an indirect relationship to it. Arthritis occurs in gouty subjects, and has been observed coincident to it; but there is little similarity between the two diseases in their purity. Charcot, Trastour, and others have observed a hereditary transmission of arthritis deformans from gouty parents, but not many such cases are on record.

That acute articular rheumatism bears at least so much as a hereditary influence upon arthritis deformans is held by some. Others maintain that it directly predisposes to it or produces it. The occasionally acute onset of the disease, with its amenability to the same remedy, and its liability to recur, favor this view; but there should be little question of the non-identity of the two affections, for in the nodular arthritis the elevation of temperature and other indications of constitutional disturbance are less marked, and there is an absence of the profuse perspiration, the tendency to rapid migration, and the cardiac complications so characteristic of the acute affection.

That the disease is a variety of chronic articular rheumatism, as was once thought, is no longer tenable. Chronic articular rheumatism is frequently of long duration, and may lead to impairment of motion; but its point of origin and course are usually different from those of the nodular disease, and it is not usually symmetrical. The last distinction is of importance if the observations of Cazalis be true that two-thirds of the cases of chronic rheumatism are unilateral. That the latter predisposes to the nodular disease there is no reason to deny, although the fact has not been established. Gonorrhœal rheumatism has closely preceded the deforming arthritis, and is considered by Ord, Hutchinson, and others, a variety of the latter affection. A great difficulty in the way of all these views is the fact that many other diseases have preceded the affection with almost or quite the same frequency as have rheumatic diseases. Tuberculosis and its neighbor, scrofula, bear probably a much less important relation to the affection, although Cornil, Charcot, and Fuller regard them as frequent antecedents with somewhat of a causative relation. Such other factors as poverty, with its insufficient or improper food and clothing, grief, anxiety, etc., need not detain us. But a prolonged residence in cold, damp, and badly ventilated dwellings, is recognized as one of the most frequent exciting causes of the disease, which does not always appear, however, until long subsequent to such exposure. Direct injury, a blow, a fall, or a fracture, is named as an occasional cause of the polyarticular form of the disease, and is probably the most common exciting cause of the monarticular variety.

A tropho-neurotic origin has been sought, Remak and Benedikt, among others, regarding the affection as a result of irritative states of the spinal cord and the sympathetic. Remak named the disease arthritis myelitico-neurotica. This theory obtains its chief support from the fact that an arthritic affection sometimes accompanies lesions of the nervous system, notably locomotor ataxia, as described by Charcot, and from its usual symmetry. The analogy between arthritis deformans and the bone lesions of locomotor ataxia are hardly apparent. The diseases develop under different circumstances and produce contrary results. The joint lesions of locomotor ataxia commence in the bone, are atrophic, and generally painless, are acute, and produce preternatural mobility rather than fixation of the joint; and, in addition to this, they develop in the presence of the characteristic manifestations of locomotor ataxia. Deforming arthritis, if the result of irritative states of the nervous system, is anomalous in being as a rule the only manifestation of such condition. Still the fact that joint lesions of another character may result from spinal disease, forbids the exclusion of nervous influence from the etiology of this affection, especially in view of the fact that so many nerve lesions leave no recognizable traces after death.

One other possible cause remains to be considered. This is the possibility of the disease having its origin in the action of microörganisms. The question has received only the most transient notice from recent authors, and little or no investigation of it has been made; but the recent discovery by various observers of microörganisms in a number of chronic diseases in which their presence had been persistently denied, renders the subject worthy of consideration. There are certain features of the disease which lend support to the supposition of such a cause. It is a well-known fact that arthritis deformans frequently follows an injury, that it frequently attacks joints that have previously been inflamed, and that in nearly all cases it develops in individuals whose bloodvessel walls are almost of necessity impaired by anæmia, malnutrition, hemorrhage, prolonged lactation, or actual disease—all of these conditions favoring the growth of germs. These facts are sufficient, I think, to indicate the desirability of research in this direction.

On the other hand, there is much to contraindicate the possibility of a mycotic origin in this disease. It is not attended by a cachexia, it does not directly affect the duration of life, it is during a greater part of its course afebrile, and it is not to all appearances contagious or infectious. I do not believe, therefore, that it is admissible, in the present state of our knowledge, to do more than to submit the three following essential factors in the etiology of the disease: First, a hereditary tendency or an impoverished state of the general system; second, a derangement of the local blood supply, probably of a tropho-neurotic origin; and, third, a directly exciting cause, as a trauma.

Pathology.—Arthritis deformans is a chronic inflammation of the articular cartilages of the joints. The process first manifests itself in an irritated state of the articular surfaces of the cartilages, but all the component tissues of the articulation soon become

congested. The synovial membrane becomes thickened and opaque, the fringes enlarged, and the villi elongated and thickened. The increased nutrition soon leads to a proliferation of cartilage cells, new cells having distinct walls forming within the membrane of the original or mother cell. Sacs or pouches of considerable size are thus formed throughout the substance of the cartilage. Owing to the pressure of articular contact, the sacs immediately upon the surface of the cartilage rupture and discharge their contents into the cavity of the joint. By a similar rupture and evacuation of distended cell-membranes beneath, the cartilage soon acquires a ragged or excavated appearance. The matrix substance becomes fibrillated and split into shreds. Fatty degeneration ensues, and causes the removal of the articular portion of the cartilage by absorption. At first there is a slight increase of synovial fluid, but later the joint becomes dry. Before this stage has been reached, however, the underlying bone has taken on a formative inflammation, fortifying itself as it were, by a thickening of its compact layer. After the removal of the articular portion of the cartilage, these compact surfaces of bone are permitted to come in contact, and by their constant attrition, become smoothly polished. Although the process is the same in all parts of the articular cartilage, the result in the peripheral zone is quite different from that just described. Here the distended cell-membranes are prevented from rupturing by the synovial membrane. The few cartilage cells normally found in the synovial fringes also proliferate. In this way new cartilage is formed in which calcareous particles are soon deposited and the process of ossification takes place, and a more or less nodular rim is formed around the articular heads of the bones. In some cases these nodules are attached by small pedicles, which fracture, and thus are formed the movable bodies occasionally found in the joint. In protracted cases the inflammation may extend to the periosteum and to tendons in or around the articulation, and we have in the one case the formation of new bone, in the other, a calcification of the tendons. Sometimes in very aged subjects a rarefying ostitis develops in the denuded ends of the bones and causes a still more extensive destruction. Tendons also which have become calcified are sometimes removed by absorption. The locking of the joints is rarely the result of true ankylosis, but is rather due to the encroachment of the nodosities upon the shaft of the bone or to the interlocking of osteophytes. The muscles that are thrown into disuse undergo fatty degeneration. The result of search for the cause of the disease has been for the most part negative.

Treatment.—The unsatisfactory results obtained from all methods of treating arthritis deformans are almost proverbial. That the disease is in a measure amenable to proper treatment, however, has been abundantly demonstrated. The systematic treatment resolves itself into three classes: first, the prophylactic, or the meeting of causal indications; second, the treatment of the acute stage; and third, the treatment of the intervals of chronicity. The first indication, therefore, is to search for the cause or any influences that may predispose to the disease, and if possible to remove or counteract them. Anæmia, malnutrition, menstrual disorders, and even such affections as are not usually considered related to the disease, but are known to be in any way capable of debilitating the constitution of the patient, should be treated. The use of iron, arsenic, cod-liver oil, and tonics is here indicated. A change of residence from a swampy to a dry locality, or from above a damp cellar to well-ventilated apartments in many cases will be followed by the most gratifying results. In the treatment of the acute attack, the patient should be confined to bed, the affected parts elevated and placed in the most comfortable position attainable. Hot or cold applications may be made if not painful. The salicylate of sodium is the only remedy which has proved of real benefit, and should be given in large doses (at least fifteen grains every three hours), until its full physiological effects are produced, and even then its administration should be carefully continued for a month or more after the attack has subsided. The remedy does not act with the promptness that attends its administration in acute articular rheumatism, but should not therefore be abandoned without a persistent trial. Anodynes, especially opiates, must be used with caution, because of the difficulty with which their use is discontinued.

Iodine is the only remedy which has acquired a reputation in the treatment of the chronic periods of the disease. It may be administered in any of the officinal forms, the tincture, the compound solution, or in combination with potassium or sodium. It should be given with regularity and perseverance. Small doses, two or three drops of the tincture or solution, or five grains of the iodides, thrice daily, well diluted, are to be employed during the first week, when they may be gradually increased to three or four times this amount. The local use of iodine is also recommended, either in the form of the tincture or a salve rubbed into the integument over the affected parts. Hot fomentations, poultices, and warm flannels are frequently useful both for the relief of pain and for the reduction of inflammation, but heat is not always agreeable. Warm baths (100° to 110° F.) are highly recommended. Medicated water and peat baths have also been lauded, but their sole virtue doubtless lies in their temperature. One other measure is of the utmost importance, and should be insisted upon, the more because of the fact that it is so frequently neglected. I refer to the regular, perseverant exercise of the affected joints at all times except during the febrile stages of the disease. Where the joint is very sensitive only the most gradual passive motion can at first be tolerated, but less limited movements will soon be yielded to. The object of this procedure is to stimulate the secretion of the synovial fluid, and thus prevent in a measure, at least, the eburnation and final rarefaction of the joint surfaces. It also aids in the prevention of the pseudo-ankylosis. I have seen marked benefit in a case after two months forced exercise of a joint thus affected without any other treatment. Finally, if there is any one feature of the treatment that is above all others essential, it is perseverance.

SOME RECENT INVESTIGATIONS CONCERNING BACTERIA IN DRINKING WATER.

By THEOBALD SMITH, Ph.B., M.D.,
DEPARTMENT OF AGRICULTURE, WASHINGTON, D. C.

The testing of drinking water as to its germ life, according to the method first suggested by R. Koch, has proved, in many cases, of great value in supplementing the chemical analysis. In fact, many of those prominent in matters pertaining to public hygiene are inclined to place more faith upon the estimation of the number of bacteria in a given quantity of water than upon the determination of chlorides and of those chemical elements, such as ammonia, nitrites and nitrates, which are usually looked upon as the products of bacterial life.

The German Imperial Health Office seems to be well aware that this method needs careful elaboration and abundant statistical material before it can be placed upon a firm basis, and before the interpretation of its results can be considered reliable. There are, moreover, many important collateral questions which must be solved before this point is reached. There are now published in the first volume of the *Arbeiten a. d. Kais. Gesundheitsamt*, three separate articles, extending and applying the gelatine plate method in endeavoring to get at the true signification of microörganisms in water. The first publication (p. 1) furnishes statistics of the chemical and bacteriological constituents of Berlin drinking water.

These tables point out very clearly the efficiency of filtration in removing the great majority of bacteria from the water, and in reducing the quantity of the chemical constituents. They also indicate the great variation which the number of bacteria may undergo in water derived from flowing streams and rivers. Thus the maximum number of bacteria contained in unfiltered water from the river Spree, in the month of March, was 5115, the minimum 936; in October, the maximum and minimum were respectively 8316 and 528.

In my own examinations of Potomac water, in part published elsewhere,[1] the number of bacteria would reach 3000 after heavy rains, and descend within a few weeks to about 300. In every case, the number of bacteria would grow *pari passu* with the turbidity of the water, indicating a washing into the stream, with the suspended matter, of the bacteria themselves, while the smaller number found in the settled water led me to infer the presence of a very small quantity of organic matter in solution. These facts force us not to rely upon one, or even a few examinations in estimating the average germ life of a given water, and from this deduce its healthfulness. Another fact brought out by these statistics, is the great value of Koch's method in determining the efficiency of filtration. This has been well shown by Frankland, and others. The method enables us to test, not merely the efficiency of a given filtering material or apparatus, but the length of time during which such a filter remains efficient. That this is a most important factor, is shown by the following statistics.[1] Water drawn in a Berlin kitchen, through a private filter, contained 3840 bacteria; the filter being removed, it contained only 35. A second examination furnished the same results, 4500 with the filter, 56 without it. To indicate the efficiency of sand filtration, used in Berlin, the following figures may be of interest. In July, 1884, about 75 per cent. of the bacteria were removed by filtration; in August, 80 per cent.; in September, 97 per cent.; in November, 42 per cent., etc.

Koch established, and made comparatively simple, the estimation of the number of microörganisms in water. But the signification of the number and kind of bacteria still remains to be determined. It may be safely assumed that the number of bacteria is a measure of organic contamination, and that the introduction of saprophytic bacteria into streams from polluted sources, may be taken as a broad indication that pathogenic bacteria, whenever present, will gain entrance through the same channels.

In order to see what relation subsists between the quality of drinking water, as indicated by taste, and by chemical analysis, another series of figures are published under the direction of Dr. Wolffhügel.[2] These statistics, collected from various cities in Germany and Austria, and compiled by various observers, do not indicate the perfect concordance between biological analysis and former estimation of quality which those would wish to see, who have looked upon this method as more satisfactory than chemical analysis. Moreover, in the reports from some cities, the bacteriological estimates of the water from various pumps which have been condemned as unfit for use on the evidence furnished by chemical analysis, show in the main a low percentage of bacteria when compared with others regarded as fit for drinking water. Thus, on page 556, we find the water of two condemned pumps containing, respectively, 11 and 71 bacteria in 1 c.c., while that of another, not condemned, is put down as containing 1485 bacteria in 1 c. c.

These discrepancies may, however, be only apparent, when we consider that, in but a few cases, two or three examinations of water from the same source were made. These examinations, in most cases, show a close agreement in the figures; in a few, the difference is very marked. Thus (p. 554), two examinations, made about a month apart, describe the bacteria as too numerous to be counted in the first case, and but 63 in the second.

From these statistics, it would appear that, in the majority of the sources receiving their supply either from ground water or spring water, the bacteria number less than 200 in 1 c. c., a small proportion reach the number 500 to 600, while a few go as high as 2000 to 5000. In connection with these statistics, Dr. Wolffhügel reserves for himself some general deductions, to be published later. Meanwhile, in order to swell the material on which conclusions may be based, it would be advisable for those practically interested to confine their examina-

[1] American Monthly Micr. Journ., 1886, p. 61.

[1] Arbeiten, etc., p. 562.
[2] Loc. cit., p. 546.

tions to variations in the number of germs in a few sources of drinking water, rather than examine a large number but once or twice. In this way the effect of the seasons, of rainfall and drought may be watched. Nor is the effect on the number of bacteria of a prolonged exhaustion of water in ordinary pumps to be overlooked.

In a third article,[1] two questions are approached from the experimental side: To what extent do pathogenic bacteria multiply in water? To what extent do bacteria multiply in samples of water after collection and before examination? In regard to the second question, the authors conclude that bacteria do increase in number within certain limits of temperature, and that water packed in ice shows a gradual decrease in the number of bacteria capable of development. Hence the necessity of examining water immediately after it has been collected, in order to avoid any errors. The great increase in the number of bacteria of drinking water after collection is a fact coming under the observation of all who have paid any attention to the subject. I, at first, suspected that the biologically sterile tube might not be chemically clean, and hence exposed the tube to the Bunsen flame until all organic matter was carbonized or broken up. This, however, did not prevent a few thousand bacteria from increasing to over sixty thousand within twenty-four hours. The changed conditions are such as to make all other organisms a prey to bacteria. The authors have also found that the manner in which the collecting tube is closed affects the diminution of the number when exposed to cold, so that tubes with rubber stoppers contained, on the average, less than those plugged with cotton-wool. This, without doubt, depends on the oxygen supply. Experiments on the effect of mechanical disturbance, such as might occur in the transportation of samples, led to no uniform results.

In endeavoring to solve the first question stated above, how extensively pathogenic bacteria are capable of multiplication, the authors sterilized filtered and unfiltered water from various sources, including river, well water, and water from a contaminated stream. As a preliminary experiment, a number of bacilli isolated from water were tested in this way. All actively multiplied for ten or fifteen days after being sown. This multiplication was determined at stated intervals of one to five days, on gelatine plates. Among the pathogenic microorganisms, the anthrax bacilli multiplied, in some cases, to the fifteenth day after sowing. The bacilli of typhoid fever increased in number up to the third day, then diminished. Even when the contaminated water was greatly diluted with distilled water, there was a perceptible multiplication, or, at least, a preservation of the vitality of the bacilli for at least twenty days. In well water and drinking water from the river, the increase was not so marked, but the vitality was not destroyed after the twentieth day. In distilled water they were traceable after fifteen days. Cholera bacilli exhibited the peculiar property of quite disappearing during the first days, but multiplying later to a very marked degree. The authors explain this strange fact, by assuming preliminary adaptation of the bacilli to the medium in which they are placed, by which their multiplication is somewhat retarded. The enormous multiplication of typhoid and cholera bacilli in sterilized milk, points out the importance of keeping a strict supervision over this important article of food, and the absolute necessity of boiling all milk in times of epidemics.

Experiments designed to test the struggle for existence of pathogenic bacteria in unsterilized water, failed by reason of the rapid growth of the bacteria originally present. Immediately after sowing, the cholera bacilli were by far the most numerous, but, within a day, other bacteria multiplied so enormously as to crowd them out of sight or existence.

When first undertaking to analyze water by this method, it seemed to me that if the collected water were allowed to stand at a given temperature, and the maximum number of bacteria determined which the water was capable of sustaining, we might have an indicator of the relative quantity of organic matter present. This the authors have virtually done, only in a way which must be more accurate in some respects. If the water be sterilized by heat, and only one species of microörganisms sown, the conditions would be more uniform, since different bacteria would multiply with different rapidity. In such experiments the change in the water, effected by sterilization, must be taken into consideration.

From recent investigations, M. Bolton[1] determined in water the presence of certain bacteria, which multiply very rapidly for a number of days, and quite independently of the quality of the water used as a culture medium. The addition of nutrient substances, in quantities too small to be measured, was sufficient to cause active multiplication. They found nourishment enough in water repeatedly distilled. Pathogenic bacteria, added to water, regularly decreased in number, independently of the quality of the water. He therefore concludes that the number of bacteria in a given sample does not furnish any safe basis for determining the chemical constitution, the degree of pollution, or the infectiousness. A knowledge of the various species of bacteria is a safer guide than their number, in estimating the quality of water.

Such researches aid in giving bacterial enumeration its proper place. They indicate the method to be pursued: a careful study of the biological properties, and the possible pathogenic effect of each species. The relation of bacteria to the processes in the alimentary canal is still an unexplored field. May not some of the speciesdaily introduced into the digestive organs, in the drinking water, give rise, under certain conditions, to fermentations and decompositions leading to catarrhal and other morbid changes?

Lines of research might be multiplied, if space

[1] Zeitschrift für Hygiene, I. Bd., I. Heft., Deutsche med. Wochenschr., 1886, p. 506.

permitted. They are comparable to clinical observations at the bedside, the value of which increases with the quantity. Since work of this nature is more laborious than intricate, and requires but little apparatus, its prosecution in every biological laboratory is to be highly recommended.

A LARGE CALCULUS REMOVED FROM THE BOWELS BY INFLATION.

By THOMAS EVANS, M.D.,
of Plainfield, Ind.

On Friday, December 4, 1885, Mrs. J. was taken with a severe attack of diarrhœa; after a few hours it suddenly ceased. Then followed pain in the bowels and vomiting. This condition of things continuing until the next evening, her husband called on me for some morphine. No relief being obtained from the medicine, I was requested early Sunday morning to visit her. I found her in a very prostrate condition, having slept none at all for the last two nights; and the pains occurring every few minutes, with vomiting and great tenderness of the hypogastrium on pressure. To the right and surrounding the umbilicus could be felt a tumor the size of a child's head. No nourishment had been retained in the stomach for two days; the bowels were constipated. The pulse and temperature were scarcely up to the normal standard.

Mrs. J. possesses a vigorous constitution naturally, is short in stature, quite fleshy and corpulent, is now in her fifty-ninth year, and is the mother of thirteen children, eleven of whom are now living and healthy. My diagnosis of the case was colic, with symptoms of impaction of the bowels. All medicines, excepting two doses of calomel, were rejected by the stomach. The injections of warm water returned from the bowels without any fecal matter.

The symptoms becoming aggravated by noon on the fourth day, at 2 P.M. I inflated her bowels with air, which at first passed up only a short distance; and then passed out by the rectum. Continuing the operation for twenty minutes, it began to move higher up; and in half an hour, concluding she could not bear any more, it was discontinued. About two hours from this time an enema brought away a small amount of fecal matter.

Fears being expressed by the patient of a displaced womb, an examination revealed a slight displacement forward, which being rectified she expressed herself as much relieved. Having requested some nourishment, soup was taken and retained; and no more vomiting followed. Soon after a moving in the bowels was felt by the patient; and about 5 P.M., while over the bed-pan, something passed from the bowels, striking the bottom of the vessel with great force and with a loud report. This was immediately followed by a very copious discharge from the bowels, over which the patient had no control. Over a gallon of fecal matter was discharged, and the condition of the patient was immediately changed; all symptoms of pain and vomiting came to an end. On removing the evacuations from the vessel a large calculus was found, measuring two and a half inches in length and four and a half inches in circumference, and weighing seven hundred and twenty grains. It was evident that this calculus had been the cause of the impaction of the bowels; and that it had been dislodged by the inflation.

The calculus is covered with a coating of lime, has a smooth, shining appearance like polished marble, is grayish-white, covered with black, brown, and yellow spots. It has the appearance as if there might have been adhesions on its surface. It was sawn through its centre six weeks after its discharge, since which time it has hardened considerably and assumed a more polished appearance. Near the centre is a dark spot one-third of an inch in diameter, which was quite soft—of the consistence of beeswax. Surrounding this are dark and light rings, showing layers of cholesterin, which increase in hardness toward the periphery; and finally an external coating of lime, varying from two lines to half an inch at the small end. Its fractured surface glistens like resin, and the sawdust dissolves in sulphuric ether, giving a straw-colored solution.

How and when this stone made its way into the intestines are questions not easily determined. Did it pass by the ductus communis choledochus by dilatation, or through it or the walls of the gall-bladder by ulceration? Mrs. J. has been in poor health for seven or eight years. Seven years ago she suffered a great deal from pain in the right side. During the winter of 1880 she was laid up with a remitting fever of a mild type for seven weeks; followed by a protracted convalescence. There were marked icterus and pain in the right side near the umbilicus, requiring hypodermatic injections of morphine. These symptoms gradually gave way; but the pain in the side never left entirely. There was a tender spot to the right of the umbilicus, radiating across the lower part of the abdomen, increased by exercise or exertion; but more annoying in bed than at any other time; compelling her to lie on the right side and keeping her awake most of the night. Every winter she has had light attacks of just such sickness. One year ago she had quite a severe attack, brought on by overwork. The pain was of an aching, worrying character, as though a heavy weight were pressing on her; spreading out on the abdomen, passing around to the right kidney, up toward the liver, with a great amount of gas and sourness of the stomach, often vomiting a great amount of bile. Scarcely anything remained on the stomach for several weeks, except milk and lime water. After a tedious convalescence of three or four months, a discharge per vaginam of pus mixed with blood appeared, continuing seven or eight weeks. This occurred last summer. Since then she had been slightly improving; and up to the time of the impaction of the bowels considered herself gradually getting well. At the same time she was unable to lie or turn over with comfort on the left side in bed. There was that ever-present weight and aching on the right side of the abdomen, keeping her awake at night and preventing her exercising through the day. Her diet had to be very spare. Very little meat could be borne, and vegetables and farinaceous articles in very small quantities, or

vomiting would follow. The bowels were never constipated, but inclined to be too loose. There were never any severe attacks of pain, indicating the passage of gall-stones through the ductus choledochus. The patient thinks she never had a chill, but considerable inward fever, causing her to drink a good deal of water.

Since the discharge of the calculus she has kept herself quiet, mostly in bed for several weeks; and for some time was unable to turn over in bed without help, or to move about on account of the soreness of the right side. She has improved under the influence of rest and warm fomentations, so as to be up and about. She called on me recently and said she was able to visit her neighbors, had a good appetite, good digestion, and although there is still a little soreness in the right side she feels well, can turn over in bed, lie on either side, and thinks she will soon be as well as ever.

The most probable view of the origin and cause of this calculus is that it had been forming in the gall-bladder for several years, and that during the latter stages of its growth it pressed against the pyloric end of the stomach, causing the frequent vomitings of the patient for several years past, and preventing the passage of the bile into the intestines at times, producing the jaundiced condition of the eyes and skin. If a stone an inch and a half in diameter can pass so small a passage as the ductus choledochus, as some authors are inclined to believe, surely it would have given some unmistakable signs in the way of pain, there having been no such pain to warrant such an event. It surely could not have passed during the last sickness; for no pain appeared till after the diarrhœa had stopped suddenly, as if the presence of some foreign body was blocking up the passage. Not till then did the pain and vomiting commence. Large quantities of bile attended the vomiting, which would not have happened had the calculus been engaged in the ductus choledochus, for its smooth round surface would have prevented its passage. The most probable view is, that the calculus passed through the walls of the gall-bladder by ulceration into the duodenum; and was in some way the cause of the discharge of pus last summer. It then found its way into the ilium, where it lodged till the time of impaction and the accumulation of fecal matter behind it, which was dislodged by the inflation of the bowels.

At this time, nine months since the discharge of the calculus, Mrs. J. is enjoying good health.

Plainfield, Ind., September 16, 1886.

MEDICAL PROGRESS.

Primary Tuberculosis of the Conjunctiva.—Rhein describes four cases of primary conjunctival tuberculosis, in which he succeeded in demonstrating the presence of tubercle bacilli in the diseased tissue. He was also able to show the tubercular character of the disease by the introduction of excised portions of the conjunctiva into the anterior chamber of the eyes of a rabbit. Careful examination of the lungs, larynx, etc., in all the four cases showed that their condition was normal. Swollen glands were found, but their appearance was secondary to that of the conjunctival lesion. —*Centralbl. f. d. med. Wiss.*, August 21, 1886.

The Removal of Hemorrhoids rendered Painless by the Injection of Cocaine.—Dr. J. P. Stallard, of Manchester, records in the *British Medical Journal* of September 25, 1886, the following interesting cases:

Case I.—A gentleman consulted me on June 12, 1886, for a painful swelling, saying he thought that his "seat had come down." On examination, I found a large venous pile, tense and shining, and tending to ulceration, the base of which sprang from just within the margin of the sphincter ani. With difficulty and pain, it was reduced; but, as it descended on the following day, it was decided that it would be best to tie it. The patient was a very sensitive man, and asked that chloroform might be given to him; but, thinking it was a suitable case, I decided to try the effects of cocaine. Five drops of a ten per cent. solution of hydrochlorate of cocaine were injected, by means of a hypodermatic syringe, into each side of the base of the hemorrhoid; and, after waiting five minutes, the tumor was seized with a vulsellum, transfixed with a double-threaded needle, and tied in the usual manner. A morphine suppository was placed in the rectum, and from the commencement of the operation up to complete recovery, a period of eight days, the patient did not experience the slightest pain.

Case II.—On June 17th, a young pregnant woman consulted me for a large venous pile, commencing to ulcerate, and occupying the position described in the preceding case. The same number of drops were injected, and the hemorrhoid was tied. She experienced no pain during the operation, which was attended by no evil consequences.

In both the above cases, no toxic effects were produced from the use of cocaine. The solution used in the second case had been kept for three months, and contained one grain of hydrochlorate of cocaine in a drachm.

Remarks.—By means of cocaine, operations for the relief of hemorrhoids can be rendered painless, but the effect of the drug soon passes off; and, to insure absolute freedom from pain, it is necessary to follow it up with morphine, administered in one of its many forms. By using cocaine as above described, the operation is rendered much easier, and can be accomplished by the surgeon single-handed, without the help of an assistant, who is indispensable when a general anæsthetic is employed.

Oil of Turpentine in Scrofulous Ozæna.—Malacrida (*Centralbl. f. Chir.*, July 17, 1886) reports the case of a girl ten years old, who had ozæna of long standing, which had long been under treatment in vain. Taking a suggestion from the cure of old fistulous tracts with oil of turpentine, the author used this drug locally, and gave the patient a supporting diet. Cotton tampons moistened with a few drops of the oil were introduced into the nose. As they caused considerable irritation, those subsequently used were wrapped with dry cotton. A perfect cure took place in a week. Five other cases treated by the same method are mentioned, in none of which was the cure delayed longer than a month.

The Treatment of Chronic Abscesses by Injections of an Ethereal Solution of Iodoform.—Verchère (*Rev. de Chir.*, June, 1886) reports twenty-three cases which were treated in this manner, and gives the following directions in regard to the operation: The solutions of iodoform should be of varying strength, one of five per cent. being used for large abscesses, and one of ten per cent. for small ones, while small, superficial abscesses may be filled with a saturated solution. If the skin over the abscess is not affected, the needle of a hypodermatic syringe is introduced in an oblique direction, so as to form a valvular fold; the pus is then drawn off, and the iodoform solution is injected. If, however, the skin over the abscess is quite thin, the pus is removed with an aspirator, and the opening made by the needle is sealed with collodion, after which a hypodermatic-syringe needle is inserted into the abscess cavity, and the injection is made as before. The object of these manœuvres is to prevent the ether from escaping through the puncture, as it at once tends to do on becoming volatilized. As the solution volatilizes, the iodoform is deposited over the entire inner surface of the abscess, and is slowly absorbed—so slowly in fact that the danger of poisoning by the drug is said to be very slight. The phenomena observed after an injection are, briefly, as follows: Rapid and sometimes excessive swelling results from the volatilization of the ether, but this soon subsides. If the skin over the abscess is healthy, the abscess cavity will speedily be replaced by indurated tissue, without the occurrence of any external change. If the skin is already inflamed, it will separate in a few days in the form of a yellowish slough, after which healing will occur by granulation, the resulting cicatrix being slight. The advantages alleged for this method of treatment are the perfect safety of the operation, the rapidity of the cure, the fact that the patient is not confined to his bed during the treatment, and the non-recurrence of the abscess.

Discussion on Castration.—From the report of the meeting of the St. Louis Obstetrical and Gynecological Society, published in the *St. Louis Courier of Medicine* for September, 1886, the following excerpts are taken:

Dr. Gregory. A few weeks ago, during the session of the American Medical Association, a physician brought his wife to this city; she is his second wife, a handsome young woman, not more than thirty years of age. She has had epilepsy for some time past—several years, and she has had one child. She has some ovarian trouble. Her husband insisted upon a laparotomy as the only thing that would cure her. She had got the consent of her father and mother, and fully made up her mind to have the operation performed, and it was done. He was in my office on Monday, and told me that he was about to go home; that the operation had been performed, and his wife had had no paroxysms since. Evidently this is the popular feeling now. I wonder that this thing does not get into our asylums—into the ordinary insane asylums. I wonder that men are not treated in a similar way. I don't see, if mania, or mental conditions approximating mania, are cured in the female by this operation, why castration should not be resorted to to cure the same class of troubles in the male. I don't know whether men will be as ready to submit to operation as women, but I don't see why reasoning from analogy does not lead us to the same conclusions.

Dr. Boisliniere. In Central Asia, little girls are spayed a short while before the period of menstruation; and they are said to make very useful house servants, and it is surprising how little importance they attach to this operation. They do not seem to consider it a dangerous operation at all. The idea which Dr. Gregory has advanced is, I think, an original one, and there is probably a great deal in it, but I think it would be difficult to popularize the idea among men.

Dr. Papin. There is a diseased person called the "old maid." A woman menstruates about thirty years of her life. Her social position, her surroundings, warrant her in wishing that she may, as her companions do, settle in life—in other words, marry. For some cause or other she never marries. Responsibilities are thrown upon her shoulders that prevent it, or she is disappointed in a love affair, or other causes prevent her from marrying. Now she will continue to menstruate from month to month, and from year to year, until the continued and never-resting functions of these organs finally attack her nervous system, and she becomes irritable. She is, in other words, an old maid. She has become peevish, fault-finding, and annoying. Now I would like to know whether it would not be proper to perform this surgical operation upon these persons?

Hydronaphthol.—Dr. Justus Wolff asserts that E. Merck's statement that betanaphthol and hydronaphthol are identical, is a mistake, which may result in the most serious consequences if betanaphthol be used instead of hydronaphthol, "as the first one is a most dangerous and deadly poison, whilst the latter is an excellent, absolutely reliable, and harmless antiseptic." The poisonous character of betanaphthol has been established a long time ago by such authorities as Kaposi, Neisser, and Piffard, and lately by Max Schwarz, while Dr. G. R. Fowler, Dr. Lawrence Wolff, and many others have proved hydronaphthol to be non-poisonous and a most effective antiseptic. Hydronaphthol is distinguished from betanaphthol, not only by its physiological action, but also by distinct chemical reactions and by its chemical constitution, as it possesses certainly more hydrogen in the molecule than betanaphthol. Of the several distinguishing chemical reactions, the following may be given as an example: If from a diluted iron perchloride solution two drops are added to an alcoholic betanaphthol solution, it becomes of a bright green color, whilst the same proportion of an alcoholic hydronaphthol solution of the same strength becomes dark yellowish-brown by addition of the same proportion of iron perchloride solution. Other reactions are also different, and the melting-points obtained by most careful determinations are for hydronaphthol 117° C., and for betanaphthol 122° C. These and other facts satisfy the author that hydronaphthol is distinct from the poisonous compound which is known as betanaphthol, and that it is not alphanaphthol nor a mixture of the two last named, and does not contain any of either. —*Druggists' Circular*, September, 1886.

An Unrecorded Danger from Continued Large Doses of Iron.—The preparations which Dr. J. Strahan has found to cause symptoms of obstruction are as

follows, namely: Ringer's pill of 5 grains of dried sulphate of iron = 9 grains of ordinary sulphate; half drachm and whole drachm doses of tincture; mistura ferri composita, P. B.; made as strong as to contain 8 or 10 grains of sulphate of iron and carbonate of potash in each dose. Any of these, if given three times, or even twice, daily, for from one to two weeks, and if natural or artificial diarrhœa do not in the meantime wash out the quantities of insoluble sulphide, will cause severe colic and constipation, which morphine and turpentine stupes seem unable even to alleviate, and which, it seemed to him, would continue indefinitely, or till death, if not removed by a smart saline purge, or other means. He has seen twenty-four hours of rhythmic agonizing pain, very like labor, with nearly constant vomiting, no sleep or ease, after a grain of morphine by the mouth, the temperature rising to 101° Fahr., and great depression of all the powers of life, from a couple of weeks' course of Ringer's pill, which had done immense good to the system at large. This has not occurred once only, but dozens of times, so that he now expects it, and provides against it. As soon as ever a large dose of any saline—he prefers an ounce of sulphate of magnesia—has well acted, all symptoms rapidly disappear. At this time, and for twenty-four hours after, the stools seemed composed half of dirty water and half of black sand. He thinks this latter fact explains the pathology of the matter. In fact, it is a real obstruction—an acute one, too—by quantities of insoluble sulphide of iron. The quantity of this black sand, which comes away when severe constipation and colic have occurred, is surprising. It seems to be much more in quantity than the whole iron ingested, although the stools have been jet black all along, through excreting the sulphide. So, it seems to him, it must lodge somewhere; perhaps in the cæcum and appendix. Then when the iron begins to sicken the patient (gastric catarrh), the sulphide, he supposes, concretes by mucus, and forms an obstruction which brings matters to a crisis. The length of time that a patient can take large doses of iron, depends on the state of the bowels; if they be kept, or remain, slightly loose, he does not suffer at all; if he becomes constipated, the iron soon sickens, and the horrible pains begin; if he were to take a smart saline purge once a week, he believes he could go on indefinitely. The saline gives the quickest relief, because it produces such a vast exosmosis of water from the intestinal wall at all points, as to dissolve the mucus which binds the sand, and then washes it out. In extreme constipation, it dissolves fecal lumps in the same way, except when the masses are enormous. It is thus the best purgative where there is a stricture in the bowels, with dilatation above, as it melts the feces into a fluid, when they can run through the narrow part.

Another great advantage the salines have, is that they cause no pain, no griping. A teaspoonful of Epsom salts every two or three hours will put an end to many a case of fecal obstruction in old people, and that without pain, where croton oil, and drachm doses of jalap, have only given rise to unendurable pain and collapse. —*British Medical Journal*, September 18, 1886.

POTASSIUM IODIDE IN DIPHTHERIA.—STEPP maintains that iodine exerts a direct curative influence upon diphtheria, and that its continued exhibition under proper restrictions is entirely harmless. It is administered as iodide of potassium with, occasionally, the addition of the tincture of iodine. For the first three years of life a two to four per cent. solution is used; for later periods, four to ten per cent.; the dose recommended is one teaspoonful hourly. The author reports cases in which the method described has been employed with advantage.—*Centralbl. f. d. gesammte Therapie*, September, 1886.

NATURE OF COBRA VENOM.—In an article in *The Journal of Physiology* for September, 1886, DR. R. WOLFENDEN presents the following conclusions:

1. That its toxicity is not due to any bacillus, bacterium, or living organism.

2. It is not due to any alkaloid.

3. It is not due to any hypothetical "cobric acid."

4. It is wholly and solely due to the proteid constituents of the venom.

The proteid constituents are

1. Globulin, which is always present, and probably kills by interference with the respiratory mechanism (asphyxia), and without paralysis—causing local inflammation, but not of great intensity, compared with daboia.

2. An albumin resembling acid albumin, which is precipitated along with globulin by saturation, and which is in some degree dialyzable. This proteid probably acts on the respiratory apparatus chiefly, like globulin, but less intensely.

3. An albumin which is precipitated by Na_2SO_4 out of the magnesic filtrate, and which is serum albumin. This is also toxic, and produces a kind of ascending paralysis with fatal termination, by suppression of the respiratory function from probable paralysis of the muscles concerned in respiration.

4. Traces in some specimens of hemialbumose, and questionable traces of peptone. I regard these as accidental, and probably due to the length of time the poison has been kept.

ALIMENTATION BY THE VAGINA.—DR. J. N. LOVE (*Weekly Medical Review*, July 17, 1886) concludes an interesting paper upon alimentation by the following remarks on the vagina as a channel through which, in certain cases, an invalid may be fed:

1. In cases which demand artificial alimentation where the conditions will permit, the vagina may be utilized to supplement feeding by the rectum.

2. In some instances disease of the alimentary canal in its entirety precludes feeding by either the stomach or the rectum; in such cases the vagina may be utilized to practical advantage.

3. That whether the vagina or rectum be used for purposes, of feeding, the materials should be as thoroughly digested previous to using as possible; the milk albumen or beef fibre completely peptonized, and all the starchy matters changed into dextrose or glucose.

4. In many instances the vagina may be utilized for purposes of general medication and stimulation, and the stomach saved for the important one of feeding.

5. In many cases vaginal feeding, stimulation, and medication is beneficial; in many others it is a potent means for saving and prolonging life.

6. In both rectal and vaginal feeding the same gentle care is necessary, and one advantage possessed by the

latter over the former, is that the vagina is much the more tolerant of intrusion, and can be utilized for an almost unlimited time without revolting.

Hydrogen Dioxide in Diphtheria.—Hofmokl records the use of hydrogen dioxide in fifty cases of diphtheria, and holds that the drug is of value in this disease, though by no means a specific.

Three parts of pure glycerine are added to two hundred parts of the two per cent. aqueous solution of the dioxide, and the mixture is used both for inhalations with a steam atomizer and internally. In the latter case one teaspoonful is given at intervals of from one to two hours. Considerable salivation results from this treatment, and the membranes are expelled usually on the third or fourth day. Neither the reproduction of the exudate nor the downward extension of the membrane is prevented, but the general condition and appetite are notably improved.—*Centralbl. f. Chirurgie*, August 21, 1886.

The Salts of Copper in Scrofulosis.—Prof. Du Molin, of Gante, in the course of experiments upon the toxic action of the salts of copper on a dog which suffered from facial impetiginous eczema, noted its cure, in the course of six weeks, with the progressing doses of from one milligramme to one gramme a day. Through analogy he applied the same treatment to the eczema impetiginosa of children, obtaining success in twenty-five cases. Extending the use of the same medication to all other scrofulous manifestations, he met with equal success, except in cases of *keratitis*, which have not always responded to the treatment. Cupric intoxication may be avoided by the use of moderate and methodically increasing doses.—*Western Medical Reporter*, Aug. 1886.

Power of an Operator Over a Patient under the Influence of Nitrous Oxide.—Dr. W. C. Bunker, of Oregon, Ill., writes as follows to *Dental Cosmos* of October, 1886:

I have been using nitrous oxide gas in my practice for a number of years. For the first two or three years I had but indifferent success, especially when called upon to remove the wisdom-teeth or second molars. To insure the mouth being open, I used to employ a rubber gag, sometimes substituting for it a large cork with a string attached. In a majority of cases, when the gag was taken out, the jaws closed somewhat and remained rigid, no proper amount of force sufficing to open the mouth until the effect of the gas was nearly spent. I finally declined to administer gas for extracting teeth back of the first molars.

Requiring the extraction of a tooth from my own mouth, I went to a brother dentist and had the gas administered. While taking it, and while under its effects, I was perfectly conscious; heard every word said, but was powerless to move a muscle. I knew when the inhaler was removed and the forceps taken up and adjusted, but felt no pain. The tooth was broken off, and two more ineffectual efforts were made to extract it. Still there was no pain. At this instant I regained control of myself, retaining a knowledge of all that had transpired.

This experience impressed me with the conviction that if patients heard and understood, they could be made to obey. It had been a habit with me to test the condition of my patients during the inhalation of the gas by requesting them to raise the left arm. They usually responded, some continuing to raise and lower the arm until the effect of the gas passed off, seeming to be impressed with the idea that they must do so.

The next occasion I had to administer gas I made the usual examination of the mouth, and, after learning which teeth I was required to remove, I turned abruptly to the patient and said, "If, while you are under the influence of the gas, you hear me request you to open your mouth, do so. You can, if you understand now that it will be necessary." I said nothing about raising his arm, but just as I thought he had inhaled enough gas, I said, "Raise your left arm," and was surprised to see that, instead of doing so, he promptly opened his mouth wide. As his breathing indicated that he had enough gas, I dropped the inhaler and extracted the teeth. After he regained consciousness, I said, "Did you hear me ask you to raise your arm?" He said, "I heard you tell me something, and as you had charged me to open my mouth if asked, I thought that was what you wanted."

I have taken advantage of this experience ever since—some three years—and have yet to meet the first failure. After charging a patient to respond by opening the mouth when told, I proceed to administer the gas, and just before he passes under its influence I say, "Remember and open your mouth when I tell you to." Thus the last thing the patient thinks of is opening his mouth, and almost invariably it is the first thing he does. I have tried the command without previous instruction, and failed to obtain a response. I think this suggestion worthy of investigation by those who use gas.

Tolerance of Narceine by Infants.—Laborde, after considerable experience with the drug, reports that for use in many diseases of children it is far superor to the preparations of morphine. It induces sleep, and notably diminishes bronchial secretion. He has found its use very advantageous in whooping-cough, and in nocturnal coughs in general. As an analgesic, it has not the power of morphine. It is best administered in syrup or in suppositories.—*Journal de Médecine de Paris*, July 25, 1886.

Paralysis depending upon Idea.—Dr. C. W. Suckling writes as follows to the *Lancet* of September 18, 1886:

In the *Birmingham Medical Review* for June, 1885, I published an account of a boy who had suffered from paralysis of one leg for two years, and whom I was able to cure immediately after making the diagnosis of paralysis depending upon idea. Since then I have met with three other cases, two of which were men. In one case there was complete anæsthesia of the hand; in another, hemianalgesia with localized and severe headache. In the four cases I have now seen, an accident occasioning slight injury was the exciting cause in each. All four cases were rapidly cured. Dr. Russell Reynolds, I believe, first described paralysis depending upon imagination. There is no malingering in these cases, but the patients are firmly convinced that they are suffering from paralysis. If the confidence of the patient be gained, an immediate recovery follows when he is told that he will be well immediately, the idea

being got rid of. In making the diagnosis, it is important to bear in mind the two classes of people in whom functional nervous disorders are met with—the neurotic and the hysterical; the features of which have been so graphically described by Dr. Clifford Allbutt in the Gulstonian Lectures for 1884. It is the neurotic that is apt to be affected by these paralyses depending upon idea, and it is these cases that are instantly cured when the diagnosis is made. The hysterical patient is cured with difficulty, and frequently relapses; the neurotic does not relapse. The neurotic individual is vivacious, good-tempered, unselfish, intelligent, active, and industrious, anxious to be cured, and grateful for recovery. The hysterical individual is listless, apathetic, lazy, selfish, with characteristic expression, not usually anxious to get well or thankful for recovery. The following is the fourth of these cases of paralysis depending upon idea that I have met with during the last twelve months.

Sarah F., a widow, aged forty-six, was sent to the Queen's Hospital, to be admitted under my care, by Dr. Middleton, of Harborne, on the fifteenth of March last, and was discharged, well, on March 28th. She has led a very industrious life, having supported her five children by needlework since her husband's death ten years ago. On October 9, 1885, she tumbled downstairs, falling down twenty-one steps on to her back. She was much hurt and "dazed," and very much frightened, thinking every bone in her body was broken. She walked about after the accident for a day or two, but suffered from pains in the back, down the legs, and round the body: these pains were intermittent, very severe, and lasted altogether three weeks. Two days after the accident she took to her bed, and a day or two later found that she was paralyzed in both her legs, and had lost all feeling in them. Since the accident she had suffered from constant headache and backache. Upon examining her, I found that she had a little power over the legs, but very little. Slight ankle-clonus could be elicited on the left side. The plantar and abdominal reflexes were lost, but the knee-jerk was well marked. There was complete analgesia, and thermal anæsthesia in both legs up to the knees. She was unable to localize tactile sensations below the knees, the anæsthesia not being complete. When touched with a sharp-pointed instrument, she said she felt as if she were being pushed. Muscular sense was unaffected. There was superficial tenderness over the lower dorsal spines, but no pain on firm pressure, or on percussion, and no irregularity of the spine. The bladder and rectum were unaffected, and I was informed by Dr. Middleton that she never lost control over the bladder, nor had any sign of bedsore during her illness. There was no œdema of the legs, no alteration of temperature, and no change in the color or aspect of the skin or nails. In fact, there were absolutely no trophic changes whatever. The response of the muscles to faradization of their nerves was normal, but there was considerable electrical anæsthesia. In summing up the symptoms present, I, of course, observed their incongruity, if we supposed the case to be one of myelitis, or, in fact, as due to any organic lesion. If the anæsthesia were due to actual lesion of the gray matter, how could the bladder and rectum escape? How was it that there was no sign of bedsore, no œdema, or other trophic change, such as muscular wasting? I diagnosticated the case immediately as being purely functional, and, the woman being of the neurotic type, as paraplegia depending upon idea. I at once acted upon this diagnosis, and told the patient that I should give her the battery, which I said would at once remove the loss of sensation, and enable her to move her legs as well as she ever did. She was delighted to hear this, and, after a minute's faradization, sensation was completely restored, and she had full command over her legs. I then told her that on my next visit I should expect to see her walking about the ward, for I was sure that she would be able to do so. I instructed Mr. Whittendale, my house-physician, to see that she got up after I left, and to apply the faradic current whenever she displayed any hesitancy. On my next visit, two days later, I found her up, and able to walk and run about the ward perfectly well. She was quite delighted at her recovery, and had been most industrious with her needle since getting up. She expressed deep gratitude, and hoped to be able to repay our kindness. I may add that I saw my patient on the fourteenth of the present month (September), and she was remaining quite well.

How was the cure effected in this case? Undoubtedly, I think, it was by the mental state of faith or expectation, or both, on the patient's part. She fully believed what I told her, and thus I was able to remove the idea she had that she was paralyzed. The essential thing, then, in these cases, is to make a correct diagnosis, and then the patients can safely, and with success, be told that they will quickly recover. Now, had this been a hysterical woman, I should in all probability have failed to cure her, or, at any rate, the cure would have been more tedious. I recently had a woman under my care, suffering from locomotor ataxy with hysterical anæsthesia. For two years I did all I could to cure the anæsthesia, and failed; but, when she left the infirmary, she applied leeches to her legs, and returned with the anæsthesia gone. Isolation, so useful in hysterical cases, is not needed in these.

In the same ward with my case of ideal paralysis, there was a young woman suffering from hysterical neuralgia, and the contrast between the two patients was very marked. The hysterical woman was listless and apathetic, did not manifest any desire to be cured, and would scarcely allow that she was any better than when admitted. When told that she was well enough to go back to her duties as a teacher, she seemed disappointed, and said that she did not intend to begin work again for some months. The neurotic woman, on the contrary, wanted to leave the hospital immediately she could walk. The hysterical woman was observed to be always sitting opposite the neurotic woman, contemplating her with her hands idly folded in her lap, watching the other busily working.

Such cases as these illustrate the enormous influence of the mind over the body. It is with these cases that the so-called faith-healers work pretended miracles. What an opportunity for a faith-healer my case would have afforded! Just as the mind has an enormous influence in causing disorders of sensation, of motion, and also of the organic functions, so also its influence can be used as a practical remedy in disease. As Dr. Wilks has well observed, "the practice of medicine is not only one of physic, but of psychology also."

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 9, 1886.

THE REPORT OF THE AMERICAN CHOLERA COMMISSIONER.

DR. E. O. SHAKESPEARE, of this city, commissioned last year by the President to investigate cholera in Europe and India, whose return to America after a year's absence we mentioned in our last issue, is busily engaged in the preparation of his official report, which we understand will be placed before Congress by the President, and will be published by the Government as a volume of considerable size.

We learn that the investigations of Dr. Shakespeare, having comprised anatomical and bacteriological studies, as well as those relating directly to hygiene, climatology, etc., have led him to conclusions concerning the nature and spread of cholera, which, in the main, accord with those enunciated by the German and Belgian Cholera Commissions. Dr. Shakespeare regards the comma-bacillus of Koch as a diagnostic sign of the greatest practical value for the early recognition of the presence of true Asiatic cholera. Irrespective of what may prove to be the real etiological relations of this microörganism to cholera, he looks upon this discovery of the German Commission as of incalculable practical importance to health authorities, of both local and general governments, whose duty it is to guard the people from the destruction of life and trade which usually follows an invasion of this disease. As to the pathogenic properties of the comma-bacillus, Dr. Shakespeare has less positive opinions. While he thinks it probable that this microörganism may also be the active cause of cholera, he feels that the proof is not yet absolute and fully convincing.

It is, therefore, evident that the conclusions of the American Commissioner are in opposition to those published by the English Commission, and in conflict with the notions advanced recently by Mr. Cuningham, the late Surgeon-General and Sanitary Commissioner with the Government of India, in his book entitled *Cholera: What can the State do to Prevent It?* Indeed, we are informed that, even in India, not one physician in fifty shares the opinions published by the late Surgeon-General.

In this connection it may be mentioned that D. D. Cunningham, of Calcutta, the well known Indian pathologist and microscopist, has, as the result of his latest laboratory work, fully accepted the claims of Koch concerning the diagnostic characteristics and value of the comma-bacillus. It will be remembreed that Dr. D. D. Cunningham was originally heartily in accord with Klein and Surgeon-General Cuningham in their contradictions of the conclusions of the German Commission.

Apropos of this important change of opinion, the rumor has reached us that the chief of the English Commission, Dr. Klein, has also found reason to modify greatly his views concerning the diagnostic value of the comma-bacillus of Koch.

INTESTINAL OCCLUSION BY GALL-STONES.

IT happens occasionally that a gall-stone of large size reaches the intestine, and, sticking fast in some part of its course, produces a fatal obstruction. The condition is not common and WISING, in the *Nordiskt Mediciniskt Archiv*, xvii. No. 16, has supplemented the report of a case by an analysis of all the recorded instances, fifty-one in number.* Of these, thirty-eight ended fatally. In a majority of the cases the stone escaped through a perforation existing between the gall-bladder and duodenum; but in four, at least, it would appear that the calculus passed through the bile passages, as no abnormal communication existed. The situation of the occlusion is rarely in the duodenum, more commonly in the jejunum or ileum, particularly the lower portion of the latter.

The attack is not often preceded by biliary colic, but usually sets in suddenly with pain in abdomen, vomiting, and the other symptoms of acute obstruction. In only five of the cases was a tumor palpable, and it is not clear whether, in every instance, this was the gall-stone. The treatment is that of ileus from other causes. Laparotomy has been performed in four cases, all of which were fatal. Washing out the stomach, as suggested by Kussmaul, might be specially serviceable in this form of occlusion, particularly if the obstruction was high up in the intestine.

The case reported in this number of THE NEWS, by DR. EVANS, is in many respects remarkable.

The calculus was of unusual size—one of the largest on record. The onset of the attack of ileus and course of the symptoms presented nothing special, and gave no clew to the nature of the obstruction. The tumor in the umbilical region was, no doubt, formed by the coil of distended intestine. The treatment pursued was extremely rational and eminently successful. We know of an unrecorded instance in which the patient after presenting the symptoms of ileus for several days passed a gall-stone nearly two inches in length. In this case the propriety of laparotomy was discussed the evening before the discharge of the calculus.

Large solitary gall-stones are not very rare, and we should say that only a limited number of them give rise to any trouble. They may exist in a normal-looking gall-bladder, but they tend in time to produce an inflammation which terminates either in an adhesive cholecystitis with obliteration of the sac, or in ulceration into a contiguous viscus, usually the duodenum or colon. The size and distensibility of the bile-ducts varies in different persons, but it is difficult to conceive that a gall-stone capable of producing intestinal obstruction, could pass the cystic and common ducts. Von Schweppel places the limit of size at one centimetre in diameter, but it is well known that permanent obstruction of the duct may be produced by much smaller calculi, and, on the other hand, the cases of Berkeley Hill and Le Gros Clark, quoted by Wising, leave no room for doubt that sufficient dilatation of the bile passages may occur to permit of the exit of a stone too large to pass through the bowel without inducing symptoms of obstruction.

FRACTURE OF THE PATELLA AND MALGAIGNE'S HOOKS.

In The Medical News of March 27, 1886, we considered the claims of Lister's method of opening the knee-joint and suturing the fragments of the fractured patella, and expressed our opinion that the simple methods which have proved so efficient in the practice of most American surgeons are to be preferred. In doing this, we made a passing allusion to the use of Malgaigne's hooks, or to one of the ingenious modifications of them made by Levis and Morton.

In regard to these instruments there is still—as there always has been—a diversity of opinion. Some surgeons praise them highly, while others characterize them as diabolical. In making this statement, it is proper to remark that the former are usually those who have given the hooks a fair trial, and the latter those who have not used them much. To the number of the supporters of the method suggested by Malgaigne, is now to be added Mr. Frederick Treves, of London.

In a short paper in the *British Medical Journal* for July 24, 1886, Treves states that he has used Malgaigne's hooks in all the cases of fracture of the patella which he has treated in the London Hospital during the twelve months preceding his report. Unfortunately, he does not give the exact number of cases. The results, he says, have been most satisfactory, judging from what can be observed in so short a time. This method has not had any unpleasant features. There has been no pain worth mentioning, no inflammatory reaction, no suppuration around the punctures, and no trouble in the joint. He adopts certain precautions to prevent these conditions. He washes the part concerned with carbolic acid solution, punctures the skin at the proper points with a tenotome, the two upper punctures opening the joint and permitting the escape of any accumulated fluid, after which the hooks are applied—the lower ones first—connected, and screwed up. The hooks are kept immersed in carbolic acid solution before being used, and, when they are inserted, the punctures are covered with powdered iodoform. The disposition of the upper fragment to ride is combated by passing a tape over the upper hooks and under the knee. The screw of the instrument is kept clear of the powder, and well oiled.

Mr. Treves operates without an anæsthetic, but under the spray, and he places the limb on a straight posterior splint before inserting the hooks, and elevates it after the operation. He thinks it important to keep the knee exposed to the air after inserting the hooks. The reason he gives for this is, that he believes a wound of the lower limb which is covered with dressings and bedclothes, is kept in a vitiated atmosphere, to its detriment. We think his practice is commendable, although we are inclined to attribute the benefit of exposure to the air more to its cooling effect than to anything which the atmosphere may or may not contain. Cumbersome dressings are a very frequent cause of distress and damage to patients, and anything which will prevent their application may be welcomed as an improvement in the practice of surgery.

This contribution of Mr. Treves to the subject of the treatment of fractures of the patella is one of decided value, and should encourage surgeons to renewed employment of the hooks of Malgaigne, or of other appliances similar in principle.

Multiplication of ideas is a good thing. With every year a taste for reading spreads among the people. Every class is provided for; no mind so immature, no child so young, but is offered its special aliment. Reading is made handy: the daily paper is presented to us in the street car; ten cents' worth of romance confronts us at every railway station. Consequently there arises among men and

women the habit of reading while in motion, which is most injurious; among children the habit of using their eyes by artificial light, after the lessons, which themselves should not be permitted at night, are got through with; consequently there is an ever-augmenting army of adults and toddlers wearing the livery of over-civilization, spectacles. As if with deliberate intent to aggravate this calamity, there is, moreover, an increasing disposition to use fine type. A large proportion of the cheap railway literature comes in characters which a paternal censorship would never allow to go into print. And worse than all, the children are brought up on it; some of the best and most widely read juvenile papers of the day are in such type as no mother should allow to enter her home. But, before parents can be expected to see this danger, the family physician must warn them.

The evil to which we have referred is not only a result of the use of fine type, but may be caused by the employment of type of improper shape, or by insufficient spacing between words and lines. Motives of economy induce the publishers of the cheaper forms of literature to reduce to the minimum the amount of unutilized space on the page—a result usually attained by the use of long and narrow type and the reduction in spaces just indicated.

The difference in legibility in two fonts of type of the same height but of different widths is surprising, and is always in favor of the broader letter. One may readily convince himself of this fact by holding a page of ordinary printed matter at the utmost limit of legibility. If now the page be rotated through an angle of forty-five degrees on its vertical axis it will be found that, from the resultant narrowing of the letters, the page becomes entirely illegible. If, on the other hand, it be rotated to the same extent on its horizontal axis, the legibility of the text will be found to be but slightly, if at all, impaired.

The reader interested in hygienic typography may be referred to the admirable essay by Javal in the 27th volume of the *Revue Scientifique*.

The question of a proper street-paving means more, involves more, and is of more importance than is here at least generally thought. It is not merely the comfort of those who drive in carriages, whether for pleasure or on duty, that is concerned. There are questions of scarcely-to-be-calculated savings of time, money, and strength, of the general cleanliness, and, therefore, of the general health, to be considered. How great a factor in the breeding, and then in the carrying, of disease-germs, and of a thousand dangerous fungi, the accumulated decaying dust and filth of our streets may be, we do not accurately know. The hopeless impossibility of cleaning with thoroughness hundreds of miles of streets paved as barbarously as ours are grows daily more evident.

As a matter of economy to horse owners, a class into which of necessity many physicians enter, a better pavement than either "Belgian blocks" or asphalt—we do not speak of the "cobble" relics of the stone age which disgrace us—is greatly to be desired. Asphalt fulfils many of the requirements, but, unless diligently swept and tended, and gravelled daily, as is done in London, it becomes a most dangerous horse-trap in wet weather. An improved pavement has been tried recently in Wheeling and other cities, and experiments are now being made with it in Chicago and Cleveland. It is composed of wedge-shaped fire-bricks set in an arch on a foundation of sand and gravel, with a top coating of pitch and sand, and its cost is, including material, but eighty-three cents per square yard. This pavement is claimed to be firm, clean, and smooth; to be water-tight; to have great power to resist pressure, owing to the combination of arch and wedge in laying; and to afford an unequalled foothold for horses in all weathers, and on all grades. In addition to all these advantages, it is noiseless, durable, and cheap.

Here, if all that is said be true, is something looking like the ideal street roadway. The experiment on some of our smaller streets might easily be tried, and perhaps some day, if we are not too supine to desire better than the bad we now have, our reproach may be removed. At present, Philadelphia, unlike a warmer place, is not even paved with good intentions.

We referred some time ago to the very favorable reports by Huchard on the prolonged use of iodide of sodium in angina pectoris. In the *Revue de Médecine*, of August 10, 1886, Laschkevitch records four cases in which excellent results followed the administration of cocaine in doses of one-half to one-third of a grain, three times a day. The attacks appear to have been relieved very quickly, though scarcely with the rapidity which characterizes the action of amyl nitrite. A combination of these remedies might prove more serviceable than either of them alone.

SOCIETY PROCEEDINGS.

THE AMERICAN GYNECOLOGICAL SOCIETY.

Eleventh Annual Meeting, held in the Hall of the Johns Hopkins University, Baltimore, Md., September 21, 22, and 23, 1886.

(Concluded from page 390.)

Thursday, September 23d.—Third Day.

Morning Session.

Dr. W. H. Baker, of Boston, read a paper on

ELECTROLYSIS IN GYNECOLOGICAL SURGERY.

The speaker referred more particularly to the use of electrolysis in cases of fibroid tumor. He laid down the

following rules for the performance of the operation: It should not be employed within a week before or after menstruation. An anæsthetic should be administered. It is better to use electrolytic needles for both the positive and negative poles. The operator should be absolutely sure of the cleanliness of his needles. The needle should be deeply buried in the tumor, in order that the current shall be insulated from the parts outside of the growth. The insertion of the needle should be made at the most prominent part of the growth, whether in the vagina or in the abdominal wall. The needles should not be too nearly approximated. If both needles are properly placed, the position of the poles makes no difference; the circuit being completed, the number of cells should be gradually increased from four to twenty or thirty (a more exact means of determining the strength of the current would be the galvanometer, but this had not given him accurate results); the length of time during which the application is continued should be from ten to twenty minutes, and should be determined by the character of the pulse. When the pulse becomes slower and weaker than normal, the number of cells should be diminished or the current discontinued. The current should be diminished gradually, and the wires should be disconnected at the battery before the needles are removed. The application should not be made at the surgeon's office. After the application the patient is to be put to bed, where she is to remain for one week. With such precautions, the speaker had never seen shock after the operation. A single treatment is often all that is necessary. He had never found it necessary to make more than three applications, and the latter number in only one case. There should be an interval of at least from one to three months between each application.

The use of electrolysis is also of service in the treatment of inflammatory effusions. The following case was related. Mrs. X., aged twenty-eight, married, the mother of one child three years old. The present trouble had existed since the birth of the child. Diagnosis of chronic perimetritis was made. The effusion was most marked on the left side behind the uterus. For six weeks ordinary treatment was given without much benefit. For the next two months the treatment consisted of hot water injections, applications of iodine, and the use of the galvanic current, with the positive pole in the posterior cul-de-sac and the negative pole over the epigastrium, using as many cells as possible. This was used every other day. This caused a decrease of the sensitiveness, but did not diminish the size of the effusion. At the end of this time, the positive electrolytic needle was inserted into the mass, and the negative sponge was pressed above the pubes. A current from eighteen cells was applied for ten minutes. At the end of a month scarcely a trace of the effusion could be felt. Before resorting to electrolytic puncture, the application of the current as first employed in this case, should be tried, as it does not require an anæsthetic and avoids the slight risk which accompanies even small wounds.

The author presented the following conclusions:

1. Electrolysis is a useful agent in the treatment of certain cases of fibroid tumors of the uterine walls and of chronic circumscribed periuterine effusion.

2. When applied to fibroid tumors of the uterus, electropuncture is a most reasonable and efficient method.

3. In the treatment of fibroid tumors by this agency, it is unnecessary to apply it often.

4. Cases of perimetric effusion to be treated by this method, should be selected with care in reference to the absence of all acute symptoms.

Dr. James R. Chadwick, of Boston, had tried electrolysis in one case of fibroid tumor, introducing the needle through the abdominal wall. This caused a smart attack of peritonitis. During the following year, there was no decrease in the size of the tumor. A few weeks later he was called in consultation to see a case which had an enormous pelvic abscess as the result of electrolysis. This deterred him from continuing the treatment further.

Dr. George J. Englemann, of St. Louis, said that by puncturing through the vagina, and, if possible, through the tissue of the uterus, we avoid the dangers of inflammation which accompany abdominal puncture. The same results can be accomplished without anæsthesia, and with less danger, by introducing one electrode in the diseased tissue and concentrating the total effect upon that electrode, by using a large electrode in connection with the other pole.

Dr. James B. Hunter, of New York, remarked that his experience with this method of treatment had been limited, but he could not say that he had seen one case of fibroid tumor permanently relieved by electrolysis. In one case in which it was freely used by Dr. Freeman and himself, he had subsequently operated and removed the tumor by hysterectomy, the patient making a good recovery. He could find no evidence of the effect of the current on the tissue of the fibroid.

Dr. Matthew D. Mann, of Buffalo, had employed this agent in one case, plunging one needle into the tumor from behind through Douglas's cul-de-sac, with a sponge electrode over the tumor on the outside. The current was kept up fifteen minutes. Six applications were employed. The size of the tumor was much diminished, and the tenderness and pain were lessened. The patient is now able to attend to her duties.

Dr. James B. Hunter, of New York, then made some remarks on

PERSISTENT PAIN AFTER ABDOMINAL SECTION.

Abdominal section is, as a rule, performed for pain, and if this still persists, one of the objects of the operation has not been accomplished. Pain before operation may be due to various causes. It may be located in the ovaries, when it will be increased by menstruation. Disease of the tubes is a cause of pain in a large number of cases. The pain of peritonitis is of great importance. Acute peritonitis may be limited to the region of the ovaries and tubes, and the pain caused by it may be periodical in character. The presence of adhesions interfering with the mobility of the intestines and other organs, is a frequent cause of pain. A severe form of pain may also be caused by displacements of the uterus.

Abdominal section is performed for the relief of pain, and the organ at fault is successfully removed, and the patient recovers, but the pain continues. If there is no marked relief at the expiration of twelve or eighteen months, if the patient has been favorably situated, the

operation may be pronounced a failure so far as the patient is concerned. Such pain may be due to former peritonitis, to peritonitis following the operation, or to some defect in the abdominal wall.

Many of the cases which have been cured of diseases endangering life still suffer pain. Peritonitis following the operation is a cause of pain in a certain number of instances. A slight amount of peritonitis often occurs after abdominal section, and it may leave some slight adhesions interfering with the mobility of the viscera. Inflammation in the region of the stump often causes its attachment to the abdominal wall, and thus causes pain. Sometimes the uterus is fixed by inflammation, and the distention of the bladder causes pain. Adhesions of the intestine may also cause pain. Pain may result from defective union of the abdominal incision allowing a ventral hernia. Pain in the cicatrix may occur, as in other situations.

In the way of prophylaxis, the utmost precaution should be taken to prevent the development of peritonitis: especial care should be taken to do no violence to the intestines; antiseptic precautions should be adopted; the stump should be tied with aseptic silk. The early and judicious use of drainage and irrigation will go far toward preventing inflammation. The cold coil with antipyrin should be resorted to, if there are any indications of peritonitis.

In the treatment of the pain, blisters, vaginal injections, and the use of iodine may be resorted to. The internal use of opium is usually demanded. Such treatment can, however, scarcely be expected to cure the pain. Rest in the horizontal position is perhaps better than any medicine. If all palliative measures have been tried, and at the end of twelve or eighteen months there is no improvement, a second operation may be warranted. The dangers of operative procedure, and the uncertainty of the operation causing any improvement, must be stated to the patient. If the patient prefers the operation, an exploratory incision should be made. In one case the speaker had found a loop of intestine attached to the uterus, which he loosened with a good result. In another case considerable relief was afforded. As a rule, however, it is not possible to separate adhesions, and if separated they are prone to unite, and fresh peritonitis is apt to follow. Often the exploratory incision is all that can be made.

Conclusions:

1. All cases of abdominal section done for the relief of pain should be carefully followed up for at least two years, and not counted as cured simply because the operation has not been fatal.

2. Peritonitis following operation is to be dreaded as much for its remote consequences as for its immediate danger.

3. Extreme caution is demanded when the operation is undertaken where there exist the physical signs of chronic peritonitis.

4. Secondary operations, as a rule, are of no value, although occasionally they may afford relief.

5. Where the operation is done for the relief of pain, a guarded prognosis should be given. There are certain chances that a perfect cure will not result even if the operation itself is entirely successful.

Dr. A. J. C. Skeene, of Brooklyn, said that among the causes of pain after laparotomy, he would place the ligature. In tying the pedicle after removal of the ovaries, some traction must be made upon the broad ligament and the nerves must be drawn upon. That form of pain may disappear. Another cause of pain is the application of the ligature just tight enough to arrest hemorrhage without destroying the nerves. He thought that we have more pain after the use of the ligature than after the use of the cautery clamp. The cautery as a means of treating the pedicle has never been thoroughly tried in this country.

In regard to what constitutes success after abdominal section, he stated that many of the cases which he had reported as failures have subsequently turned out to be most successful.

Dr. R. Stansbury Sutton remarked that Dr. Hunter had, in his paper, alluded to a case on which he operated two and a half years previously. In this case the ovary was surrounded by a coil of intestine which had endergone fatty degeneration to such an extent that its own weight was sufficient to cause it to break. He, Dr. Sutton, removed the ovary with the diseased bowel and brought the edges of the intestine together. The woman recovered, but she was not cured of her pain. It is not often that we have the opportunity during life to determine the results of a resection of the intestine. He asked Dr. Hunter to state what he had found.

Dr. W. Gil Wylie, of New York, objected that the author appeared to have completely ignored the general condition of the patient. What will cause pain in one person will not in another. With reference to peritonitis, he regarded it as a condition behind which there is some disease. In chronic peritonitis there is often some cause which keeps renewing the inflammation. In many of the cases that suffer after operation, the pain is due to imperfect operation. Sometimes a small portion of diseased tissue is left. He had taken the precaution to destroy the diseased tissue that may be left beyond the ligature, either by carbolic acid or preferably by Paquelin's cautery. This has lessened the mild attacks of peritonitis. Sometimes the inflammation is centred around the ligature, leading to abscess and the formation of a sinus. In some of these cases the trouble can be cured by dilating the sinus and fishing out the ligature. In many cases the peritonitis is due to the bursting of a small cyst. He had intentionally burst these cysts on the table, put the patient to bed, and watched the case.

Again, in cases where there is chronic inflammation of the lining membrane of the uterus this is not always cured by removal of the tubes and ovaries. This may cause pain not only in the uterus, but reflexly in other parts of the body. These pains can often be cured by dilating the uterus and applying carbolic acid.

Dr. Robert Battey, of Georgia, stated that he experienced the difficulties alluded to by Dr. Hunter. All are familiar with the neurotic woman. As a result of a carious tooth, an intense neuralgia may be set up which may continue for years, and not be relieved by the removal of the diseased tooth. This is probably due to an alteration in the nerve tissue itself. He had carefully considered the explanation that these pains persisting after abdominal section were due to inflammation and adhesions, but he had wholly failed to find a satisfactory explanation in this quarter. The neurotic cases which have given him the most trouble have been

almost uniformly those where he was unable to find any such deposit in the pelvis.

The speaker had said that at the end of twelve or eighteen months we should give up these cases as failures. He would qualify that statement by more than doubling the limit. Some of the cases which were most unsatisfactory at the end of a year, had achieved the most gratifying cure by the lapse of time.

Among the causes which produce this neurotic condition, he inclined to rank, in the first place, an acquired neurotic habit from long suffering. In looking for causes, he had been much struck by one point—that alluded to by Dr. Skene—that is, the use of the ligature, and especially a rather loosely tied ligature. Dr. Skene suggests the use of the cautery and clamp. The speaker formerly used a method which has not been alluded to, and that was the separation of the ovary from its attachment by the écraseur. In these cases he did not have any troublesome neuroses, and there was no hemorrhage. He had been seriously considering a return to this method of treatment.

With regard to treatment by a second opening of the abdomen, he called attention to the fact that by a simple opening of the abdomen, for purely diagnostic purposes, unaccompanied by any great disturbance of the parts, the condition of the patient is often greatly improved, especially as regards pain. In a case of gonorrhœal inflammation, he opened the abdomen after the failure of all other methods of treatment. Finding everything glued down by adhesions, he abstained carefully from all manipulation after satisfying himself of the entire impracticability of any operation. The patient, without any deception on his part, gained the impression that the ovaries and tubes had been removed. She has now been under observation two months, and the relief has continued. Before the operation, she used full doses of morphia, but since then she has used no anodyne whatever. She has not menstruated since the operation.

He thought that, after removal of the ovaries and tubes, the uterine trouble will get well, but the cure may be hastened by applications to the interior of the uterus of a solution of iodine in carbolic acid.

Dr. H. P. C. Wilson, of Baltimore, was satisfied that while cases do occur where the pain after laparotomy continues as a result of local adhesions, yet the majority of cases belong to the class in which the condition is due more to the neurotic element than to the operation. Most of these are long-standing cases where the mental condition has become so morbid that the patient is almost insane on the subject of her ovaries and tubes. Even if these organs are removed, the neurotic condition may remain for a long time. Where the woman has to work, and has not time to think of herself, these pains more rapidly disappear than where she is pampered with every luxury. Nothing is so good for the relief of these pains than exercise by walking. There is one remedy of which he uses more than any other drug in the materia medica: that is assafœtida. He never orders less than sixty pills. This tends to keep the mind occupied, and these conditions are more mental than physical.

Dr. Matthew D. Mann, of Buffalo, supposed that Dr. Skene,in speaking of the ligature, referred to silk. He did not see that the objection would hold against catgut. Dr. Mann had used this in a number of cases and had no trouble with it. As regards the time after operation at which recovery may occur, he had seen it take place long afterward.

Dr. Hunter, in reply to Dr. Sutton, said that the patient was suffering much pain, which was increased on defecation. On opening the abdomen a little to the right of the original incision, he found the attached portion of the gut. A white oblique line showed where the two portions of the gut had united, and this was fastened to the abdominal wall. It showed a very satisfactory result. The condition was neither improved nor made worse by the operation. The neurotic condition has been referred to, but he considered this secondary. As regards chronic metritis, he agrees with Dr. Battey that usually after removal of the ovaries nothing more is required. He was willing to admit that his limit was too short and should be extended to two or three years. It is not well to expect any improvement after removal of the ovaries and tubes for at least twelve months. As long a time as this is required by the system to become accustomed to the changed condition.

Dr. James R. Chadwick, of Boston, then read a paper on

THE BLUE DISCOLORATION OF THE VAGINAL ENTRANCE AS A DIAGNOSTIC SIGN OF PREGNANCY.

He had made it a point in all cases of early pregnancy to make a note of how much discoloration he could detect. He had tables of four hundred and forty cases examined. He had divided the discolorations into four groups, 1st, *doubtful*, where it was so faint that he could not be certain of its presence; 2d, *suggestive*, where it was more marked; 3d, *characteristic*, where the discoloration, though faint, is confined to the anterior wall of the vagina and more particularly to the urethra, just below the meatus and on either side of the meatus. In every instance, with one exception, where this was present, the woman was pregnant; and 4th, *marked*, where the congestion has become deep and exhibits the appearance constantly seen during pregnancy. He did not claim that the characteristic discoloration is seen in every case, but if carefully looked for, it would be found quite pronounced in the majority of cases. The color varies from a violet to dusky, or almost black. He claimed that this sign was of especial value in cases of retroversion, where the size of the uterus could not be determined, and in extrauterine pregnancy. He had obtained much assistance from it in a few cases of pregnancy accompanied by fibroid tumors, and also where there was a large accumulation of abdominal fat This sign is of decided value in the early months of pregnancy, but its absence should not be accepted as a positive proof against pregnancy, Cases were cited in which the discoloration had been observed in the seventh or eighth week of pregnancy.

Dr. H. P. C. Wilson considered this one of the most valuable means of diagnosticating pregnancy in the early stages. It is invaluable in cases where women wish to deceive you.

Dr. A. J. C. Skene regarded this as a most reliable sign in the early months of pregnancy. He believed it to be an illustration of the physiological hyperæmia of the formative stage of development.

Dr. Joseph Tabor Johnston, of Washington, stated that some years ago he had referred to this point, and

the discussion which followed seemed to indicate that the discoloration was a congestion produced by interference with the return of the venous circulation by the pressure of the enlarged uterus. It was held that the same discoloration could be produced by any other tumor which would have the same effect as the pregnant uterus.

Dr. William H. Parish, of Philadelphia, remarked that in regard to the continuance of the discoloration after labor, he had noted that in primipara where involution of the vagina takes place completely, the discoloration disappears with corresponding rapidity. Where there is subinvolution, the blueness may continue for a longer time. In multiparous women, where the blueness was marked, he had associated it with a condition of subinvolution of the vagina.

Dr. Chadwick, in closing the discussion, said that he had failed to note any persistence in the discoloration described. The general discoloration may persist, but the characteristic blueness will be found to disappear. He had looked for this sign in forty or fifty cases of fibroid tumor and had not found it in a single instance.

Afternoon Session.

Dr. R. Stansbury Sutton exhibited the specimens from three cases of

SUPRAVAGINAL HYSTERECTOMY

and made some general remarks on the operation.

Dr. W. Gil Wylie thought that, in the large number of cases, all that is necessary can be done by the vagina. In many cases of fibroid tumor, however, where hysterectomy has been performed for hemorrhage, curetting the cavity of the uterus would probably have obviated the necessity for the operation. Fibroid tumors cause hemorrhage by enlarging the uterine cavity. Where there is hemorrhage, there is nearly always granulation. With the curette, not only may the hemorrhage be brought to a normal standard, but he had seen the tumor diminish in size. It had appeared to him that fibroid tumors have a period of development and a period of decay. After a fibroid tumor has continued five or eight years, its vitality is lessened and it may diminish in size. This is not the case in all instances, and we meet with cases in which, if hysterectomy is not performed, the patient will die as the result of the hemorrhage.

Dr. Reamy, of Cincinnati, thought that if Dr. Wylie uses the curette in cases of fibroid tumor, he must, notwithstanding the adoption of all antiseptic precautions, have a certain number of cases of septicæmia. Curetting is much more likely to be followed by septicæmia when there is a fibroid tumor of the uterus than when the operation is done for ordinary fungous granulations. He believed that curetting under such circumstances would be almost as dangerous as the removal of the tumor.

Dr. Wylie, in reply, said that, so far as his experience went, he had had no trouble whatever. He invariably uses antiseptics before the operation and douches out the cavity afterward. He had never had septic poisoning in any case of curetting, and would not hesitate to use the instrument in any case of fibroid tumor with hemorrhage. He employed the bichloride solution, one to two thousand, in the vagina and one to five thousand in the uterus.

Dr. Wilson said that where we have excessive hemorrhage from a fibroid tumor, he believed that there is no remedy so efficient as the curette. He had never seen any evil results from its use.

Dr. Reeve asked whether any of the members had any experience with incision of the cervix in the treatment of fibroid tumors. This was highly recommended some years ago.

Dr. Sutton stated that he had tried division of the cervix and had stopped the hemorrhage, and had seen rapid fatty degeneration of the tumor occur in one case. He had tried curetting, the injection of iodine, and many other plans of treatment, and had obtained good results by all.

Dr. William H. Parish, of Philadelphia, then read a paper on

THE HIGH MORTALITY OF THE RECENT CÆSAREAN OPERATIONS IN THE UNITED STATES, WITH THE REPORT OF A CASE.

S. M., married, was admitted to the Philadelphia Hospital, while in labor, September 20, 1885. She was the mother of two children, the last of which was born twelve years previously. Labor had begun on September 18th, the membranes soon rupturing. She was seen by two physicians, who had her sent to the hospital. The cord had prolapsed and the pulsations had ceased before she was sent to the hospital. On admission, she was found much exhausted, with the cord protruding from the vagina. The resident physician not recognizing the gravity of the case, Dr. Parish was not summoned until some hours after her admission. At this time the uterus was in a state of tonic spasm. The patient was etherized. The vaginal examination revealed merely a rigid condition of the cervix. The pelvic canal was roomy. The hand was introduced into the vagina and two fingers into the uterus. This examination showed two hard intramural fibroid tumors about the internal os. The author concluded that Cæsarean section should be performed without delay, and three of his colleagues were sent for in consultation. They all agreed that attempts at enucleation should not be made, but they did not agree as to the necessity of Cæsarean section. They were in favor of craniotomy. The skull was perforated, but it was found impossible to grasp and crush the head. Various instruments were tried without avail. The necessity for Cæsarean section was then conceded by all. The uterus had been emptied of its waters for at least forty hours. The vagina and lower part of the uterus were washed out with a solution of corrosive sublimate. The abdomen was opened and the section of the uterus made. The cervix was closed by tying around it a rubber drainage tube. At once a very offensive gas escaped. A large child was removed. The placenta was not in the line of the incision. Antiseptic precautions were employed during the operation. Deep and superficial sutures were introduced into the uterus, and the abdominal incision closed. A hypodermatic injection of ergotin was at once administered. After the operation the tube around the neck was removed. The patient died twelve hours later from exhaustion and rapidly developing septicæmia. At the autopsy the lips of the uterine incision were found in contact. Three dense intramural fibroid tumors were found.

Dr. Parish then referred to the great mortality of this operation in the United States, and presented the statistics of Dr. Robert P. Harris, of Philadelphia, of which the following is a synopsis:

Cæsarean operations in the United States .	144
Women saved, 37.5 per cent. . . .	54
Children living when delivered . .	64
First fifty operations, saved, 54 per cent.	
Second fifty operations, saved, 24 per cent.	

Operations performed in good season when the condition of the woman was favorable have in this country saved seventy-five per cent. of the women, and eighty per cent. of the children.

Cæsarean section has been performed in thirteen cases where the obstruction was due to fibroid tumors, and of this number four recovered and five children were living. The time in labor in the saved cases was nine and one-half hours, fourteen hours, three days, and four days.

The following rules were then given for the performance of the operation:

1. Carefully determine the degree of obstruction and operate early in labor, as soon as the os is sufficiently dilated to permit drainage and before the rupture of the membranes. 2. Operate with full antiseptic precautions. The spray over the abdomen is unnecessary. 3. Control hemorrhage by compression of the cervix, either with a rubber tube or manually, preferably by the latter means. 4. Introduce numerous deep and superficial sutures so as to approximate accurately the muscular walls of the uterus, but do not carry the sutures into the endometrium. Removal of a section of the muscular wall is unnecessary. 5. Protect the peritoneum from the discharges, and if it becomes soiled it should be carefully cleansed. 6. Ergotin should be administered at the beginning of the operation.

Dr. Reamy stated that in three thousand cases of labor he had never made a Cæsarean section nor any of its modifications. It is only now that the people are coming to recognize that craniotomy is not to be performed in any but the rarest instances, and that the sacrifice of life is unjustifiable. The explanation of the better results in other countries is not so much in the skill of the operators as in the condition of the cases when operated upon.

Dr. Parish agreed with Dr. Reamy, that craniotomy should be an operation of exceeding rarity. The people are not yet ready in this country to accept Cæsarean section, but one of the great troubles is with the general medical profession, who regard this as an operation almost necessarily fatal.

Adjourned.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, September 24, 1886.

First Vice-President, Dr. J. C. Cameron, in the Chair.

OVARIAN TUMOR.

Dr. Trenholme exhibited a large ovarian tumor, weighing some sixty pounds, which he had removed from a patient a few weeks ago. The woman was aged fifty years, and had suffered for years from this tumor, which had been frequently tapped. Extensive adhesions to the parietes, intestines, stomach, and liver were met with, and separated with great difficulty; the patient recovered well from the operation, but died of exhaustion on the eighth day. Dr. Trenholme remarked that the extensive adhesions found in this case were due to the frequent tappings, a practice which he deprecated. He had, during the past three months, performed ovariotomy four times, with three recoveries.

CASE OF SCURVY.

Dr. R. L. MacDonnell related the clinical history of a case of scurvy which had ended fatally by cerebral hemorrhage. The patient, a young farm laborer from the eastern townships, had for the last year lived on a diet composed exclusively of bread and butter, tea, milk, sugar, with no other vegetable than potatoes, and no meat whatever. Three months ago his health began to break down; he suffered from weakness, drowsiness, and indisposition to work, bleeding gums, and epistaxis, while the body became covered with bruise-like patches of discoloration, which appeared first upon the legs and then spread over the body. There had been rapid loss of weight. The main symptoms on admission were the presence over the body generally of small purplish patches of a petechial kind, sponginess, ulceration, and recession of the gums, and great debility. After four days' residence in the Montreal General Hospital, severe headache and vomiting set in, the patient became very feeble, semi-conscious, and died.

Dr. R. J. B. Howard, who had made the autopsy, exhibited the brain, lungs, and heart. A large hemorrhage had taken place into the right cerebral hemisphere under the lateral ventricle, forming a cavity with ragged walls, which occupied the whole of the right temporo-sphenoidal lobe, and extended forward into the frontal and backward into the occipital lobe, converting the lower part of the right hemisphere into a mere shell. The surface of the heart was covered with extensive subpericardial hemorrhages, and in both lungs there were many hemorrhagic infarcts, but no subpleural effusions.

ANEURISM OF THE THORACIC AORTA.

Dr. Kennedy related a case of death from aneurism in which he had a day or two ago performed a post-mortem. The patient, a man aged forty-one, for the last three years had suffered intensely from neuralgia of the lower left intercostal, and had consulted many physicians without obtaining relief. He died suddenly while sitting in a chair. The most-mortem revealed the cause of death to be the bursting of a large aneurism of the thoracic aorta in the left pleural cavity. The ribs and left sides of the vertebral column were much eroded. Dr. Kennedy remarked that it was strange that the cause of the neuralgia had never been recognized during life. There was also found a large aneurism of the abdominal aorta.

Dr. George Ross said that a year ago he had seen this patient, and had carefully examined him for aneurism, but there were absolutely no physical signs to be found. Suspecting, however, that the severe and persistent pain was due to the pressure of an aneurism, he kept the patient in bed and put him on large doses of iodide of potassium, with the result of almost entirely

relieving his pain. This confirmed his diagnosis of aneurism.

CASE OF BRAIN INJURY DUE TO ENTRANCE OF A TIN PEA-SHOOTER THROUGH THE ORBITAL OPENING.

Dr. Casey Wood related the following case: R. R., aged four years, was running along the street, holding in his hand a tin pea-shooter, three-eighths of an inch in diameter and eighteen inches long. He fell and struck his head against the end of the tube when held upright in his hand. The hollow cylinder passed through the left lower eyelid, about a quarter of an inch from the margin of the orbit, and penetrating two and three-quarter inches, inflicted an injury to the brain. The tube was with difficulty withdrawn by a passer-by, who noticed upon the end of it some putty-like substance mixed with blood.

The accident occurred on the 10th of May, about ten o'clock A. M., and when the child was seen shortly afterward he was unconscious. There were extensive contusion and œdema of tissues surrounding wound. The left pupil was dilated, with no response to light; the right pupil was normal and responded to light. The pulse was very weak and slow. Vomiting almost constant. Respiration was labored and slow. The child was pale and restless, and the vomiting continued during the day. There were slight proptosis, complete motor and sensory paralysis of right side, with convulsive movement of right arm and leg—these movements being chiefly marked in right arm. The convulsive movements continued all day, and for a time before they ceased there was simply spasm of right arm. Child was unconscious at 9 P M. Temperature, 100 F.

Dr. Wood advised the parents to have the useless eyeball removed, so as to establish proper drainage from the cerebral wound, but this was refused. He attempted to keep wound open by introducing a probe, and inserting a drain of cotton, which, however, proved inefficient.

There was much inflammatory action about the orifice of the wound, and the eye was involved. A week after the accident, the patient had a distinct return of consciousness, which lasted a day or two. Ten days after, the patient became comatose, and died on the 29th of May, nineteen days after the injury. Dr. Wood was unable to obtain leave to make a post-mortem examination, but thinks there is little doubt that the track of the wound, after piercing the left lower eyelid, extended from a point midway between the outer and inner angles of the foramen, destroyed the nerve, and passed through the roof of the orbit, and entered the brain near the fissure of Sylvius. The author went on to say that there was no doubt that the patient died of septic meningitis, and thought it a matter for regret that the proper treatment, viz., enucleation of the eyeball, cleansing the wound, and establishing a deep drain, was not carried out, because of the objection made by the parents.

Dr. Shepherd thought, with Dr. Wood, that the only hope of recovery in these cases was the proper cleansing and drainage of the wound, and keeping the parts perfectly aseptic. He related a case of injury to the skull, due to a kick of a horse, where there was an extensive depressed fracture; the brain could be seen pulsating. As there were no symptoms of compression, Dr. Shepherd had treated the wound antiseptically; the bandage was put on firmly, and within a few minutes the patient had a severe epileptiform convulsion, and lost consciousness. On removing the bandages, the patient recovered and had no more fits, and the wound healed rapidly. When last seen, five months after the injury, the patient was perfectly well. The slight extra pressure caused by the bandages was sufficient to produce grave symptoms.

NEW INVENTIONS.

A NEW SERIES OF METRIC TEST-LETTERS AND WORDS FOR DETERMINING THE AMOUNT AND RANGE OF ACCOMMODATION.[1]

By CHARLES A. OLIVER, M.D.,

one of the ophthalmic and aural surgeons to st. mary's hospital, philadelphia, etc.

This set of reading-types has been made upon the same basis that governed the test-types presented at last year's meeting of the Society. By reason of this conformity an examination of acuteness of vision and accommodative action by means of these two series serves to place the results upon a uniform and proper foundation. The following advantages over other reading-types may be claimed:

First, the Letters. The Snellen block letter has been preserved.

Second, the Character and the Arrangement of the Words. The letters C D E T O L F are made into words of one or two syllables, and placed in columns. They are so arranged that a word composed mainly of vertical and horizontal strokes is followed by a word made of a majority of curved lines, no matter in what vertical or horizontal direction the columns may be read.

Third, the Sequence. The smallest type is placed first, each increasing type following in succession, until one equivalent to two dioptrys is reached, which finishes the card, leaving but a half dioptric separation between this card and the large one.

Fourth, the Interspace. Each word and letter is surrounded by a space equal to or greater than its own area, thus preventing any letter or word from being confounded with its neighbors.

Fifth, the Gradation. The following sizes are employed: 0.25 D., 0.50 D., 0.75 D., 1 D., 1.50 D., and 2 D.

Sixth, the Construction. The letters are phototypes. The card is made of heavy neutral gray cardboard, with rounded corners. The letters are printed upon a sunken surface, thus keeping them free from dirt by contact through handling, or by the card being placed upon dirty surfaces.

James W. Queen & Co., of 924 Chestnut Street, Philadelphia, have kindly superintended the construction of the cards, and to them the author here desires to express his thanks for careful and satisfactory work.

[1] Abstract of a paper read before the American Ophthalmological Society, July 22, 1886.

NEWS ITEMS.

PARIS.

From our Special Correspondent.

Treatment of Glaucoma.—At a recent meeting of the Academy of Medicine, M. Panas spoke in high terms of a new therapeutic remedy suitable to some forms of glaucoma. Eserine, though one of the most active myotics, cannot always be endured, and pilocarpine in some respects is preferable, although less active. The different collyria which are used are composed either of five centigrammes of eserine to five grammes of water, or of ten centigrammes of pilocarpine to five grammes of water. The improvement is very rapid, but in order to obtain a cure, one of these collyria must be used for several months. When first used, five or six instillations should be administered in twenty-four hours, afterward gradually decreasing the applications to one or two instillations *per diem*. Those forms of glaucoma in which this treatment has proved beneficial are precisely those in which iridectomy or sclerotomy has been inefficacious.

Connection Between Noises in the Ear and Stomach Affections.—Dr. E. Ménière, in an article in the *Revue de Laryngologie et d'Otologie*, mentions the frequent connection which exists between noises in the ear and stomach affections. Dyspeptic or gastralgic patients suffering from these complaints are very numerous. In some cases dyspnœa is accompanied with noises without the hearing being in any way affected. In those cases where there is no aural lesion the cause of the symptoms should be sought for in the internal ear, and it will be found that some connection exists between complaints of this kind and vertigo of the stomach. The noises in the ear vary, sometimes resembling whistling, boiling water, but never the isochronous beatings of the pulse. Otologists should, therefore, carefully find out, when patients complain of noises in the ear and deafness, whether this state is not due to disturbance of the digestive organs. Noises in these cases are more frequently noticed during the second or third year, and even later. According to M. Ménière, they affect only one ear. M. Leden speaks of having met with cases in which both ears are affected. When considerable deafness occurs, it is often incurable; under these circumstances increase or decrease of noises is, in some cases, identical with the dyspeptic state of the patient. Local remedies give, as a rule, very poor results; the most rational course is to treat perseveringly the stomach affection, which undoubtedly is the origin of these complaints, which are at once painful and liable to bring on serious disorders. In some cases the lesions of the internal ear, although not serious, may prove sufficiently lasting as to determine the persistence of noises which are more or less noticeable.

Hysteria in the Army.—The question of male hysteria is one of great interest to army physicians. They have frequently to diagnosticate simulated hysteria and epilepsy. In some cases the diagnosis is easy, as the phenomena are identical with those of female hysteria, but these cases are exceptional, military hysteria presenting, as a rule, milder aspects. When stigmata appear in persons subject to epileptic fits, a positive diagnosis is indicated; in less evident forms it is more difficult to arrive at a definitive diagnosis. In order to determine the nature of the nervous disturbance of the patient, a careful examination should be made to detect any of the sensitive and sensorial modification or any of reflex action, suppression of pharyngeal reflex action, persistence of reflex action in the tendons. Also, if electro-muscular contractility is preserved whether, there is perversion of the muscular sense. Furthermore, a military doctor must be able to detect hysterical paralysis which may be occasioned by traumatism. This kind of paralysis is not included in those diseases which give the right to retire from service, but only enables the patient to obtain a sort of renewable pension, so that besides the scientific interest which the disease presents, physicians should study it from an economical point of view and thus be on their guard against deception and also against faults in the diagnosis. The diagnosis is more difficult when the hysterical patient is clever at deception or under the influence of an undue indulgence in alcohol or absinthe. M. Emile Duponchel has written a book entitled *L'hystérie dans l'Armée*, which exhaustively treats the subject.

Pasteur's Critics.—A Paris correspondent of the London *Standard* says: "After having been the idol of an hour, and after seeing the French in their enthusiasm subscribe a large sum of money for the establishment of an institution which is to bear his name, M. Pasteur is now becoming the object of virulent attacks. It is chiefly among the radicals, and those whose scientific knowledge is very limited, that M. Pasteur's detractors are to be found. A certain number of doctors have, it is true, recently pronounced against the efficacy of his treatment against hydrophobia; but the great majority of the medical faculty reserve their judgment for the present. Dr. Lallier, one of the medical celebrities of Paris, in a long conversation I had with him on the subject, spoke in the highest terms of the patient researches which have already enabled M. Pasteur to make valuable discoveries. As for M. Pasteur's good faith, Dr. Lallier has not the slightest doubt, for he is well acquainted with him, and is quite sure that he would never affirm anything unless he was himself perfectly convinced of its truth. Though Dr. Lallier admits that the inoculations appear to have protected those who followed M. Pasteur's treatment from hydrophobia, at least in the great majority of cases, he nevertheless holds it necessary not to pronounce definitely in favor of that treatment, and for the following reasons: First, because sufficient time has not yet elapsed since the first person was inoculated by M. Pasteur to prove that the germ of hydrophobia has been destroyed or rendered innocuous. But that is not Dr. Lallier's main reason for refusing to pronounce on M. Pasteur's treatment. He pointed out to me that there was an obscure point which rendered that treatment a mystery. When a person is vaccinated against smallpox a virus is introduced into his system which gives him the disease in an attenuated form. The vaccine, to use the word commonly employed, 'takes,' and the vaccinated person has a certain amount of fever. In the case of persons being vaccinated against smallpox, after they have already been attacked by that disease, Dr. Lallier affirms that till now there has been no

proof forthcoming to show that the intensity of the attack of smallpox is diminished by the vaccination. M. Pasteur's treatment, therefore, puzzles him, for, when inoculated by M. Pasteur, the patient has only the germ of hydrophobia in his system, but the liquid substance which is introduced into his body has no apparent effect —that is to say, the patient is not in the least ill, and does not suffer from even the attenuated symptoms of hydrophobia. By vaccination the patient is given smallpox in a mild form when he has not the germ of that disease; whereas when a person is inoculated against hydrophobia he has already the germ of that disease, and is not given it in any form whatever."

Unusual Suicide.—Mr. William Allen reports, in the *Dublin Journal of Medical Science* for March, 1886, a case of a prisoner who, on being informed that his wife had just been arrested, started off at full speed toward a wall some fifty feet away, and dashed the vertex of his head against it. So great was the concussion that the body rebounded three feet from the wall, and the man dropped dead without a struggle. The case is of interest from a medico-legal point of view, as had the man not been seen by witnesses to commit suicide, it might reasonably have been supposed that he had been struck by a keeper, or a fellow convict.

Diet Tables.—We have received from Messrs. Reed & Carnrick, of New York, a series of diet tables for use in the more common diseases, the lists being arranged in a manner convenient for removal and presentation to the patient. No such list can be complete, nor yet of universal application, but the one before us is a very creditable attempt and will often be found useful.

Effect of Wind on Traps.—The *Plumber and Decorator* cites a case where the seals of traps were affected by a high wind. The house in question was two stories high, with a basement; the horizontal soil-pipe was about thirty feet long from a running-trap to where it joined the vertical soil-pipe, which was forty-five feet high, carried well up above the ridge of the roof and about ten feet distant from it. On the basement, the first and the second floors were the usual fixtures, each with its own branch from the soil-pipe. The fresh-air inlet was two inches, the soil-pipe four inches, open at the top. The closet has a short hopper, and most of the traps were S-traps, with five-inch seals and no vents. Although the discharge of any fixture in the house has scarcely any effect on the seal of the traps of any other fixture, yet the wind caused a fluctuation of nearly one and one-quarter inches. There was no more wind than might occur occasionally in an ordinary season. The observer purposes to try the effect of ventilating-caps to see if they will prevent the fluctuation of water in the traps caused by wind.

A similar case occurred some years ago at Roxbury, Mass. In this case the soil-pipe extended above the roof, but there was no air-inlet on the house-drain. When the wind was blowing strongly the seals of the traps in the bath-room were disturbed, and an experiment showed that the air in the soil-pipe was rarefied, producing a suction tending to break the trap-seals. In this case the want of an air-inlet seemed to be the cause. In the English case the air-inlet was probably too small when the great length of soil-pipe was taken into consideration.

Minnesota Opium.—During the year 1885, Emil Weschke experimented on the cultivation of different species of Papaver at New Ulm, Minn., and from the unripe capsules of P. somniferum prepared a quantity of opium which, in the air-dry condition, contained 2.8 per cent. of moisture, and, after drying, yielded 15.23 per cent. of morphine, 0.325 per cent. of narcotine, 0.416 per cent. of codeine, and 3.5 per cent. of meconic acid. The author does not believe that the cultivation of the poppy for the production of opium in this country would be attended with profit.

Surgeon Barbers.—The *Boston Post* says that "barbers were originally surgeons," and adds, apparently with much feeling, "a great many of them are now."

Milk and Throat Disease in Canterbury, England.—The medical officer of health of Canterbury has reported a sudden outbreak of throat disease, which, in eight days, attacked no less than 231 persons, without fatal effects in any instance. So far as can be judged, the epidemic was due to milk, for of 160 houses served from the dairy which is in suspicion no less than 94 were affected, and, so far as can be gathered, out of 36 houses partly supplied from the same dairy and partly by other milkmen 21 were affected. In the other instances of houses affected the persons in question seem almost exclusively to have been those who were either attacked late during the outbreak, and under circumstances which admitted of their having derived the infection from antecedent cases, or else persons who may easily have partaken of the suspected milk elsewhere than in their own homes. So far, says the *Lancet*, the reports on the case are, we trust, incomplete, for by far the most interesting feature of the case is the implied sickness of animals in connection with the outbreak, and the history as to this is as yet very imperfect. Indeed, we only learn of a lamb in the suspected dairy premises having suffered from "sore throat," and of cows having had "diarrhœa." The connection now established between disease in the human subject and affections of a specific character in lower animals, and especially in cows, is of far too great importance to admit of such a case being passed over by such vague accounts in so far as these animals are concerned. It is to be hoped that skilled veterinary and pathological aid was secured, either through the Local Government Board or otherwise, and that a more complete report will be issued.

Medical Instinct in Animals.—Animals get rid of their parasites by using dust, mud, clay, etc. Those suffering from fever restrict their diet, keep quiet, seek dark, airy places, drink water, and sometimes plunge into it. When a dog has lost its appetite, it eats that species of grass known as dog's grass, which acts as an emetic and a purgative. Cats also eat grass. Sheep and cows, when ill, seek out certain herbs. An animal suffering from chronic rheumatism, always keeps, as far as possible, in the sun. The warrior ants have regularly organized ambulances. Latreille cut the antennæ of an ant, and other ants came and covered the wounded

part with a transparent fluid secreted in their mouths. If a chimpanzee is wounded, it stops the bleeding by placing its hand on the wound or dressing it with leaves and grass. When an animal has a wounded leg or arm hanging on, it completes the amputation by means of its teeth. A dog on being stung on the muzzle by a viper was observed to plunge its head repeatedly for several days into running water. The animal eventually recovered. A sporting dog was run over by a carriage. During three weeks in winter it remained lying in a brook, where its food was taken to it. This animal recovered. A terrier hurt its right eye. It remained under a counter, avoiding light and heat, although it habitually kept close to the fire. It adopted a general treatment, rest, and abstinence from food. The local treatment consisted in licking the upper surface of the paw, which it applied to the wounded eye; again licking the paw when it became dry. Animals suffering from traumatic fever treat themselves by the continued application of cold water.

Providing for the Family of Professor von Gudden.—A gratuity of £10,000 has been granted from the Bavarian Civil List to the widow of Professor von Gudden, of Munich, who perished with the late King of Bavaria in the lake at Castle Berg. He left a family of eleven children.

Consumption of Tobacco in Europe.—M. Paul Leroy-Beaulieu, writing in the *Economiste Français*, gives the following figures, showing the quantity of tobacco consumed in the different countries of Europe, and the rate per 1000 inhabitants: Spain, 110 pounds; Italy, 128 pounds; Great Britain, 138 pounds; Russia, 182 pounds; Hungary, 207 pounds; France, 210 pounds; Denmark, 224 pounds; Norway, 229 pounds; Austria, 273 pounds; Germany, 336 pounds; Holland, 448 pounds; and Belgium, 560 pounds.

A Case of Rabies cured by hypodermatic injections of corrosive sublimate and atropine is reported by Dr. de Pietra Santa, in the *Journal d'Hygiene*. The man was bitten by an undoubtedly rabid dog, and developed symptoms of hydrophobia two and a half months later.

Large Bequest to a Western Medical College.—The late Samuel Ensworth has bequeathed a sum of about $100,000 in trust for the erection and maintenance of the St. Joseph Medical College and a hospital to be erected in St. Joseph upon such a site as may be selected.

A New Disinfecting Compound for purifying the atmosphere of the sick-room has just been presented to the Berlin Medical Society. Oils of rosemary, lavender, and thyme, in the proportion of 10, 2½, and 2½ parts respectively, are mixed with nitric acid in the proportion of 30 to 1½. The bottle should be shaken before using, and a sponge saturated with the compound and left to diffuse by evaporation. Simple as it is, the vapor of this compound is said to possess extraordinary properties in controlling the odors and effluvia of offensive and infectious disorders.

The Twins of Locana, who have been shown in almost every town of Europe as the successors of the renowned Siamese twins, are at present dying in Vienna, or at least are very ill. These twins, now aged ten, are united from the sixth rib downward. They have but one abdomen and a single pair of legs. One of these is under Jacob's control; the other, under that of John. They cannot walk, and cannot easily keep their balance. One is much stronger and healthier than the other, and eats more; it is Jacob, and he keeps his brother alive. Some time ago both quarrelled over a toy, and John got so excited that he fell into a state of syncope, or trance, from which he did not recover till the next day. He had already had an illness of the same kind, and Virchow, of Berlin, had prognosticated that a second one would kill him. This, Jacob knew well; so, of course, the illness of his brother (an apparently lifeless body) gave him all the more concern, since the death of his brother would but shortly precede his own. The physicians are doing their best to save the unfortunate children. Of course, no operation can be thought of in the present case. Even in that of the Siamese twins, there were great difficulties attending a surgical intervention; and, before it was resolved to intervene, death had already done its work. If the twins recover they will go to the States, where they were engaged, it is said, at the rate of $6000 per year; if not, their skeleton is already promised to a London anatomical museum for eight thousand pounds.

Value of Life.—Dr. Charles L. Dana discusses in the *Forum* the question, "Is life worth saving?" He places the value of an adult life to the State at at least $750, and its annual productive power at $95. One-half of all the deaths occur during the productive age, so that the 200,000 deaths at this period, which occur annually in the United States, represent an enormous loss to the country. It is also calculated that every death represents about two years of sickness, and that there are in this country about 1,500,000 persons sick all the time. In England and Wales it has been found that every workingman averages a week and a half of sickness in the year. It is estimated that the wage-loss from sickness in France is $70,000,000 each year, and from death $188,000,000.

Food Adulteration.—In an examination of foods by the chemists of the Massachusetts Board of Health, the following forms of adulteration were of most frequent occurrence:

Milk—addition of water or coloring matter, and abstraction of cream.

Butter—substitution of foreign fats, and addition of coloring matter.

Spices—addition of starch and other foreign powders. Especially true of pepper and mustard.

Cream of tartar—substitution of starch, gypsum, and other cheaper substances.

Baking powders—alum and other injurious ingredients. Baking powders have no legal standard, other than that of freedom from harmful ingredients.

Lard—presence of cheap fats and oils.

Olive oil—substitution of cheaper oils.

Jellies and preserved fruits—Substitution of cheaper fruits, and addition of coloring matter.

Vinegar—absence of the required amount of acetic acid, and addition of coloring matter.

Honey—substitution of cane sugar, glucose, and other substances.

Molasses—addition of glucose, presence of tin or other foreign substances.

Sugar—glucose, poisonous coloring matter.

Maple sugar and syrup—glucose.

Confectionery—terra alba, poisonous coloring matter, fusel oil, arsenical wrappers, etc.

Coffee—mixture or substitution of various cheaper substances.

Canned fruits, vegetables, and meats—metallic poisons.

The Drug Clerk.—The most satirical shot at illegible prescriptions that we have yet seen is the following from the *Medical Age:*

A gentleman received a note from his lawyer which he was unable to decipher. On his way to his office he met a friend at the door of a drug store. The friend, after vainly attempting to read the note, suggested that they step inside and hand it to the druggist, without comment. The druggist, after studying it in silence for a few minutes, stepped behind his prescription case, and in a short time returned with a bottle of medicine, duly labelled and bearing directions. When the gentleman saw his lawyer, he was informed that the note was a notice for him to call at his office between three and four P. M. of the following day. It is a pretty difficult matter to "stick" the regulation druggist.

The Seventeenth Annual Session of the Medical Society of Virginia, will be held at Fredericksburg, Va,. October 26, 1886.

Hydrophobia in 1806.—It has recently come to light that the State of New York, in 1806, paid to John M. Crous a thousand dollars for a remedy against hydrophobia which he considered infallible. The measure was advocated by DeWitt Clinton and Chancellor Kent. This remedy consisted of one ounce of the jaw-bone of a dog, burned and pulverized; the false tongue of a newly foaled colt, dried and pulverized; and a "scruple of verdigreas," raised on the surface of old copper by laying it in moist earth. The warrant of the Comptroller on which the money was paid, and the receipt of Crous, are on file with other State papers at Albany.

The Male Nipple.—During the late war, at a period when the success of the Union cause was pretty well assured, President Lincoln was invited by some distinguished engineers of the army to inspect a plan which had been drawn for a very elaborate and expensive system of defence for the City of Washington. After examining the drawings attentively he inquired what was the necessity for the works. "The defence of the capital," was the reply, "in the contingency of a Confederate invasion." The President thereupon was reminded of a story of a debating society of a Western town, where the question was discussed, "Why does a man have breasts?" Several nights of debate failed to elucidate the problem until the matter was submitted to a referee, who decided "that if, under any circumstances, however fortuitous, or by any chance or freak, no matter of what nature, or by what caused, a man should have a baby, there might be breasts to nurse it."

President Grévy, now nearly eighty years of age, lost his first tooth the other day. The Paris journals mention the fact as an event, and *Le Voltaire* regards it as an event of grave political significance. "Good teeth," says *Le Voltaire*, "are essential to good digestion, and bad digestion have played a great *rôle* in the history of kings and rulers. It is lucky for us," it continues, "that President Grévy has such sound teeth. To that fact must be attributed his unchanging calm, his ataraxy, the perfect equilibrium of his physical and intellectual functions, which have made him the most prudent of statesmen, and the most constitutional of presidents."

The French Academy of Medicine Prizes for 1887.—The arrangements for the prizes offered by the French Academy of Medicine for competition during 1887 are as follows: The Academy Prize (10,000 francs): "Vaginal Hysterectomy, the Indications and Operative Procedures." The Argenteuil Prize (10,000 francs); this prize, which is sexennial, will be awarded to the author of the most notable improvement in measures for the cure of urethral strictures, or to the author of the best work on the treatment of other diseases of the urinary passages. The Barbier Prize (2000 francs) will be given to the discoverer of the most efficient means of curing diseases considered incurable, such as rabies, cancer, cholera, etc. "Encouragement" may be accorded to those who come nearest to attaining the object without actually accomplishing it. The Henri Buignet Prize (1500 francs) is for the best written or printed work on the applications of physics or chemistry to medicine. Foreigners are not allowed to compete for this prize. The Capuron Prize (1000 francs): "Post-partum Involution, the Changes and Pathological States which result." The Civrieux Prize (1000 francs): "Vesical Neuralgias." The Daudet Prize (1000 francs): "Actinomycosis." Authors must present original observations made in France. The Desportes Prize (1200 francs) for the best work on "Practical Medical Therapeutics." The Ernest Godard Prize (1000 francs), for the best work on "External Pathology." The Hygiene of Infancy Prize (1000 francs): "A Clinical Study of Athrepsia." The Laval Prize (1000 francs), for the most meritorious medical student. The Lefèvre Prize (2000 francs): "On Melancholia." The Auguste Monbinne Prize (1500 francs) is a fund to be expended for scientific missions, etc. The Portal Prize (600 francs): "On Primary Renal Tuberculosis." The Saint-Lager Prize (1500 francs), for experiments to produce goitre in animals by administering substances extracted from the water or earth of goitrous regions. The prize will not be awarded unless the experiments have been successfully repeated by the Academy's commission. The Vernois Prize (800 francs), for the best work on hygiene. Competing essays for all these prizes must be sent to the Academy before May 1, 1887, written in French or Latin, accompanied by a sealed envelope and a device to identify the author. The condition of concealment of the author's name does not apply to competitors for the Argenteuil, Barbier, Buignet, Desportes, Godard, Monbinne, and Vernois prizes.

A Bald and Toothless Future.—In the October number of the *Popular Science Monthly*, Mr. V. G. Eaton writes under this caption, and from his paper the following extracts are made:

In most of the Eastern cities, fully thirty per cent. of the men over thirty years of age show unmistakable signs of baldness, while nearly twenty per cent. have spots on their heads that are not only bald, but actually polished with the gloss that is supposed to belong to extreme old age alone. I have been in the majority of the churches and theatres in all the large Eastern cities, as well as in Chicago, St. Louis, and other places of the West, and have verified my assertion by actual count. From my observation I find that bald-headed men are most plentiful in New York and Boston. After these come Philadelphia, Washington, and the Western towns.

Here are a few observations taken in Boston. Trinity Church: 243 men; 71 actually bald, 46 indications of baldness. King's Chapel: 86 men; 38 actually bald, 14 indications of baldness. Hollis Street Theatre, orchestra, at performance of the "Mikado:" 63 men; 27 actually bald, 10 indications. Boston Theatre—Judic: 126 men; 51 actually bald, 43 indications.

These observations were taken from the more cultivated classes of society, and do not give a fair representation of the Boston head, as repeated calls at the dime museums and cheaper variety performances demonstrated. For instance, of the thirty men seen in the seats of the World's Museum in Washington Street, but eight were bald, while only five others had thin hair, showing that baldness was simply a question of a very few years. Again, of forty men at Austin and Stone's Museum, twenty-two had their heads well covered; and at the Windsor Theatre (variety) I found less than twenty-five per cent. who had thin hair.

On the other hand, at shows and entertainments of more refinement, the bald-headed element was considerably larger. Of two nights when Patti sang at the Boston Theatre there were forty-six per cent. of bald heads on one occasion, and forty-two on the other. When De Lussan appeared in "Fra Diavolo" I discovered thirty-eight per cent. of baldness, and at one of Matthew Arnold's lectures there were forty-six per cent. In fact, out of hundreds of observations, extending over several years, I have found that the higher the price of admission, and presumably the more refining nature of the performance, the larger the per cent. of bald heads. One night I counted the occupants of a few settees in my immediate vicinity at an exhibition which John L. Sullivan gave at the Mechanics' Fair Building, and was surprised to find that less than twelve per cent. of the men were bald. As this was a show where the spectators had the privilege of retaining or discarding their hats at pleasure, I think it was not a fair test.

The same rule can be applied to the early decay of human teeth, and with the same results. Old men now living tell of a time when dentists were almost unknown. The family physician used to keep a pair of forceps and tooth-keys to pull out such teeth as insisted on aching for an unreasonable length of time, while the idea of false teeth was so strange that the person who had a set was an object of curiosity for the whole neighborhood. Now nearly half the people over twenty years of age have one or both jaws occupied by artificial teeth, and the sign of the dentist occupies a conspicuous place on many a street corner.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from September 28 to October 4, 1886.

Gibson, Jos. R., *Major and Surgeon.*—Granted two months' leave of absence, from September 25, 1886, on surgeon's certificate of disability, in lieu of the unexpired portion of the ordinary leave of absence granted him in S. O. 158, A. G. O., July 10, 1886. —*S. O. 227, A. G. O.*, September 30, 1886.

Gardner, Wm. H., *Major and Surgeon.*—Ordered from the Department of Texas to the Department of the East.—*S. O. 227, A. G. O.*, September 30, 1886.

Wales, Philip G., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended to include November 5, 1886.—*S. O. 226, A. G. O.*, September 29, 1886.

Kendall, Wm. P., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month.—*S. O. 81, Division of the Pacific*, September 24, 1886.

Mason, Chas. F., *First Lieutenant and Assistant Surgeon.*—Ordered for temporary duty at Fort Verde, Arizona Territory.—*S. O. 90, Department of Arizona*, September 20, 1886.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending October 2, 1886.

Gutteras, D. M., *Passed Assistant Surgeon.*—To Receiving Ship "Franklin," for temporary duty, October 3d.

Wentworth, A. R., *Assistant Surgeon.*—Detached from the Navy Yard, League Island, and to the U. S. S. "Galena," October 1st.

Scott, H. B., *Assistant Surgeon.*—Ordered to Navy Yard, New York, October 1st.

Ashbridge, Richard, *Passed Assistant Surgeon.*—Detached from the U. S. S. "Swatara," October 1st. Granted six months' leave.

Berryhill, T. A., *Assistant Surgeon.*—Detached from the Museum of Hygiene, and ordered to Receiving Ship "Minnesota."

Arthur, George, *Passed Assistant Surgeon.*—Detached from the Navy Yard, New York, and ordered to the Museum of Hygiene.

Percy, H. T., *Passed Assistant Surgeon.*—Detached from U. S. S. "Galena," proceed home, and wait orders.

Shafer, Joseph, *Assistant Surgeon.*—Detached from the U. S. S. "Minnesota," and ordered to the U. S. S. "Swatara."

Steele, J. M., *Passed Assistant Surgeon.*—Detached from the Naval Academy, and granted six months' leave.

Biddle, Clement, *Passed Assistant Surgeon.*—Ordered to Naval Academy, Annapolis, Maryland.

Official List of Changes in the Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Week Ending October 2, 1886.

Purviance, George, *Surgeon.*—Granted leave of absence for twenty-five days, September 30, 1886.

Stoner, G. W., *Surgeon.*—Granted leave of absence for twenty-three days, October 1, 1886.

Carter, H. R., *Passed Assistant Surgeon.*—To proceed to Galveston, Texas, as an inspector, September 30, 1886.

Ames, R. P. M., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, to take effect when relieved, September 30, 1886.

Wasdin, Eugene, *Assistant Surgeon.*—Ordered to examination for promotion, September 30, 1886.

Brooks, S. D., *Assistant Surgeon.*—Granted leave of absence for thirty days, to take effect when relieved, September 30, 1886.

Williams, L. L., *Assistant Surgeon.*—Relieved from duty at Mobile, Alabama. Ordered to Marine Hospital, Wilmington, North Carolina, September 27, 1886.

Perry, T. B., *Assistant Surgeon.*—Relieved from duty at San Francisco, California. Ordered to Marine Hospital, St. Louis, Missouri, October 1, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIX. SATURDAY, OCTOBER 16, 1886. No. 16.

ORIGINAL ARTICLES.

SOME PHASES OF CEREBRAL SYPHILIS.[1]

BY JULIUS ALTHAUS, M.D., M.R.C.P. LONDON;
CORRESPONDING MEMBER OF THE NEW YORK ACADEMY OF MEDICINE; SENIOR PHYSICIAN TO THE HOSPITAL FOR EPILEPSY AND PARALYSIS, REGENT'S PARK, LONDON.

MR. PRESIDENT AND GENTLEMEN: It is to me a source of the greatest possible gratification to meet in this noble hall, and in the first city of your great continent, so many representatives of American medical science as are assembled here to-night; and you must allow me to thank you most heartily for the very kind and flattering reception which you have accorded to me. For many years past I have wished to cross the Atlantic, in order to make the personal acquaintance of many eminent colleagues who were already well known to me by reputation; and to learn something of the aspects of American medicine in your hospitals and universities.

I am not one of those who consider the old world to be effete and played out—sclerosed, as it were, through loss of nerve-cells and the undue proliferation of the lower tissues—unable to do much further original work, either in our own field of labor or in other cognate departments of research; yet I have felt at once, on my arrival amongst you, that in this new world of yours, of which I have as yet such a short experience, the air is fresher and keener, the minds more open and unprejudiced, the desire for greater and better knowledge more eager—in fine, the gray matter of the cortex more on the alert than in some parts of Europe, where the old conservative notion of "rest and be thankful" prevails to an undue extent, and where anything that is new is pretty sure to be looked upon with suspicion in leading circles, simply on account of its being new. Personally, gentlemen, I cannot help feeling it a special privilege to address you to-night under the presidency of my old friend and fellow-student, Jacobi, whom I first met, now thirty-six years ago, in Germany at the University of Bonn-on-the-Rhine. I trust that on this occasion your eminent President, as well as yourselves, will extend to me that kind indulgence which I now make bold to claim at your hands as your visitor to-night.

The fact that the structure and functions of the brain may be peculiarly and specifically affected by the syphilitic virus, seems to have escaped the acumen of the old masters in our profession. When syphilis first appeared in Europe, toward the end of the fifteenth century, and for a very long period afterward, the terrible external manifestations of this appalling disease engrossed the attention of medical practitioners to an unusual degree; nor were these symptoms of the malady of France unknown to the laity. Thus Shakespeare's Timon says to the two courtesans, Phrynia and Timandra:

> "Give them diseases! bring down rose-cheek'd youth
> To the tub-fast, and the diet. . . . Consumption sow
> In hollow bones of man; strike their sharp shins,
> And mar men's sparring. Crack the lawyer's voice,
> That he may never more false title plead,
> Nor sound his quillets shrilly: hoar the flamen,
> That scolds against the quality of flesh,
> And not believes himself; down with the nose,
> Down with it flat; take the bridge quite away
> Of him, that his particular to foresee,
> Smells from the general weal; make curl'd pate ruffians bald,
> And let the unscarr'd braggarts of the war
> Derive some pain from you; plague all,
> That your activity may defeat and quell
> The source of all erection."

While the clown in Hamlet, in the gravedigging scene, says in answer to the question how long a man will lie in the earth ere he rot, that he will last for eight or nine years—

> "If he be not rotten before he die,
> As we have many pocky corses nowadays
> That will scarce hold the laying-in."

While, therefore, impotence and disease of the cranial bones were thus early stated to be a result of syphilis, yet nothing was known for a long time about any specific disease of the viscera, and more especially of the brain and spinal cord, as arising from venereal infection. When it, however, eventually became obvious that some nervous complaints, such as paralysis, epilepsy, and insanity, frequently occurred in those who had previously suffered from the more ordinary forms of constitutional syphilis, this was explained by that convenient figment, a metastasis having taken place from the skin and mucous membranes to the brain, whereby the latter suffered, without being actually diseased.

This fantastic view of the matter, however, did not commend itself to the clear intellect of such men as Hunter and Astley Cooper, who, on the contrary, stated plainly that the brain as well as the other internal organs were insusceptible to the venereal poison. This latter doctrine held the field for a very considerable time, as may be seen from a perusal of the works on diseases of the nervous system which appeared in the first half of the present century. Thus I find that Abercrombie, in his work on the diseases of the brain and spinal cord, which was for many years the great authority on nervous affections, and the first edition of which appeared in 1828, never once mentions the word syphilis at all. In speaking of the causes of brain diseases, the Edinburgh professor alludes to continued fever, and the exanthemata; injuries to the head; suppressed evac-

[1] Read before the New York Academy of Medicine, October 7, 1886.

uation of certain secretions, such as the catamenia and the urine; scrofula, passions of the mind, stimulating liquors, and exposure to the intense heat of the sun. *Voila tout.*

The same remark applies to the works of Sir Charles Bell, Marshall Hall, and Romberg. In the clinique of the latter in Berlin, which I frequented assiduously in 1853 and 1854, and where I had the opportunity of seeing a large number of cases of all kinds of nervous diseases, I remember only a single instance where that great master allowed syphilis to have been the cause of the patient's illness; and that was a case of paralysis of the third nerve, which was stated to be due to syphilitic periostitis at the base of the skull. In 1854 and 1855, I likewise attended the syphilitic cliniques of Von Baerensprung at Berlin, and of Sigmund at Vienna, and saw numerous cases of primary and secondary affections, but not one of cerebral or spinal syphilis. Nor did the great leaders of the Vienna school of medicine, such as Skoda and Oppolzer, whose teaching I followed in the winter 1855–56, draw attention to this subject in their otherwise admirable clinical lectures. Canstatt's text-book on special pathology and therapeutics, which was at that time in the hands of almost every student of medicine in Germany, and also constituted the principal guide of the practitioner, was likewise absolutely silent on this subject in the chapter on nervous diseases; while in that on syphilis the practitioner was actually cautioned not to believe in such a thing as syphilis of the brain—a most astounding statement when we consider that perhaps eighty per cent. of all cases of brain diseases which occur in patients between twenty-five and forty years of age are actually owing to that disorder! The same ideas prevailed in France, where Trousseau and other masters whose wards I frequented in the summer of 1855, never mentioned cerebral syphilis at all, and invariably attributed any nervous symptoms in syphilitic patients to cranial periostitis.

The only man who about that time knew that the brain was liable to specific disease was Professor Waller, of Prague, whose lectures I attended in the summer of 1856. He told his hearers then that he had seen red and white softening, and a deposit of solid effusions in the white as well as the gray matter of the brain. According to him, the symptoms during life were indistinct, and we could only diagnosticate cerebral syphilis where the patient suffered at the same time from external manifestations of the disorder. He had known patients in the later stages of the disease to suffer from epilepsy, paralysis, and mental hebetude; but the brain might also suffer at an early period, synchronously with the ulcerated throat, and he had seen cases in which a most violent form of headache was the principal symptom, and where, in spite of active treatment, the patient had died comatose. I believe that these observations of Waller's have never been published, and what I have just mentioned is culled from notes which I took at the time his lectures were delivered.

With this solitary exception, then, all that was taught until a comparatively recent time on this subject was, that syphilis might produce an affection of the dura mater analogous to that of any external periosteum; that the membrane might become inflamed, and an intracranial node be formed, which would irritate the surface of the brain, and might give rise to neuralgic, convulsive, and paralytic symptoms. Cases of this kind have been described, amongst others, by Sir Philip Crampton, Graves, and MacDowell, of Dublin, by Reade, of Belfast, and by Todd, of London.

A new era in the history of our subject began with the great impetus which was about that time given to the study of pathological anatomy. Amongst the many successful workers in this most attractive field of research, two men stand forth conspicuously, so far as our subject is concerned, viz., Virchow, whose investigations cleared up the nature of syphiloma of the brain and its membranes (1869), and Heubner, who gave us a clear insight into the syphilitic alterations which are apt to occur in the cerebral arteries (1874). These researches may, each in its own way, be considered as landmarks in the history of cerebral syphilis. The foundations of the doctrine were now securely laid, so as to be beyond cavil; and it became clear that, although subsequent work might amplify our knowledge in this respect, it could no longer reverse what was once firmly established.

The salient feature of this work is, that the peculiar and specific alteration which occurs in the brain as a consequence of constitutional syphilis, is not inflammation, but that it bears throughout the character of a neoplasm. A foreign tissue is apt to be deposited in the dura mater, the subarachnoid space, or the cerebral substance, and forms the several kinds of tumor known as syphiloma or gumma. Apart from this, however, there occurs a special disease of the cerebral arteries, which likewise appears in the form of a neoplasm, inasmuch as a deposit takes place between the endothelium and the elastic fibres of the vessel, whereby its diameter is at first reduced, and the lumen eventually completely blocked up by thrombosis, causing ischæmia, starvation, and softening of the area of cerebral tissue which is supplied by the suffering vessel. Syphiloma and arterial thrombosis cover indeed the immense majority of cases of cerebral syphilis which are met with in practice. There remains a residuum of cases in literature in which no structural change could be discovered after death, and in which the symptoms were generally attributed to congestion; it is, however, a suggestive fact that during the last ten or fifteen years, during which the finer methods of microscopic research have been so much improved, the record of such cases has almost ceased; and it therefore appears probable that one or the other of the two fundamental lesions which I have just mentioned, and their consequences, may in the future be generally found to exist in fatal cases of this description; while in many of those which do not prove fatal, I believe anæmia rather to be the cause of the symptoms than congestion, to which it is usually attributed.

While, therefore, Virchow's and Heubner's work must be looked upon as epoch-making in the pathology of cerebral syphilis, correspondingly good clinical work has been done elsewhere. I shall probably not be contradicted when I say that Fournier's book, *La Syphilis du Cerveau*, which ap-

peared in Paris in 1879, has very greatly extended our acquaintance with the more common, as well as the more unusual, clinical forms of brain syphilis. Fournier has distinguished six different forms, viz., the cephalalgic, the congestive, the convulsive or epileptiform, the aphasic, the mental, and the paralytic; and his description of the symptoms which occur in these several forms is more minute and exhaustive than any other which had been given before, and will on that account always remain a monument of able and painstaking industry. A disappointing feature of Fournier's work is that he does not generally point out clearly the connection which exists between clinical signs and pathological lesions, and appears to be only slightly acquainted with the modern doctrine of cerebral localization, which in this department of clinical medicine finds its most interesting and striking practical applications.

I now proceed to the more particular object of my paper, which is to draw your attention to some manifestations of cerebral syphilis with the peculiarities of which we are as yet imperfectly acquainted. Time will only allow me, on this occasion, to revert to two amongst the numerous subjects which crowd on one's attention in thinking of brain syphilis, and those which I have selected are syphilitic coma, and syphilitic hemiplegia.

That coma, coming on more or less suddenly in an apparently healthy man, or in one who shows at the time unmistakable symptoms of venereal disease, may be a manifestation of this latter distemper, is not generally known in the profession. We are all familiar with uræmic, alcoholic, and diabetic coma, with the coma of cerebral hemorrhage, and that of opium poisoning; with that which occurs after the epileptic fit, with or after severe hysterical and hystero-epileptic convulsions; after prolonged exposure to extremes of temperature, whether of heat or cold; after erysipelas of the face and head; from compression of the brain by a depressed fracture of the skull, by extravasated blood, meningitis, and the presence of pus and other products of inflammation. Nor must we forget that several chronic affections of the nervous system, more especially tabes spinalis, and general paralysis of the insane, are apt, toward their termination, to be attended by attacks of coma. Most of these conditions are described in the text-books, while syphilitic coma is not even mentioned. Fournier is almost the only author who has pointedly alluded to this condition, and related an example of it which occurred in his practice. A knowledge of syphilitic coma is, however, of great practical importance, inasmuch as it requires an entirely different treatment from that of other forms of coma; and an incorrect diagnosis is, in such a case, likely to seal the fate of the patient.

I have seen altogether eight unmistakable cases of syphilitic coma. They all occurred in males between twenty-five and forty-two years of age. In every one of them there was a definite history of primary and secondary syphilis; in four there was at the time a specific rash on the scalp, and other portions of the skin; and in one an ulcer on the tongue. In one case the coma appeared eight months after infection; in six, between three and five years; and in one case seventeen years afterward. In two cases no other cerebral symptoms had occurred before the coma, while six other patients had at various times suffered from giddiness, epileptiform convulsions, and transient loss of power in the limbs.

Amongst the exciting causes of the attack I have noticed overwork, anxiety, trouble, and sexual and alcoholic excesses. In two cases no exciting cause whatever could be ascertained. Six of the patients were professional men, and two were men without any regular occupation.

The symptoms of syphilitic coma, I venture to classify as 1st, premonitory signs; 2d, symptoms of the initial stage; and 3d, symptoms of the final stage of coma.

A. I have noted the following premonitory symptoms of the attack of coma: headache, a feeling of confusion and drowsiness; indistinct utterance; a perception of black specks floating before the eyes, with sudden loss of sight for a short time; numbness of the limbs, and some loss of muscular power. In six cases such symptoms occurred either a few hours, or a day or two before the attack, while in two other cases they appeared to have been entirely absent.

B. The initial stage of syphilitic coma appears to set in habitually during sleep; the patient being discovered by his friends or servants in the morning in a state of apparent insensibility, from which he cannot be roused. He is lying quietly on his back, apparently quite unconscious, and, as it were, in a profound sleep. He is evidently not suffering any pain; he does not moan, threw himself about, or put his hand to his head. The face is absolutely devoid of expression; there is a complete blank, and no distortion of the features. The complexion is generally pale. Sometimes he can be roused by shouting to him; he may speak a word or two, and appears to recognize the voice of a friend better than that of a stranger. When asked whether he can see you, he may answer that he is blind. When requested to put out his tongue, he is seen to make an effort to do so. Sometimes the only response is a movement of the lips, at other times the tip of the tongue is protruded, which is then seen to be dry, and covered with whitish fur, through which some few red papillæ are seen to project; but it shows no lateral deviation. When food is put into his mouth, the patient makes an effort at deglutition, and generally succeeds in swallowing small quantities of fluid. The eyes are closed. On opening the lids the eyeballs are seen to be deeply retracted into the orbit, one sometimes more so than the other; and they are seen to diverge somewhat in their direction, which imparts to them a peculiarly dazed and stupid expression. The deeper the coma, the greater, *cæteris paribus*, is the degree of divergence. The pupils are small, and insensible to light. On account of the position of the eyes, an ophthalmoscopic examination is generally not practicable, but reveals nothing unusual when practised. The reflex excitability of the conjunctivæ is either very much blunted or entirely gone. The breath is sometimes offensive.

The muscles of the limbs and the body are in a state of perfect relaxation. The body will retain

any position which is given it. On lifting the arms or legs, no resistance is encountered; and on releasing them, they drop back heavily by their own weight, like inanimate matter, as in a dead body from which rigor mortis has disappeared. There is no difference at all between the two sides of the body; no appearance of hemiplegia, or rigidity, or tremor, but a dead level of paralysis, with complete loss of muscular tone, everywhere.

Sensibility and reflex excitability are greatly diminished, or quite gone. I have already mentioned that the conjunctival reflex is lessened or absent, and that there is no light reflex in the pupils. Tickling the soles or the knees produces no withdrawal of the legs; but on smartly pricking the skin with a pin, there is generally a slight response. Where the coma is not very deep, the patient may express by a grunt his dislike of the proceeding. The deep reflexes or tendon phenomena are either absent, or can be elicited only with considerable difficulty, and then appear slight and sluggish.

There is either from the first or very soon, incontinence of the excretions, especially of the urine, which is apparently secreted much in the usual manner, and dribbles away as it reaches the bladder, through paralysis of the sphincter. The feces are also apt to come away involuntarily, but occasionally there is obstinate constipation, which only yields to powerful purgatives or enemata, and the evacuation then takes place in bed, the patient having no sensation of its coming away and being unable to give a warning.

The pulse is habitually slow, beating at the rate of 40, 50, or 60 in the minute. In one case I have known it to go down to 36, while in another it was 86. The quality of the pulse varies in the different cases: it may be hard and wiry, showing the sphygmographic signs of increased tension, or tolerably full, or small and feeble, when the sphygmograph indicates low tension.

Respiration is slow and shallow, the excursion of the chest-walls and diaphragm being insignificant. The rate of inspirations varies like that of pulsation, but is generally less than in health. The average rate appears to be from eight to ten.

The temperature is below the average, and ranges habitually between 96° and 97°. In one case I have known it to go down to 95°.

In two cases there was an eruption of herpes on the face, large groups of vesicles being formed on inflamed patches on both cheeks. On the first day the liquid was clear; on the second it became opaque, and the epidermis then gradually peeled off in small patches. Otherwise the skin is generally dry, there being little or no perceptible perspiration.

What is the condition of the brain in the cases which I have just described? It is evidently a complex one, for while we have, on the one hand, symptoms of paralysis, there are, on the other hand, signs of irritation of the nervous centres. The loss of consciousness, and of voluntary motion and sensation, shows that the function of the cineritious substance of the hemispheres, and notably that of the frontal and temporal lobes and of the central convolutions, is in abeyance; while the state of the pulse, respiration, and temperature shows that the cardiac, vasomotor, respiratory, and thermic centres in the medulla oblongata and the pons Varolii are in a state of irritation. Such a coincidence of paralysis and irritation is by no means so singular as it might appear at first sight, if we consider the various degrees of excitability which exist normally in different portions of such a highly complex organ as the brain is known to be. Of all parts of the encephalon, the gray cortex is the most highly vitalized, and the one that requires the most active circulation of the blood, the most incessant supply of oxygen, in order to be able properly to discharge its function. Any interference with the supply of arterial blood to the cortex, however temporary, acts like a blow with a hammer on a magnet—that is to say, it destroys its function for the time being by suddenly disturbing its molecular condition. In poisoning by carbonic acid there is at first a short stage of irritation of the cortex, shown by headache, giddiness, and noises in the head, but this is rapidly succeeded by depression, consciousness being lost and a state of coma induced. At this time, however, there is still irritation of the medulla, shown by a slow pulse, increased blood-pressure, and convulsions, and this stage is only eventually succeeded by paralysis, when respiration becomes feeble, the blood-pressure falls, and death results from apnœa. That in patients suffering from syphilitic coma there may be a short stage of cortical irritation, is rendered probable by the premonitory symptoms which I have mentioned, such as headache, giddiness, and a feeling of confusion.

A coincidence of depression and irritation may be observed in much less complex structures than the brain. Thus we have in the early stage of an acute attack of sciatica, whether of rheumatic or traumatic origin, on the one hand, symptoms of depression, viz., numbness in the foot and loss of power in the muscles supplied by the sciatic nerve; and, on the other hand, concurrently with them symptoms of irritation, viz., acute pain in the whole or part of the limb, and convulsive twitches in the muscles which are under the influence of the suffering nerve.

That there is irritation of the lower centres in the first stage of syphilitic coma, seems to me to be proved by the slow pulse, the increase of blood pressure which is present in the majority of cases, the retarded respiration, the lowered temperature, and finally by the state of the pupil and of the ocular muscles. There is a centre for these latter parts in the posterior portion of the floor of the third ventricle and the aqueduct of Sylvius, and therefore in intimate connection with the upper portion of the pons Varolii, which has been shown by Hensen and Voelcker to have definite relations to the iris and the other muscles of the eye. Irritation of this centre would explain the contraction of the pupil, and the different forms of ocular spasm which are found to be present in syphilitic coma; just as paralysis of the same centre is known to lead to the different forms of ophthalmoplegia.

The initial stage of syphilitic coma lasts, in general, from two to five days; and is followed either by recovery, or merges into the final stage which leads to death. In the former case the patient gradually

begins to show signs of returning consciousness; he opens his eyes from time to time, moves them about in different directions, and recognizes the people about him. He regains command over the sphincters, and calls the nurse when desiring to pass his excretions. The power of swallowing is improved; he begins to take food with some amount of relish, recovers his muscular power, sits up in bed, has natural refreshing sleep followed by wakefulness, and presently wants to get up and begins to go about again. In ten days or a fortnight, he may apparently be well, and able to resume, at least to some extent, his previous occupation.

In other cases recovery is more slow and imperfect. The speech remains indistinct and halting, the memory is weak. An hour after having seen a person, or read a newspaper, the patient remembers nothing about it. The power of moving the eyes freely remains impaired. He does not seem to take much interest in his affairs, or show much affection for his family. At times, however, he appears to realize his position acutely and bursts out crying, while at other times he is absent-minded and drowsy.

> "All is but toys; renown and grace is dead;
> The wine of life is drawn, and the mere lees
> Is left this vault to brag of."

Eventually, however, even in these less favorable cases, the brain power may be more or less restored, showing but little deterioration compared with what it was previous to the attack.

This is the bright side of the picture, and as recovery generally takes place in consequence of an energetic specific treatment, the doctor may well take credit to himself for having saved his patient's life or reason. But there is also a darker side, since in some cases all the resources of our art prove unavailing. The patient then, after having been for a few days in the condition previously described, gradually sinks into what I propose to call the *final stage* of syphilitic coma.

This stage is characterized by an intensification of the symptoms of unconsciousness, loss of voluntary power, sensation, and reflex excitability; while the signs which I have referred to irritation of the pons and bulb, now pass into such as denote a paralytic state of these organs. The face is livid and cyanosed; the conjunctivæ are injected, covered with shreds of mucus, and insensible to touch or irritation. The mouth is wide open, from paralysis of the masseter muscles, causing the lower jaw to drop. The breath is fetid; the power of swallowing lost. There is either excessive secretion of buccal mucus, or great dryness of the lips, tongue, and cavity of the mouth, which are often covered by sordes. The surface of the body is bathed in clammy sweat. The pulse, where it has been hard and wiry, rapidly loses that character, and becomes small, feeble, and very quick, going up to 140, 180, or more. It eventually cannot be counted, and shows sphygmographically the characters of collapse, there being only a very slight elevation followed by a proportional depression, but without waves, aortic notch, or dicrotism. Respiration, from having been retarded is now accelerated, with thirty to forty or more inspirations per minute. It may become stertorous, and pass into the Cheyne-Stokes type, or neurolytic catarrh of the air-passages sets in, with excessive secretion of bronchial, tracheal, and laryngeal mucus, while on auscultation râles are heard all over the chest. This may pass into hypostatic pneumonia, when the mucus becomes tinged with blood. At the same time the temperature is found to rise from 95° or 96° to 104° or 108°. The pupils become enlarged, and show their maximal dilatation at the moment of death. Eventually the face assumes the Hippocratic expression, and is occasionally so altered within a few minutes that the patient's friends have difficulty in recognizing him. This stage generally lasts from twenty-four to thirty-six hours, and terminates in dissolution; the patient passes away to

> "The undiscovered country from whose bourne
> No traveller returns."

Of the eight cases of syphilitic coma which have fallen under my observation, six ended in recovery and two in death in the first attack. In three of those who recovered from the first attack, however, relapses took place after some time, and one of these latter patients eventually died, after having survived five such attacks in three years.

I regret to say that I was not allowed to make a necropsy in either of the two fatal cases; and I am therefore unable to describe to you the exact lesion which caused the illness and the final result. Reasoning from analogy, however, it seems to me highly probable that we have in these cases to do with an affection of an important cerebral artery, which becomes gradually occluded by specific deposit in the way so clearly described by Heubner; and that the vessel principally implicated is the basilar artery.

The basilar artery gives branches to the cerebellum, pons, and medulla oblongata, and terminates in the A. cerebri profunda, thus supplying the vitally most essential parts of the brain; and it is obvious that an interruption of the blood supply by this vessel must lead to a profound alteration of the parts nourished by it. Sudden occlusion of this artery by acute inflammation or deposit leads rapidly to a fatal result, the principal symptom being profound coma from the beginning of the illness. Hayem has recorded the case of a woman, aged thirty-three, who was brought into the hospital in a comatose state, in which she had been found at home shortly after having been seen engaged in her usual occupations. This patient died in twenty-one hours. The autopsy showed acute inflammation of the basilar artery; all the coats of the vessel, but more especially the internal one, being much thickened, and in one place so much so that the lumen of the vessel was entirely occluded. There were hyperæmia, swelling, effusion, and abundant production of young cells and nuclei. Where the vessel was not occluded by inflammation it was filled with a thrombus, part of which was soft and pinkish, while another part was hard and resisting, the clot being apparently due to rupture of the internal coat of the artery through the effusion, after which the blood had become coagulated and mixed with the broken-up structures. The brain matter was firm, with the exception of the

pons, which had a pasty consistency, more especially in its lower portion, which is in direct connection with the basilar artery; but there was no actual softening. Indeed, there had been no time for the production of such a change.

Similar cases have been seen by Vulpian, Martineau, Gougenheim, and Bastian. The case of the latter observer was that of a watchman, aged forty-three, who had been apparently in his usual health, and was suddenly taken with coma, which proved fatal in less than six hours. After death there was found an aneurismal dilatation of the posterior half of the basilar artery, which was perfectly occluded by a soft, colorless clot, uniformly adherent to the aneurismal walls. The middle cerebellar arteries were in connection with the aneurismal swelling, and likewise occluded. Otherwise nothing of importance was discovered in any one of these cases; and the symptoms which were present are indeed well explained by the sudden anæmia induced in the vasomotor, cardiac, and respiratory centres in the pons and bulb through the basilar artery becoming impervious. The only difference between the cases of acute inflammation and of sudden coagulation, on the one hand, and those which I have described as such of syphilitic coma, on the other hand, appears to be the extreme rapidity of the course of events in the former class, while this is much slower in the latter. When a specific deposit takes place in the basilar artery, therefore, it seems that much more time is required for producing occlusion of the vessel than is the case in ordinary inflammation, or thrombosis. For the same reason I should expect that, in addition to the occlusion of the vessel in a fatal case, there would also be found some degree of softening in the pons and bulb. While, therefore, there appears good reason to believe that syphilitic coma is due to specific disease of the basilar artery, I admit that this view still stands in want of corroboration by actual inspection.

The diagnosis of syphilitic from other forms of coma is sometimes easy, and sometimes extremely difficult. The history and attendant circumstances of the case must guide us in the recognition of such conditions as coma from exposure to extremes of temperature, from injury to the head and meningitis, from erysipelas of the face, etc. The coma which accompanies ingravescent apoplexy from cerebral hemorrhage, occurs habitually in men past fifty years of age, while syphilitic coma occurs either in young men, or in those in the prime of life. Moreover, there are in the former habitually the well-known symptoms of hemiplegia, which are absent in syphilitic coma. The cases most likely to be confounded with the latter are those where hemorrhage takes place into the pons, causing great contraction of the pupils, retraction of the eyeballs into the orbit, and paralysis of all four extremities. In such cases the question likewise arises whether we may not have to do with opium-poisoning. In endeavoring to decide these questions we must remember that in syphilitic coma the pupil is not extremely contracted, while in opium-poisoning and hemorrhage into the pons it is so to the utmost possible limit. Where laudanum has been taken, this may be smelt in the breath; and if the unconscious patient be seen to scratch himself vigorously, we would conclude for opium, itching being a frequent symptom of poisoning with it. Finally, in opium-poisoning there is retention of the urine, with a full and often greatly distended bladder, which sometimes reaches up into the epigastrium, while in syphilitic coma the bladder is empty, and the urine found to dribble away as it is secreted.

The coma which follows an epileptic fit, and severe hysterical and hystero-epileptic convulsions, is habitually of a much shorter duration than syphilitic coma. Moreover, the epileptic fit, even where it has not been witnessed, leaves evidence in a bitten tongue, foam at the mouth, and petechiæ of the face. The history of the case may also be of use. A young woman was admitted a few months ago into the hospital under my care in a comatose condition, and the mother stated that the girl had had fits, and had for some time past been unable to feel anything in her left side. Here we had, therefore, to do with hemianæsthesia in a young woman, and fits which led me as such to suspect hystero-epilepsy; and this was confirmed by the further progress of the case. In this instance the coma lasted for thirty-six hours.

Alcoholic coma occurs frequently in the London docks, where the men who are employed there are apt to develop a craving for sucking raw spirit from a barrel through a straw, until they fall down dead drunk; and, if discovered near the barrel in this state, the diagnosis is indeed readily made. But under other circumstances difficulties may arise. The smell of alcohol in the breath is of very little diagnostic use, as a man beginning to suffer from the first effects of cerebral hemorrhage is apt to take brandy for reviving himself, or is given it by sympathetic bystanders. More trustworthy information may be obtained from the urine. When small doses of alcohol are taken, this is eliminated partly by the breath, and partly undergoes combustion in the blood and tissues, and can therefore not be discovered in the urine; but large doses, such as are sufficient to produce coma, are eliminated unchanged by the urine; so that, if the latter be found to have an alcoholic smell, this is enough to establish the diagnosis. The temperature is generally lowered in alcoholic coma, but rarely more than one or two degrees, so that, for instance, a temperature of 95° would speak against it. Another important sign is that the pupil is enlarged in alcoholic coma, while in syphilitic coma it is small.

The diagnosis of uræmic coma will be easy where the history of the case is known; but where it is not, difficulties may be experienced. This kind of coma may occur quite suddenly, without any premonitory signs, for the patient may fall down unconscious while writing at his desk, or driving in a carriage. In general, however, it is preceded by headache and vomiting, and occasionally by defects of sight and hearing; after this, epileptiform convulsions set in, and leave the patient comatose. The breathing is then stertorous, and the pupils are dilated. The patient may then recover for a time, but is seized again by a fit, and becomes

once more comatose. It is, therefore, seen that in uræmia we have to do with fits and remissions, and that there is not that dead level of unconsciousness as in syphilitic coma. Anasarca is frequently present; there is generally no incontinence, but retention of the urine, which is scanty, and if a specimen be obtained, it is found to contain albumen and tube-casts. Finally, the presence of urea can be shown in the blood by raising a blister, evaporating the serum which is effused, treating the residue with alcohol, and then adding a few drops of nitric acid, when crystals of nitrate of urea will be formed.

Finally, how are we to distinguish syphilitic from diabetic coma, or, as it is sometimes called, Kussmaul's coma, or acetonæmia? About one-half of the patients who succumb to diabetes, die comatose; and as the coma sometimes sets in quite suddenly, and apparently without any warning, Prout, and Frerichs after him, were quite justified in saying that the diabetic lives habitually on the brink of a precipice. There are three different kinds of diabetic coma. The most common is that with which Kussmaul's name is connected, and which occurs chiefly in young persons, and where the course of the disease is rapid. This is sometimes ushered in by epigastric pain, vomiting, diarrhœa, or obstinate constipation. The patient is then seized by a peculiar form of dyspnœa; he lies gasping for breath, respiration being very much accelerated, while the respiratory movements are free, and the air-passages pervious. The breath has a peculiar odor, like cider, apples, or chloroform, which is owing to the presence of acetone in the expired air. The urine is abundant and contains sugar; in almost all cases it likewise shows a peculiar reaction with perchloride of iron, which imparts to it a deep reddish or Burgundy color, which disappears on heating or acidulation. This reaction is generally owing to the presence of aceto-acetic acid in the urine. This acid, however, is a very unstable compound, and easily splits up into acetone and carbonic acid, so that acetone is also habitually found in the urine. It appears probable that, besides these two substances, there are other poisons present in it, more particularly diacetic ether, trimethylamine, and beta-oxybutyric acid, which are formed in the blood in consequence of the abnormal tissue-changes, and poison the nervous centres unless they can be quickly eliminated. In consequence of this, the patient becomes drowsy, and there may be at the same time a restless delirium. There are sometimes remissions, but eventually the coma deepens. The pulse is quick; the temperature normal, subnormal, or very low indeed—down to 90° in the rectum. The pupils are sluggish, the surface of the body is cold, and death is sometimes preceded by convulsions. The peculiar form of dyspnœa, and the presence of acetone and its allies in the breath and urine, are sufficient to guide us in our diagnosis of these cases.

There are, however, two other forms of diabetic coma, the knowledge of which we owe chiefly to Frerichs and Dreschfeld. The first of these is what may be properly called diabetic collapse. It occurs more in elderly persons, especially when they are stout and subject to gout and nephritis, and after they have been diabetic for some considerable time. There are the usual symptoms of collapse, which soon passes into coma and death; and the condition is probably owing to fatty degeneration of the heart and sudden failure of its action, especially after overexertion or excess.

The last form of diabetic coma, and which is only rarely met with, is that where there is a first stage of excitement resembling that of alcoholic intoxication, and which is, after a time, succeeded by coma and death. In these cases acetone has also been discovered in the urine, and in one of them large quantities of alcohol were found in it, although it was ascertained with certainty that the patient had not taken alcohol in any form or shape. These latter two kinds of diabetic coma cannot therefore possibly, on account of the great dissimilarity of symptoms, be confounded with syphilitic coma.

The *prognosis* of syphilitic coma is always grave. Although it is not by any means as hopeless as that of uræmic and diabetic coma, which almost invariably prove fatal, yet there is proof that the terribly subtle and rancorous poison of syphilis has insinuated itself into the cerebral arteries; and even if neutralized by treatment for a considerable time, will probably sooner or later return to the attack, and eventually overcome all resistance. The prognosis of the individual attack is, however, on the whole, not very unfavorable, more especially if specific treatment is resorted to in the beginning. My two cases in which the first attack proved fatal, had been treated simply with stimulants until symptoms of paralysis of the pons and bulb had supervened, so that they were practically hopeless at the time the specific treatment was commenced. What is likely to occur after the patient has recovered from the attack, depends to a great extent upon the degree of perseverance with which he may allow a specific treatment to be carried out. Some patients are averse to swallowing medicine unless they are at death's door, and give up treatment as soon as they feel tolerably comfortable. For these the prognosis is of the worst description; for they are certain either to succumb to a similar attack sooner or later, or to end their days in a madhouse as general paralytics. Where, on the contrary, a patient will submit to two years' consecutive treatment for the distemper under which he is laboring, he appears to have a fair chance of escaping further trouble from this source.

The *treatment* of syphilitic coma should be partly symptomatic, and partly specific. Systematic feeding with easily digestible substances, more especially milk, chicken broth, beef tea, and small doses of alcohol, is of the greatest importance. The food may be peptonized if considered advisable. If the patient should appear in imminent danger of death, hypodermatic injections of ether sometimes turn the balance in his favor. I once injected forty minims at a time, with the result that the patient rallied almost immediately. The average dose is twenty minims three or four times a day. Ammonia has appeared to me of little use in this condition. Blistering the back of the neck or the forehead, however, seems sometimes to be beneficial. Ice or other

cold applications to the head are unnecessary where the temperature is normal, and hurtful where it is diminished; while in the later stages of the complaint where the temperature runs up very high, I have found them quite useless. The cold douche which is often so beneficial in the coma of meningitis, has appeared to me to do more harm than good in some of the cases now under consideration, while in others it scarcely seemed to warrant the trouble which was required for administering it.

The principal part of the treatment is the specific one by mercury, which should for obvious reasons be administered either by inunction or by hypodermatic injection. For inunction we may use the old-fashioned blue ointment, which is probably, after all, the most effective of all external applications, as mercury appears in the urine after a single inunction of one drachm, which contains twenty grains of metallic mercury; or the oleate may be used, containing ten, fifteen, or twenty grains of the yellow oxide for an application. Three inunctions of this are, however, required for showing mercury in the urine. The yellow oxide may also be rubbed up with lanolin, and seems to be rapidly absorbed in this combination. For hypodermatic injections I consider the perchloride to be the most effective preparation, and this should be injected deeply into the substance of the glutæi muscles, in order to avoid irritation and the formation of abscesses, which is so apt to occur when this remedy is injected into the subcutaneous areolar tissue. We may, however, also use the albuminate, the peptonate, the cyanate, and the foramid of mercury, in doses of one-sixth to one-third of a grain, once a day.

Time warns me that I shall have to bring my remarks to a close, and I will, therefore, at once proceed to the second portion of my discourse, which will treat of some of the clinical peculiarities of syphilitic hemiplegia as compared with ordinary hemiplegia.

The symptoms of the ordinary attack of hemiplegia, owing to hemorrhage into the central ganglia or embolism of the Sylvian artery, are rarely reproduced in the attack which is owing to syphilitic infection. While, in the former, we meet with the well-known symptoms of apoplexy to which more or less complete motor paralysis of one side of the body is added, we find in the latter a number of different types, which all show great variations from one another, as well as from the non-specific attack of hemiplegia. There are, however, some features which all these several types have in common, viz:

1st. The immense majority of the patients are males, according to my experience ninety-five per cent., while both sexes suffer about equally from ordinary hemiplegia.

2d. The patients are young or comparatively young subjects, viz, between eighteen and forty years of age:

> "For in the morn and liquid dew of youth
> Contagious blastments are most imminent."

3d. They show a peculiar behavior of the deep reflexes or tendon phenomena, which has not been previously described, and to which I shall presently refer in a more pointed manner.

One of the several types of syphilitic hemiplegia is shown by the case of a clerk, aged twenty-eight, who was under my care at the hospital in November, 1884. This young man told me that he came from a healthy stock, but had, for many years past, committed excesses in drinking, smoking, and sexual indulgence; that he had had gonorrhœa half a dozen times, and a hard chancre, followed by specific eruptions, four years ago. After that he continued apparently quite well for three years; but unquestionably that terrible bacillus was breeding in his lymphatic system all the time, for he found one day that his left eyelid drooped, and that he had difficulty in seeing with the left eye. At that time he happened to be in Australia, and six months afterward took passage home. He had been on board ship for a fortnight, and never thought that there was anything the matter with him, when, one day, while sitting on deck, he experienced a feeling of faintness and giddiness; there was no loss of consciousness or language, no headache or sickness, no incontinence of the excreta, but he had a strange feeling of loss of power gradually stealing over his right side, and in half an hour found that he could not use his hand, and that he walked lame. The paralysis was incomplete, for he has always been able to move the arm and hand in different directions, although slowly and sluggishly, and has not been obliged to take to his bed for a single day.

Such an evolution of symptoms points very plainly to brain disease of syphilitic origin; indeed, the diagnosis might in this case almost have been made without inquiry about a previous specific sore or secondary symptoms. This man had had a stroke of paralysis of the right side at twenty-eight years of age, without any other systematic affection which could account for it; and we may take it for granted that if hemiplegia occur in a patient between twenty and forty years of age, who has no heart disease, diabetes, tabes, kidney disease, alcoholism, etc., and in whom there has been no preceding acute illness, such as pneumonia, typhoid fever, etc., there is the strongest presumption that the affection is venereal. Another characteristic sign was that there had been no apoplexy at the time the stroke took place; for while the ordinary attack of hemiplegia from softening or hemorrhage is habitually accompanied by loss of consciousness and incontinence of the excreta, the syphilitic patient, when struck by hemiplegia, often assists himself, being fully conscious at the invasion of the paralysis. Then again the palsy had been incomplete from the beginning, and had remained so throughout its further progress. This incomplete character of the paralysis is another peculiar feature of syphilitic hemiplegia; for while in the idiopathic form there is complete loss of motor power, at least for the first few days or weeks of the illness, this is somewhat exceptional in the syphilitic variety, which is more frequently paresis than paralysis.

I have stated that the first nerve symptom which occurred in this patient was drooping of the left eyelid, and difficulty of seeing with the left eye.

On examining the eye, I found there was external as well as internal ophthalmoplegia, owing to paralysis of the third, fourth, and sixth nerves. This paralysis was complete in the superior and inferior recti, and the inferior oblique muscles; and incomplete in the levator palpebræ superioris, the internal and external recti, and the superior oblique. There was also paralysis of accommodation, and of the sphincter and dilator of the iris. The pupil was large, of ovoid shape, insensitive to light, and only slightly influenced by eserine and atropine. Dr. Laidlaw Purves reported the ophthalmoscopic appearances of the fundus of the eye to be normal, the tension likewise normal, no bulging or tenderness to pressure, vision $\frac{16}{cc}$, color-vision fair. The right eye and eyelid were quite normal, and there was no sign of disease in the other cranial nerves. The complication of hemiplegia of one side with ophthalmoplegia on the other side is again most significant for syphilis. In the ordinary form of hemiplegia the only cranial nerves which are affected are the portio dura and the hypoglossus of the same side. In syphilitic hemiplegia, on the contrary, we frequently meet with palsies of the nerves of the eyes, more especially the third, but also the fourth and sixth. Such palsies, indeed, were long ago called by Ricord the signature of syphilis on the eye of the patient. Ptosis alone is very common; and still more common is ptosis combined with paralysis of the rectus superior, or the rectus internus. Besides these, there are all possible varieties and combinations of ocular palsies, occurring in about three out of every four patients suffering from cerebral syphilis.

A second type of syphilitic hemiplegia is that in which the paralysis is preceded by headache of a peculiar character; and of this the following is a good instance:

An architect, aged thirty-seven, single, consulted me in December, 1881. He had not inherited any neurotic tendency, and had been in excellent health —saving an attack of smallpox when quite young— until 1873, when after impure connection he was troubled with a chancre, which was soon followed by roseola, sore throat, and ulceration of the tongue. These symptoms continued for about twelve months, but eventually yielded to mercury and Zittmann's decoction. The patient then remained apparently in good health for six years, when he was seized with headache of extreme violence, which occupied the very centre of the head, and came on periodically three or four times in the course of the twenty-four hours. It lasted for about an hour each time, and was so severe as to drive him nearly frantic. It was not like neuralgia, rheumatism, or megrim, but more deep-seated and inside the head, as if blows from a heavy hammer went right through the substance of the brain. The patient was singularly enough all the time treated with quinine, which did no good, and the pain continued with the same maddening violence for six months, when the patient one day fell down in a fit, speechless, but not unconscious, paralyzed on the right side, but retaining full control over the excreta. From that day he never has had any more headache. In ten days he recovered his speech, but the paralysis of the side remained. After a time he was seized with such severe pain in the spine that as many as five hypodermatic injections of morphia per diem were required to ease him; and shortly afterward he lost power over the left leg, the bladder, and the bowels. The bladder at the same time was so irritable that the patient had to introduce the catheter, which he did with the left hand, every hour by day and night. His speech and all the intellectual faculties were normal, there was no ocular paralysis, but paralysis and rigidity of the right arm and both legs, paralysis of the bladder, and great sluggishness of the bowels. No similar evolution of symptoms ever takes place in cases of idiopathic disease.

A third type of syphilitic hemiplegia is that where both sides of the body are affected in succession, the attacks following one another either within a few days, or weeks, or months. A case of this kind was that of an officer, aged forty, single, who came under my care in April, 1880. He had enlisted in the British army when seventeen years of age, and served chiefly in India. His health had on the whole been good, but in 1875 he had gonorrhœa and syphilis, and was treated with mercurial inunction. Rather more than three years after this he was told off to take part in the campaign in Afghanistan, and suffered a good deal from exposure to the extreme cold prevalent at that time. Presently he began to suffer from headache, giddiness, and general malaise, which continued for about a week. One night, being too restless to sleep, and feeling very unwell, he got out of his tent and began to walk about in camp, but found that he had great difficulty in moving. He therefore went back to his tent, and after awhile fell asleep. On waking in the morning he was surprised to find himself paralyzed—the left side, and that the excreta had passed under him. He could not put out his tongue, had great difficulty in speaking and swallowing, and his pupils were very large. Five days afterward he felt that he was losing power in the right side of the body; and this became worse day by day, so that at the end of ten days he was completely paralyzed and had lost the power of speech. During the whole of this time he never once lost consciousness, but constantly suffered from faintness, giddiness, and headache. He was put on iodide of potassium, and within a month from the commencement of the illness began to improve. The speech returned, although there was still difficulty of articulation; he recovered a degree of motor power, more especially in the right side; was invalided and sent home, and bore the journey fairly well. I have seen him quite lately; he remains in much the same condition, is totally disabled so far as locomotion is concerned, but his intellectual faculties have remained quite clear.

In other patients months may intervene between the successive attacks of hemiplegia. Such was the case of a woman, aged thirty-four, whom I saw at the hospital in December, 1883. She had been quite well up to the time of her marriage, five years ago. Her husband was a soldier, had served in the British army in almost every quarter of the globe, and no-

toriously led a very wild life. A month or two after her marriage, the wife was seized with ulcerated throat and an obstinate skin eruption. Three years afterward she suddenly found that her left eyelid drooped, and there are now ptosis and paralysis of the rectus internus. Six months after that she had a stroke of right hemiplegia with aphasia, and four months after this left hemiplegia. She made a good recovery so far as the aphasia and the paralysis of both sides were concerned, but the ptosis and palsy of the rectus internus remained unaltered.

The last type of syphilitic hemiplegia to which I will draw your attention to-night is that where the paralysis comes on quite slowly. In February, 1885, I was consulted in the case of a young man, aged twenty-three, who after infection only eight months previously, was taken with insidious symptoms of gradually increasing hemiplegia of the left side. As he was in a highly nervous condition, and so depressed in spirits that he would often burst out crying apparently for no reason, his affection had been diagnosticated as hysterical, and he had been treated with iron and phosphorus and shower baths. The loss of power had appeared at first in the left leg, the patient being unable to lift his foot well from the ground, and scraping it when walking. After a time the fingers of the left hand had likewise become affected; the patient was very clumsy in dressing and eating, and had to give up playing on the piano. Paralysis of the lower branches of the portio dura eventually came on, causing deformity of the face when laughing, and difficulty in whistling. Headache and drowsiness then intervened, and the intellect became clouded.

This case was peculiar from the unusually early appearance of so-called tertiary symptoms, viz., eight months after the primary sore; and this had at first no doubt prevented a due appreciation of the cause of the illness. Treatment by inunction was now resorted to, and showed the disease to have been truly specific, for there was manifest improvement in a few days, and the patient eventually made a very fair recovery.

You will readily admit that the several types of syphilitic hemiplegia which I have just sketched, differ *toto cælo* from the ordinary form of hemiplegia which occurs in the aged from hemorrhage or softening, while they differ no less considerably from one another. Indeed, while twenty cases of ordinary hemiplegia taken quite promiscuously are very much alike, there is hardly a single case of syphilitic hemiplegia which exactly resembles another; and it is this extraordinary variety in their clinical aspect which constitutes one of their most characteristic features. But is this peculiar grouping of symptoms sufficient to render the diagnosis of specific brain disease certain? Such is not the opinion of Fournier, who states that there is not a single pathognomonic symptom whereby we can distinguish idiopathic from syphilitic hemiplegia, and that we must rely for our diagnosis not only upon the peculiar development of the nerve symptoms, but also on the presence of venereal affections in other organs, such as the skin, the testicles, and the bones; on the fact that syphilitic hemiplegia occurs not so much in the aged as in persons in the prime of life; and that we can arrive at certainty only by the results of specific treatment, as the latter may cure the syphilitic variety, while mercury and iodide of potassium remain ineffectual in ordinary hemiplegia.

I am bound to say that I consider this latter test, viz., by the results of treatment, a very fallible one, as specific treatment fails to cure a very considerable number of cases of hemiplegia where there can be no doubt whatever about the specific nature of the complaint. I have, however, for some time past been of opinion that there exists one truly pathognomonic symptom whereby we are able to distinguish at a glance the syphilitic from the ordinary form of hemiplegia; and this symptom is an excessive exaggeration of the deep reflexes or tendon phenomena, which is present in syphilitic cases, and wanting in idiopathic cases.

In 1882, I showed a syphilitic patient, at the Clinical Society of London, in whom this symptom was so characteristic that it attracted my special attention. In that case the tendon phenomena were so much increased in the paralyzed leg that it shook fearfully on the least provocation, such as a sudden noise, opening the door, introducing the catheter, sneezing, coughing, etc. Percussion of the patellar ligament, of the tibia, and in fact of almost any point of the limb, induced violent so-called spinal epilepsy, which lasted for a considerable time, and was very greatly in excess of what is seen in ordinary hemiplegia. Another patient, when his patellar tendon was only touched, stamped the ground so violently as (according to his own saying) almost to bring the house down; and it is an interesting fact that this excessive exaggeration of tendon reflexes is not at all in proportion to the degree of the paralysis or muscular rigidity which may be present. Indeed, I have seen it in cases of syphilitic hemiplegia as well as of monoplegia, where the loss of power, although quite definite, was yet comparatively very slight; and it is a symptom on which I now chiefly rely in my diagnosis of these cases. Of course, it can only be utilized where the reflexes on the healthy side are normal, for there are patients, more especially of the neurasthenic type and also those suffering from the various forms of spastic paralysis, in whom these reflexes are everywhere greatly exaggerated, and in whom, therefore, such an appearance would not have the same significance. The exaggerated response occurs in the upper, as well as in the lower extremity, with equal force and readiness; but the symptom is habitually not quite so marked in cases where the paralysis has come on gradually as where there has been a sudden stroke.

I regret I have no time left to speak of the influence of treatment in this and similar conditions. It is, however, a singular fact that, while the therapeutical results in syphilitic nervous affections are sometimes exceedingly gratifying, they should, in other instances, be just the reverse. There is a general impression in the profession that the prognosis in specific lesions is altogether better than in ordinary idiopathic disease; but this is only partially true, for many patients suffering from cerebral affections on a syphilitic base, even if energetically treated on

a specific plan, do not recover, and either remain stationary, or undergo a rapid process of further deterioration, ending habitually in general paralysis of the insane. This apparently incongruous fact is, however, well accounted for by the circumstance that in brain syphilis we have to do not only with specific lesions, but also with the secondary consequences of such; and that these latter cannot, in the nature of things, be expected to yield to antisyphilitic treatment. No doubt a gumma in the subarachnoid space may be absorbed, and thickening of the dura mater reduced; but where a gumma has already caused wasting of the cranial nerves by strangling their substance, or where the occlusion of an important cerebral artery has led to softening of a certain area of cerebral tissue, such secondary and non-specific lesions cannot be cured, for no amount of mercury and iodide of potassium, or, in fact, any other drug, can restore nerve cells and fibres which have once perished. It is, therefore, only possible to cure those patients in whom the primary specific lesions have not as yet conduced to secondary ordinary lesions. The lesson which we have to learn from this should, therefore, be to subject patients, as soon as they show the slightest definite symptom of specific brain disease, at once to an energetic antisyphilitic treatment, so as to disperse the primary and truly syphilitic lesions, and to prevent, so far as possible, the formation of secondary ordinary lesions, against which latter our remedies are known to be powerless. What occurs in syphilis of the brain thus affords a striking illustration of the truth of the old Hippocratic maxim, *ὁ δὲ καιρὸς ὀξύς*, "the opportunity is fleeting." Let us, therefore, always endeavor to make use of it before it is too late.

THE PROGRESSIVELY INCREASING MORTALITY OF THE CÆSAREAN OPERATION IN THE UNITED STATES.

By ROBERT P. HARRIS, M.D.,
of Philadelphia.

An abstract report of what I stated through Dr. W. H. Parish, before the American Gynecological Society at its late meeting in Baltimore, has been furnished our medical journals for publication, in such a condensed form that it must necessarily fail in accomplishing the purpose for which the full record was prepared. The reporter, by reducing the facts to four lines, and leaving out entirely the most startling portions presented, has destroyed the progressive character of the statement. Forty years ago, this country stood in the fore front among the nations of the world in respect to its proportionate success under the Cæsarean operation; to day, judging from the work of the last five years, we are almost at the bottom of the list. And this retrogression has taken place notwithstanding the fact that the possibility of the success of this operation in the United States, when performed under favorable circumstances, has amounted to a saving of seventy-five per cent. of the women and eighty per cent. of the children. To show that this is a possibility still attainable under proper care and management, we have only to cite the fact, that during the past year European operators have, by the improved methods of Sänger and Leopold, saved 18 out of 20 women, and 19 (possibly 20) children.

Prior to 1846, my record shows a credit to this country of 21 operations, with 13 recoveries and 10 children saved. In contrast with this, the last 21 operations, covering nearly six years, show a mortality of 18 women and 14 children; of the last, three having been destroyed by craniotomy, and one by the forceps, its cranium having been fractured.

In the decade from 1846 to 1855 inclusive, the record is as follows:

Number of operations	25	Children delivered alive	13
Women saved	12	Children delivered dead	12
Women lost	13		

From 1856 to 1865 inclusive, ten years:

Number of operations	25	Children living	10
Women saved	12	Children dead	15
Women lost	13		

From 1866 to 1875 inclusive, ten years:

Number of operations	36	Children living	11
Women saved	10	Children dead	25
Women lost	26		

From 1876 to 1886 inclusive, ten and one-half years:

Number of operations	37	Children living	16
Women saved	8	Children dead	21
Women lost	29		

As there have been 5 Sänger operations performed in the United States, all ending fatally, with 3 children lost, there must be some readily ascertainable reason for the difference of results here and in Europe. We know that these operations were performed with care, as have been many others in the last ten years, which were likewise fatal; but the most careful of operators cannot overcome the difficulties engendered by long delay and futile intermeddling on the part of one or several accoucheurs, preceded, as in some instances, by the patient waiting for nature, of a midwife. It is one thing to operate as soon as the proper time arrives, and quite another to do it under a conviction that this time has in all probability passed many hours, some days, or even a week or two. There would appear to be an intimate connection between the living of the fœtus and the success of the operation, an association which has also been very marked in the Sänger cases. If our obstetricians had as good a knowledge of pelvimetry as prevails in the maternities of Austria, France, Germany, and Italy, there would be much less delay, and fewer attempts to deliver, either by forceps or craniotomy, in cases of pelvic deformity, or other forms of obstruction. If the pelvic space is first accurately ascertained, its measure of diminution should at once determine the possibility or impossibility of delivery by version, the forceps, or craniotomy. It is certainly bad practice to fail first in craniotomy, and then be forced to deliver the destroyed fœtus, by opening the abdomen and uterus, with the increased risk to life engendered by the futile intermeddling.

The declination of the family is sometimes given as a reason for delay; but this objection to the use of the knife would not hold, if the parties in interest

were made to understand that the operation was absolutely requisite, and that to delay was to lose the patient. Reduce the mortality, by promptness, decision, and the best improvements in operating, and the dread of the knife will diminish as success becomes more frequent. Properly educate the obstetrician, and the surgeon will soon show what measure of fatality truly belongs to his part of the work. We are certainly justified, from the Sänger successes, in our claim that *per se* the Cæsarean operation is far less fatal than it has been made to appear in the United States. The *possibility* of the operation is certainly far beyond its present *probable result* in this country, as calculated from past experience.

As this statement of results has been made entirely in the interest of science and humanity, the writer hopes that our medical journals will give it the widest publicity possible. Out of 144 cases in my private record, 63 were communicated, either by the operators or by other correspondents; hence the value of the statistics, as showing the mortality under the operation. But for these unpublished cases, we should have made a much more encouraging exhibit.

THE USE OF KAVA KAVA AS A DIURETIC.

By HERBERT C. ROGERS, M.D.,
of Brooklyn, N. Y.

I first noticed the diuretic properties of kava kava nearly two years ago, when I commenced using it in gonorrhœa.

Among the cases recorded in my note-book are the following:

Case I.—Charles W., aged twenty-seven, United States, in the steamship business. Family history good. Patient states that three days ago, while attending to his duties, he was suddenly seized with a chill and headache, and toward evening commenced vomiting. Yesterday he first noticed that his ankles and legs had become swollen; he also noticed that he was compelled to make water frequently, and that only a small quantity passed at a time.

When I was first called to see him, November 2, 1885, his legs and feet were greatly swollen. He was also quite weak, and suffered somewhat from dyspnœa. Abdominal and thoracic viscera were normal. Temperature, pulse, and respiration were normal. The urine presented a dark, smoky appearance; amount, seventeen ounces during twenty-four hours; it contained albumen, nearly seventy-five per cent.; sp. gr. 1.018, blood, and epithelial casts. As the patient was complaining bitterly of headache, I administered a hypodermatic of $\frac{1}{10}$ gr. pilocarpine. In a few minutes the drug began to show its physiological action, and in a short time he was covered with a profuse perspiration. The patient was placed upon milk and Vichy water; also to take thirty minims of the fl. ext. kava kava in half a glass of water, every three hours.

Nov 3. Patient during the preceding twenty-four hours has passed nineteen ounces of urine; chemical and microscopical appearances same as at last examination. He still complains of the pain in his head, but says it is not so severe as it was yesterday. He has not vomited since the evening of the 2d, and his bowels have moved three times. Ordered forty minims of kava kava every three hours.

4th and 5th. Patient feels a little better. Has passed twenty-one and twenty-five ounces respectively; the urine is clearer, and the albumen amounts to about thirty per cent. (by volume).

10th. Up to the time of the present note the patient has been gradually improving. The amount of urine passed is between thirty-five and forty ounces; albumen about fifteen per cent. As he has been suffering intensely from odontalgia for the past two days, and was unwilling to have his teeth drawn except while subjected to an anæsthetic, he was this afternoon put under the influence of nitrous oxide and three of his teeth were extracted.

11th. Patient is sitting up to-day, and is feeling quite nicely. During the preceding twenty-four hours he passed thirty-seven ounces of urine. The albumen is slightly increased, probably due to the anæsthetic administered yesterday. Sp. gr. 1.020. Treatment continued.

16th. Patient up, and about his room. He has passed, during the previous five days, two hundred and forty ounces—an average of forty-eight ounces per day. The swelling of his feet has disappeared, and also the swelling under the eyelids. The urine is clear, and contains about five per cent. of albumen. He has passed since last note from forty-five to fifty ounces per day. Sp. gr. 1.021. His appetite is good, and he is feeling much better. He was advised to continue taking the kava kava regularly for a month or six weeks—the dose to be ten minims in water three times a day.

Dec 3. I examined patient's urine, sp. gr. 1.027. He is passing from forty-seven to fifty-one ounces a day. The dropsy has entirely cleared up, and he is feeling quite well, with the exception of being a little weak. He left for the South to-day.

In a letter received from him about the middle of April, he writes that he is feeling better than he ever felt in his life. He has gained ten pounds in weight. His urine is free from albumen. He is passing from forty-eight to fifty-three ounces per day, of a sp. gr. 1.022. He has not taken any medicine since February.

Case II.—Jennie M., aged thirty-five, single, United States, a type-writer by occupation. Ill nourished and confined closely to office. When seventeen years old, patient suffered from scarlet fever. While recovering from this, she noticed that her feet and legs were becoming swollen, and also that her stomach and abdomen were increasing in size, so that she was obliged to let out her clothes. All these symptoms disappeared in a short time under treatment, when she resumed her employment. One week ago, while at work, she was taken with vomiting, which was followed by pain across the loins, and her feet and legs commenced swelling. She also suffered from headache. Her urine had been scanty for a long time.

I was called to see the patient October 6, 1885. Found her legs and feet much swollen. She was suffering also from hydroperitoneum. Her urine

was scanty, of a smoky color, and loaded with albumen, fifty per cent.; it also contained blood, granular, and waxy casts. Complete anorexia. She complained of a dull, aching pain over the lumbar region. She suffered from constant nausea, but seldom vomited. She was ordered forty minims fl. ext. kava kava in half a glass of water, every four hours; and a pill containing two grains citrate of iron and quinia three times a day. She was also ordered to drink as much fresh milk as possible with Vichy water.

Under this course of treatment the hydroperitoneum and anasarca of the lower extremities gradually diminished, and the quantity of urine passed during the twenty-four hours increased from twenty-nine ounces on date of my first visit, to fifty-one ounces on November 29th. The sp. gr. on October 6th was 1.018, and on November 29th, 1.022. The urine is much clearer, and the albumen amounts to about twenty-five per cent.

The treatment has been continued up to the present note, when I diminished the fl. ext. kava kava to half the quantity—twenty minims to be taken three times a day.

Dec. 20. The patient has recovered sufficient strength to go about, and is feeling quite comfortable. Her urine still contains a small amount of albumen. She is passing from forty-eight to fifty-one ounces a day. Her appetite is good, and she feels sufficiently restored to return to her occupation. She will report occasionally, and bring specimens of her urine to be examined. She will take for the present five drops of the tr. ferri mur. three times a day. The kava kava was discontinued December 1. 1885.

Case III.—Henry Z., lawyer, aged thirty-one. Born in England. Father died of apoplexy. Mother still living and enjoying good health, being eighty-five years old. Patient has been in good health until three years ago, when he was confined to bed by rheumatism, which lasted two weeks. He was attended by a homœopathic physician, who informed him, after he was able to go out, that his heart was not affected. To use the patient's language, he has "never fully recovered from this sickness." Shortly after this attack of fever he went South and remained until last December, when he was called home on account of business. At this time he was feeling better than at any period since his illness. About two months ago he began to notice that he was a little short of breath, which difficulty troubled him most when he was addressing a jury. As he was busy, he found no time to take rest. He also noticed that his feet and ankles were a little swollen at night on reaching home, and that he was obliged to sleep with his head quite high.

I first saw the patient March 13, 1886, when he came to consult me about the symptoms narrated above. Upon examination, I found that his feet and ankles were moderately swollen; slight hydroperitoneum. Examination showed that the heart was hypertrophied; the apex beat was heard and felt the strongest in the fifth intercostal space and a little more than one inch to the left of the nipple line, and a mitral regurgitant and an aortic direct and regurgitant murmur were readily heard. His temperature was normal. Pulse 110. His urine was quite clear, and contained merely a trace of albumen; no casts; acid; sp. gr. 1.020, and he was passing thirty-three ounces in the twenty-four hours.

Patient was ordered milk, Vichy water, and infusion of digitalis ʒij every two hours.

March 15. Patient feels about the same. The digitalis caused so much stomach disturbance that he omitted it for the preceding twenty-four hours. Thinking that the stomach trouble was, perhaps, due to other causes, I ordered two minims fl. ext. digital. in water three times daily. At the end of forty-eight hours, however, he was suffering as much as ever from his stomach, and I had to omit the digitalis. His condition was about the same, with the exception that he did not suffer from shortness of breath. He was ordered to take ten minims of the fl. ext. convallaria majalis and forty minims of the fl. ext. kava kava in half a glass of water every three hours; to continue on with the milk diet; and in addition to take ʒij of whiskey three times a day.

22d. Patient is feeling much better. The diuretic effect of convallaria and kava kava is very marked to-day. He says he is passing enormous quantities of urine. The anasarca of feet and ankles is nearly gone. The hydroperitoneum has entirely disappeared. The urine is free from albumen. The heart is acting with more regularity. The appetite and digestion are good.

28th. As to-day was quite warm and pleasant, my patient accompanied me around part of my route. He says he can go up and down stairs slowly. He does not suffer from dyspnœa. The swelling is entirely gone from his feet and ankles. His appetite is good, and he is able to lie down at night. I stopped all medicine; but a few days later he called at my house complaining of slight dyspnœa and a little swelling about the ankles. I ordered five minims of the kava kava and five minims of convallaria majalis three times a day.

April 3. Patient was able to return to his office to-day, and to attend to light office business.

May 25. Met patient in court to-day. He informs me that he is feeling very well, and that this morning he made an address in court, nearly three hours in duration. He is still taking the medicine. He sleeps well, and his appetite is good.

Case IV.—Was asked to see, in consultation, a young lady, sixteen years of age, who had had scarlet fever three or four weeks ago. The attack was quite mild, and she was confined to bed less than ten days. Up to this present attack the patient had always enjoyed good health. I found her very weak. She had great swelling of her feet and legs; was passing but a small quantity of urine per day, which was loaded with albumen. There were complete loss of appetite and some headache. She was put upon milk, and forty minims of kava kava in half a glass of water every three hours, and ten drops of tr. ferri mur. three times daily. In the course of a few weeks, as I am informed by her mother, the œdema entirely disappeared, her appetite became good, and she went back to school.

The fluid extract of kava can be given in doses of from five minims to a drachm, repeated every three, four, or six hours according to the result desired. The preparation which I have used is the fluid extract prepared by Parke, Davis & Co., whose fluid extracts are arranged to represent one grain for each minim.

377 Gates Avenue.

ANTISEPTIC SURGERY IN THE PENNSYLVANIA HOSPITAL.

By CHARLES BINGHAM PENROSE, M.D.,
RESIDENT PHYSICIAN.

In June, 1886, an attempt was made, with the permission of the visiting surgeons, to introduce thorough antisepsis into the surgical wards of the Pennsylvania Hospital. Before this, a modified form of antisepsis had been used. Instruments were, sometimes, placed in solutions of carbolic acid. Wounds were washed with solutions of carbolic acid, or of bichloride of mercury. Vessels were tied with catgut or silk. Rubber drainage tubes were used, and wounds were generally closed with silver sutures. Carbolized oil, dry carbolized gauze, or gauze wrung out of a solution of bichloride of mercury, constituted the dressing. Iodoform was used freely.

Many of the materials necessary for a thorough antiseptic operation were at hand, but, in most cases, discouraging failure was the result of all attempts at such an operation. The nurses were untrained in antiseptic methods. They considered their hands clean if washed two or three times during the day. They placed dressings on chairs or beds; a favorite place was the ward carriage. Dry carbolized gauze was thrown about, apparently with the idea that the little carbolic acid in it was an absolute preventive against all contamination. It was most difficult for the busy operator, assisted by men ignorant of antiseptic principles, to observe all antiseptic precautions. He was, consequently, content with modified antisepsis—that is, with careless antisepsis. Some of the channels by which septic matter might enter the wound were closed, but at the same time many remained open.

The statistics of the Hospital were good. They could, however, have been better; and the good results were obtained with much unnecessary labor and expense. Cellulitis often followed amputations of fingers. Pus often appeared under scalp wounds. Large amputations were dressed every few days, and the healing of stumps was often much delayed by unabsorbed catgut ligatures. In fact, many patients who had been discharged from the Hospital with stumps entirely closed, returned, weeks afterward, with small abscesses caused by unabsorbed catgut ligatures.

The object of the writer is not to decry the methods which had been previously used, and which he himself had used for several months; but it seemed to him that it might be useful briefly to describe the methods which were afterward more successfully pursued: the simple ways of preparing the necessary materials; and to give an account of some of the results that have been obtained.

It cannot be said that all cases have had the benefit of thorough antiseptic treatment. The Hospital was deficient in many important particulars necessary for antiseptic surgery, and the nurses were untrained. All the minor operations, however, and several major operations have been performed in a thoroughly antiseptic manner.

Method of Proceeding.—The part to be operated upon was shaved, washed with turpentine or ether, scrubbed with a nail-brush and soap, and finally washed off with a solution of bichloride of mercury, 1 part to 1000 parts of water. It was placed upon a rubber sheet wet with a solution of bichloride, and towels wrung out of the same solution were placed about the part. Upon the ward carriage were two vessels containing bichloride solutions; one solution of 1 part of bichloride to 1000 parts of water, the other, 1 part to 2000. To each vessel was attached a rubber hose. During the operation the weaker solution was kept constantly running over the wound. All arteries were tied with catgut. Catgut drains were used in all smaller wounds where drains were necessary. In larger wounds rubber drainage tubes and bone drainage tubes were used. Instruments were boiled after every operation, and during the operation they were placed in a three per cent. solution of carbolic acid. New sponges were used for every operation. Catgut sutures were employed in all but a few cases where fine silk was necessary.

As before mentioned, the catgut which had previously been used in the hospital was rarely, if ever, absorbed. This catgut was obtained from Seabury & Johnson, and was preserved in carbolized oil. It was not pliable, and was difficult to tie. It is probable that, in many cases, this gut was not absorbed because the wounds were not dressed antiseptically, and suppuration took place. In an antiseptic operation it should, at least, have become encysted. Much better catgut was prepared by the following method: Ordinary commercial gut, such as is used for musical instruments, etc., was placed in oil of juniper for about two days, in order to remove the oil of the gut. It was then washed, and preserved in alcohol. Gut thus prepared is absorbed in from five to ten days, according to the size. If placed in a watery solution for a minute before using, it becomes as pliable as silk. In cases where it was necessary for the sutures to be stronger, and to be absorbed less rapidly, chromicized gut was used. The gut was chromicized by Lister's method. One part by weight of catgut was placed in a solution containing $\frac{1}{200}$ part of chromic acid, 1 part of carbolic acid, and 20 parts of water. In about forty-eight hours the color of the solution changes from an orange to a faint olive color. The gut was then washed, and preserved in alcohol. Gut thus prepared is absorbed in from ten days to three weeks.

The catgut which was used for drainage was generally absorbed in five days.

Bone drainage tubes were made from chicken bones. The bones were cleaned, washed with ether, and placed for about two days in a solution of hydrochloric acid, one part of acid to five of water. After the calcareous elements had thus been dissolved, the endosteum was easily removed. They were then placed in oil of juniper for two days, and afterward

preserved in alcohol. These drainage tubes are absorbed in about five days.

Much stronger tubes have been made of parchment, at the suggestion of Dr. W. B. Hopkins. The parchment was softened in a solution of bichloride (1 to 1000), and was then rolled into the requisite shape. The tubes were then placed in oil of juniper for three days, and preserved in alcohol. No opportunity has yet occurred for using these tubes.

Rubber drainage tubes were kept in a three per cent. solution of carbolic acid.

As already stated, sponges which had been used were always thrown away after the operation. Cheap sponges were bought; the carbonate of lime was dissolved by soaking for several hours in dilute hydrochloric acid, one part of acid to ten of water. They were then bleached by the following method: Place the sponges for a few minutes in a solution containing 180 grains of potassium permanganate to five pints of water; squeeze dry, and place in a solution made by dissolving ten ounces of hyposulphite of sodium in sixty-eight ounces of water and then adding five fluid-ounces of hydrochloric acid. This solution should be made several hours before using, and should be filtered. When placed in the last solution, the sponges immediately become bleached; they should then be removed and washed with water. These sponges were kept in a solution of bichloride (1 to 1000), and during an operation they were washed in the bichloride solution.

Wounds were dressed with protective, and several layers of gauze wrung out of the bichloride solution (1 to 1000)—the surface next the skin being thickly covered with iodoform. If necessary, over this was placed corrosive cotton, or corrosive jute, and a gauze bandage wrung out of the bichloride solution.

It is, unfortunately, not possible accurately to compare the statistics of the Hospital when modified antisepsis was employed with the statistics of the past three months, because no regular statistics of the results and complications of the smaller wounds were previously kept. The writer, however, can recall at least a dozen cases of cellulitis of the hand and arm following wounds, which occurred in his own ward during the four months previous to the introduction of thorough antisepsis. On one occasion there were three men in adjacent beds; one with cellulitis following amputation of the fingers, a second with cellulitis following a lacerated wound of the wrist, and a third with cellulitis following a dog-bite.

During the last three months over five hundred wounds requiring sutures have been treated at this Hospital. One hundred and fifty of these were scalp wounds; fifty were amputated fingers. Among the others, were eleven compound fractures of fingers, six compound dislocations of fingers, seven wounds requiring the suturing of tendons, twelve pistol-shot wounds of the hand. One case of cellulitis has followed these injuries. This occurred in a man with a crushed heel, admitted seven hours after receiving the injury. The skin and fascia had been torn from the os calcis, leaving the bone exposed. The wound was dressed in the usual way. The temperature remained normal for four days after admission, and he had no pain. On the fifth day he complained of pain, and the temperature rose to 100°. The dressing was removed and the foot was found to be red, swollen, and tender. The stitches were cut, and irrigation with bichloride (1 to 5000) was started. In twelve hours the temperature fell to normal. In two days a permanent dressing was again put on, and he made a speedy recovery.

There have been two cases of surgical erysipelas, one occurring in a scalp wound which was first seen four days after the injury had been received: the other, in a case of compound fracture of the skull, where the delirium of the patient rendered it impossible to retain the dressing in place.

It must not be forgotten that these five hundred wounds were all dirty wounds, occurring in laborers injured at their work, or in men from the slums of the city, who take their baths yearly, if at all.

Felons, abscesses, etc., have been freely laid open, scraped thoroughly with the finger-nail or a spoon curette, and scrubbed with a solution of bichloride (1 to 1000). Catgut drains, when necessary, were introduced, the wounds were wholly or partially sutured, and an antiseptic dressing was put on. These cases healed under one or two dressings, like simple lacerated wounds. Poultices were never used after an incision had been made.

Poisoned wounds, dog-bites, human bites, etc., were enlarged if necessary, and thoroughly washed with a solution of bichloride (1 to 500). Out of twenty-four such cases, there has been but one case of cellulitis following the injury.

The following is a list of the major cases which have been treated with thorough antisepsis during the last three months:

I. Razor cut of wrist: division of ulnar artery, tendons of palmaris longus, flexor carpi radialis, and flexor sublimis digitorum. The tendons were sutured with catgut. Dressing removed after fourteen days; wound closed, with the exception of small ulcer where the catgut drain had emerged. Discharged with good use of hand.

II. Hand crushed by wheel of carriage: compound fracture of four metacarpal bones. First dressing removed after ten days, to take out rubber drainage tube. When the second dressing was removed, ten days later, the wound had completely closed.

III. Compound fracture of thigh, lower third, from direct violence. External opening closed when first dressing was removed, at the end of nineteen days.

IV. Compound fracture of humerus, middle third, from direct violence. Catgut drain introduced. First dressing removed after twelve days; small, superficial ulcer left.

V. Compound, comminuted fracture of humerus, from direct violence. External opening closed in eighteen days, after two dressings.

VI. Compound, partial fracture of radius, caused by fall of gravel bank; large, lacerated wound, full of dirt. Dressing removed after fourteen days; wound closed.

VII. Ununited fracture of radius. The bones were exposed, the ends freshened, and fastened to-

gether with silkworm gut. Dressing removed after twelve days; wound closed.

VIII. Compound fracture of ulna and radius, from direct violence. Wound enlarged about three inches. Wound closed when first dressing was removed, after fourteen days.

IX. Amputation of breast, and removal of axillary and subclavicular glands for carcinoma. Rubber drainage tube removed on fifth day. Second dressing removed on twelfth day; wound closed.

X Amputation of leg, at middle third, for crush. Bone drainage tubes introduced. First dressing removed after two weeks: second and last dressing removed two weeks later.

XI. Crushed leg, which had been amputated at upper third, twenty-four hours before admission. When admitted, temperature 103°; stump full of blood, and dressed with lard. Stump was opened, flaps scrubbed with bichloride solution; rubber drains introduced, and stump closed. Cured in twenty-five days, after three dressings.

XII. Compound, depressed fracture of skull. The skull was trephined, and the compressing fragment of bone removed. Catgut drain introduced, and wound closed. When the first dressing was removed, at the end of fourteen days, there was complete union.

XIII. Cervical adenitis: removal of large number of glands from clavicle to mastoid process. Catgut drain introduced, and wound closed. First dressing removed in nine days, small ulcer left.

XIV. Incised wound of leg: division of part of tibialis anticus muscle, extensor longus digitorum, two peroneals, soleus, and gastrocnemius, and the musculo-cutaneous nerve, and anterior tibial artery. Muscles and nerves sutured. Complete union on ninth day. When discharged, there was no anæsthesia or paralysis.

XV. Multiple incised wounds of foot from lawn mower: several tarsal and tarso-metatarsal joints opened, and compound fracture of several tarsal bones: division of all the flexor tendons. Tendons sutured, and catgut drain introduced. When the dressing was removed, at the end of two weeks, all the wounds were closed. When discharged, there was perfect use of the whole foot, with the exception of two toes.

XVI. Crush of foot: several large, lacerated wounds; compound, comminuted fracture of great and little toes. Amputation of great toe. Cured in seventeen days, after one dressing.

XVII. Strangulated inguinal hernia and epiplocele. Excision of large part of omentum, and division of internal and external abdominal rings. Sutures introduced in sac, and in columns of ring. Catgut drain. Complete union when the first dressing was removed, after twelve days.

This list comprises all the major cases which have been treated antiseptically during the past three months at this hospital; they are not merely the picked cases which have done well. Many other major operations have been done with modified or careless antisepsis, with the usual results, some good and some bad.

With regard to the deleterious effects of antisepsis, little need be said. In no case has a patient exhibited symptoms of mercurial poison. In a few cases, some irritation of the skin has been produced by the bichloride. The only cases in which such irritation has been of any consequence, were those in which the skin had been badly bruised. In such cases weaker solutions than 1 to 2000 should be used in the dressings. The writer of this article suffered from a mild attack of mercurial stomatitis, produced by unnecessary handling of bichloride solutions. No other person connected with the hospital has been poisoned.

The cases mentioned in the statistics of this paper were dressed by Dr. T. S. K. Morton, and the writer. Dr. Morton expects, in several months, to report the further results of antisepsis in the Pennsylvania Hospital.

MEDICAL PROGRESS.

Acute Rheumatism in both Mother and Newborn Child.—Schaefer records the case of a woman, aged thirty-five, who on the fifth day of an attack of acute articular rheumatism, gave birth to a healthy child. On the third day after birth the child was taken sick with fever (99.9° F.), anorexia, and swelling of the superior surfaces of both feet. On the following day there was swelling of the first phalangeal joint of the left index finger, and a doughy swelling of the region of the left hip-joint; temperature 102.2° F. On the day thereafter there were redness and swelling at the wrist and at all finger-joints.

Peacock (*Lancet*, 1882) describes a similar case, treated with salicylate of sodium.—*Centralbl. f. klin. Med.*, Aug. 14, 1886.

Night Palsy.—Dr. W. E. Stevenson, in the *Practitioner* of June, 1886, contributes a short article on a special form of numbness of the extremities occurring, for the most part, during the night, and to which Weir Mitchell has given the name of night palsy. Dr. Ormerod's description is quoted as follows: "The symptoms are remarkably definite in character. They occur in women, usually about the climacteric period, and begin in the night. On waking, the patient has a feeling in the hands and arms (commonly on both sides) of numbness, deadness, pins-and-needles; sometimes there is actual pain, severe enough to wake her. There is also loss of power, the hands and arms become useless, and she cannot hold things. This may so far predominate that the patient comes to be treated for a supposed paralysis. Sometimes, also, the patients say that the hands swell, the veins swell, etc., at the time. The symptoms pass off in a little time, and rubbing suggests itself as a natural remedy. But occasionally they manifest themselves in the daytime also, and then principally when the patient sets about her ordinary work—washing, scrubbing, needlework, etc." The author has had several cases of the affection, and his observations agree, in the main, with the foregoing description. Though mostly seen in women at or near the climacteric age, it is occasionally met with in men, in whom it is likely to be more severe and obstinate. Some attribute it to anæmia; others to gastric disturbances. All of the

author's patients recovered with rest, bromide of potassium, and galvanism.

Sodium Phosphate in the Treatment of Pelvic Peritonitis.—Chéron, treating by mistake an extensive pelvic exudation for a fibroid, by subcutaneous injections of sodium phosphate, found that the former rapidly disappeared. The solution used consisted of sodium phosphate, sodium sulphate, āā 5; aq. destill. 120. Of this, four grammes were injected deep into the tissue every eighth day. In two months the entire exudation had disappeared. Four other cases gave like results. The hypodermatic needle must reach the subcutaneous connective tissue, and the injection be slowly made. The point where the needle enters must afterward be gently rubbed for one or two minutes.—*Centralblatt für Gynäkologie*, No. 15, 1886.

A Suggested Alteration in the Compound Liquorice Powder.—Dr. Martin Oxley writes as follows to *The Lancet* of October 2, 1886: "Having found that the above preparation produced very severe griping in many instances where I had ordered it, the griping being particularly severe in some of my younger patients, I have ordered the following formula for some time past, in which anise fruit is substituted instead of the fennel and one-fourth part of ginger is added. The altered formula runs thus: Senna and liquorice-root, of each 2 parts; anise fruit and sulphur, of each 1 part; sugar, 5¾ parts; ginger, ¼ part. This altered preparation is quite as satisfactory in its laxative properties, is less liable to gripe, and is as pleasant to take as the official powder, and I would suggest its trial in cases where the powder as now prepared produces the disagreeable effects to which I have referred."

Crime and Responsibility.—In an article thus entitled, in the *Canada Medical and Surgical Journal*, of October, 1886, Dr. Daniel Clark presents the following conclusions:

1. The natural history of crime shows that brains of chronic criminals deviate from the normal type and approach those of the lower creation.
2. That many such are as impotent to restrain themselves from crime as the insane.
3. That immoral sense may be hidden from expediency by the cunning seen even in the brutes, until evoked by circumstances.
4. No man can shake himself free from the physical surroundings in which he is encased.
5. Crime is an ethical subject of study outside of its penal relations.
6. Insanity and responsibility may coexist.
7. Some insane can make competent wills, because rational.
8. The monomaniac may be responsible should he do acts not in the line of his delusion, and which are not influenced thereby.
9. Many insane are influenced in their conduct by hopes of reward or fear of punishment in the same way as the sane; the rudiments of free-will remain.
10. Many insane have correct ideas in respect to right and wrong both in the abstract and concrete.
11. Many insane have power to withstand being influenced even by their delusions.

The Treatment of Lupus by Local Applications.—Dr. P. G. Unna, of Hamburg, writes as follows in *The Lancet* of September 25, 1886:

Mr. Beiersdorf (40, Wöhlers Allée, Altona) has, upon my suggestion, composed the following five plastermulls for the cure of lupus. Each roll (length one metre, breadth twenty centimetres, equal to one-fifth square metre) contains—

Salicylic acid.		Creasote.	
10.0	grm.	20.0	grm.
20.0	"	40.0	"
30.0	"	50.0	"
40.0	"	40.0	"
50.0	"	50.0	"

Any one wishing to avoid, from the first change of the plastermull, the painful first period after its application, and in this way to institute a completely painless treatment for lupus, may paint the raw surface with a four per cent. aqueous solution of cocaine ten minutes before applying the second plaster. For this short anæsthesia cocaine is as efficient as it was found useless in attempting to produce a lasting diminution of the pain, in addition to the salicylic acid. But creasote is, to my mind, not only the morphine of the skin; it has another especial value in the treatment of lupus—its antiseptic power. It is not only a correctant of the salicylic acid, but also the best adjuvant we can find. At least, excepting cod-liver oil, I know of no antituberculous remedy in which I have so much confidence as in good beech tar creasote. In any case of this phthisis of the skin, with which we are now concerned, it is a remedy which, applied in the concentration and in the manner indicated, deserves every consideration. This supposition has, moreover, been proved in practice to be correct. The salicylic creasote plastermull is a remedy which brings about a cure of lupus without any extraneous aid. The strongest plaster necessary for the case should always be employed at the commencement, since at first a relatively normal skin-surface has to be attacked; under these the lupus tubercles can be seen to soften and break down. The action can be accelerated, as is the case with all plastermulls, by covering them with hot poultices. The dressing should be changed once, or at the most twice, daily, with or without the application of cocaine, and the parts cleaned, according as the susceptibility of the patient will allow it, with linimentum calcis, oil, lard, or even with soft-soap and hot water. As soon as it is found that with this simple treatment the excavations are getting shallower, and that no new ones are appearing, we may assume that the whole of the lupus nodules have fallen out. It is then advisable to have recourse to weaker salicylic-creasote plastermulls, and finally, when the lupus seems to be totally destroyed, but the process of skinning over is sluggish and a quicker completion is wished for, to still weaker means, such as mercurial-carbolic or zinc-salicylic plastermulls, or to a simple healing remedy like iodoform, ichthyol, etc. Smaller and more isolated nodules are generally completely cured under the salicylic-creasote plastermulls, even those which are richest in salicylic acid. In general, I consider it better to let the strong plastermull lie somewhat longer than is apparently necessary, so as to give a chance to even the deepest-lying nodules to shell out,

and for the same reason the plaster should overlap the edge of the lupus patch by at least half an inch.

This is the simplest possible form of the treatment of lupus; but it can, of course, be further developed and enriched by combining it with other methods according to the individual case. These various modifications, which cannot all be mentioned here, do not alter the original idea, which consists in keeping up a continual but never excessive exfoliation of the affected portions by means of a highly elective substance (salicylic acid), which destroys the weaker tissue of the new growth, whilst a second substance (creasote) renders the process painless and at the same time exercises a directly destructive action on the bacilli.

A by no means slight advantage of this process of treatment is the cosmetic improvement which it effects, for in this concentration the salicylic acid assists powerfully in removing old stringy and lumpy scars, and after every removal of the scabs which it produces the surface is found to be in a distinctly smoother condition. On the other hand, it leaves sometimes a longer-lasting redness, which probably results from a paresis of the capillaries or from the destruction of the stratum granulosum, the layer which causes the white tint of the skin. This is best met by using an ichthyolic ointment or by painting on a zinc-ichthyol-gelatine preparation afterward.

The Management of Placenta Prævia.—Malcolm McLean, in a recent article on the management of placenta prævia, thus concludes:

1. In any case, avoid the application of all chemical styptics, which only clog the vagina with inert coagula, and do not prevent hemorrhage. At the very first, the patient should be put in a state of absolute rest, body and mind, and a mild opiate is often desirable at this stage, to quiet irritation.

2. Inasmuch as the dangers from hemorrhage are greater than all else, to both mother and child, at the earliest moment preparations should be made to induce premature labor, and labor being once started, the case should be closely watched to its termination by the accoucheur.

3. In primiparæ and mothers with rigid tissues, the vagina should be well distended, by either the colpeurynter or tampon, as an adjuvant to the cervical dilatation.

4. In the majority of cases, and in all cases where there is reason to believe that rapid delivery may be required, it is more safe to rely on the thorough, continuous, hydraulic pressure of a Barnes's dilator than on pressure on the fœtal parts.

5. Where the implantation is only lateral or partial, and where there is no object in hurrying the labor, bipolar version, drawing down a foot and leaving one thigh to occlude and dilate the os, may be practised, according to the method of Braxton Hicks, except in cases where the head presents well at the os, when,

6. The membranes should be ruptured, the waters evacuated, and the head encouraged to engage in the cervico-vaginal canal.

7. In the majority of cases, podalic version is to be preferred to the application of the forceps within the os.

8. In some cases, in the absence of assistance or the necessary instruments, the complete vaginal tampon, in part or wholly of cotton, may be applied and left *in situ* until (within a reasonable time) it is dislodged by the uterine contractions and the voluntary efforts of the mother. In case of favorable presentation—occiput or breech—the tampon will not materially obstruct the descent of the child; and in some cases the tampon, placenta, and child will be expelled rapidly and safely without artificial assistance.

9. The dangers of septic infection by means of the tampon or India-rubber dilators are so slight, if properly used, as not to be considered as seriously impairing their great value.

10. Whenever it is possible, dilatation and delivery ought to be deliberately accomplished, in order to avoid maternal lacerations.

Finally. As cases of placenta prævia offer special dangers from post-partum hemorrhages, septicæmia, etc., the greatest care must be exercised in every detail of operation and nursing to avoid conveying septic material to the system of the mother.—*Canada Medical and Surgical Journal*, October, 1886.

Prophylaxis of Cooks' Conjunctivitis.—Dr. G. C. Simmons, of Sacramento, Cal., writes as follows to the *Boston Medical and Surgical Journal*, of October 7, 1886:

A Chinese cook in our employ had suffered repeatedly from attacks of conjunctivitis owing to his labors over a hot cook-stove. These were soon cured by the use of collyria of borax and camphor, and a caution as to the real cause. But only to return. To our surprise, not long ago he appeared in large Chinese spectacles—tortoise-shell rims and plates of mica, transparent and non-magnifying. With these he goes happily to his work, and so far with no fear of a return of the conjunctivitis, and reasonably, too, as mica is notably a protector against heat. Consulting standard works on ophthalmology I find no reference to their use in occupations exposing one to conjunctivitis from heat, and the idea is certainly worthy of our remembrance.

Acute Melancholia caused by Impacted Feces.—H. A. Hutchinson, M.D., presents the following case in the October number of the *American Journal of Insanity:* Mrs. S., aged forty years, was recently admitted to the Western Pennsylvania Hospital for the Insane.

At the time of her admission she was suffering from acute melancholia, was very weak, extremely emaciated, skin bronzed, dry and harsh, hair dry and falling out, and all the secretions of the body were perverted.

In her conduct she was very suicidal, destructive of clothing, and presented the appearance of abject despair. Conversation was entirely incoherent, though she gave evidence of a few systematized delusions—that her body was infected with vermin and snakes, and her clothes with moths, which she tried vainly to drive away by frequently tearing her clothing and burning it.

The previous history of the case, obtained from her husband, was that of a gradual decline in bodily health during the past year, and the appearance of insanity within the last three weeks. Constipation had been constant, and more recently there had been inability to void urine, requiring the use of a catheter. Menstruation had ceased some years previously.

The family history told of three other members who had been insane, neither of whom recovered—two sisters and an uncle. The cause of insanity was stated as unknown. The medical treatment combined tonics, frequent applications of blisters to the nape of the neck, laxatives, and at night large doses of bromide of potassium and chloral.

Laxatives, when employed, were said to have always caused free movements of the bowels, but their use was followed by increased excitability.

Upon being admitted to the hospital, the patient was immediately placed in bed, and thoroughly examined.

In addition to the already detailed marked evidences of her exhaustion, a distinct tumor could be felt through the thin abdominal walls, following the course of the rectum and sigmoid flexure, and making the introduction of a catheter to relieve her distended bladder almost impossible.

The tumor was at once thought to be an accumulation of hardened feces, and the cause of ill-health and consequent insanity. Removal of the mass was accomplished only after much persistent effort for several days, and the employment of the various suitable injections, together with the free use of the scoop.

Rapid improvement in the patient's mental condition followed this procedure, and in less than one month she was discharged in perfect health of body and mind.

Pomade for use in Blenorrhœa.—Unna commends a composition of the following formula as a local application in cases of chronic urethritis:

Nitrate of silver	1 part.
Balsam of Peru	2 parts.
Yellow wax	2–5 "
Cacao butter	100 "

A metal sound, smeared with the pomade, is introduced into the urethra. In some cases four to six such applications have been sufficient for the production of a definitive cure. In others, it has been necessary to repeat this series from two to four times. In certain patients, also, it has been found needful to supplement this treatment by injection of sulphocarbolate of zinc.—*L'Union Médicale*, September 11, 1886.

Albuminuria in Diabetes.—Dr. Robert Maguire read before the Pathological Section of the Brighton meeting of the British Medical Association, a paper entitled as above, of which the following is an abstract:

Albuminuria is a complication of diabetes which is frequently overlooked, and which may be of grave or of insignificant import, according to the various conditions under which it may arise. It may occur as a chronic or as an acute albuminuria. In the chronic form the albuminuria is associated with an organic change in the kidneys and urinary tract, or it may be due to derangement of the circulatory apparatus of the kidney.

In *post-mortem* examinations made in long-standing cases of diabetes, it is common to find the kidneys hard and tough; and, when examined microscopically, they show an overgrowth of the interstitial tissues round the vessels and glomeruli and between the tubules. The capsule of the kidney may be slightly adherent; but it is rare to find a condition which could be called granular kidney. Doubtless, this interstitial overgrowth has for its cause the irritation of the kidney by continuous overwork. It is a condition which, as might be expected, is occasionally associated with the presence of albumen in urine, but in only small amount. Such albuminuria has usually little or no influence upon the course of the diabetes; this goes its way as if no such complication had arisen. It must be remembered that one is now speaking of diabetes complicated by interstitial overgrowth in the kidney, and not of those cases of gouty interstitial nephritis, which may present at times an insignificant glycosuria, in addition to the persistent albuminuria. The albuminuria has in these two conditions an essentially different prognosis. Occasionally, however, as Dr. Pavy has pointed out, albuminuria may, to a certain extent, displace a glycosuria, and become the prominent symptom of the case.

Fatty degeneration of the kidney may, again, occur in diabetes, and give rise to an albuminuria, which exerts little influence on the progress of the case.

There is another organic change which I have sometimes seen in *post-mortem* examinations on diabetics, and which may conceivably give rise to albuminuria, although I offer this as a suggestion, and without proof of any kind. I allude to the thickening of the walls of the bladder, and with this—in all probability, in consequence of this—a dilatation of the ureters and of the pelvis of each kidney; in fact, a mild condition of hydronephrosis. We know from experimental evidence that ligature of the ureters will cause albuminuria, and it is possible that continuous high pressure in the pelvis of the kidney, produced in the way I have mentioned, might determine an albuminuria in diabetes.

Such are the organic kidney changes under which diabetic albuminuria may occur; and it is somewhat remarkable that these, which under other conditions would be considered grave lesions, are here commonly of so little consequence. This becomes almost a paradox, when we find that one form of functional albuminuria which may occur in diabetes is a very bad omen. In the later stages of diabetes as asthenia progresses, the heart begins to fail, and one of the early signs of this is a slight albuminuria, due to the deficient circulation of blood through the kidneys. At the same time, we find, of course, general asthenia, and not unfrequently nervous symptoms, such as great depression of spirits with hysterical phenomena, mental torpor, and drowsiness. This, however, is not true diabetic coma, and must not be confused with it. The albuminuria is in itself of little consequence, but the general condition producing it is very serious. The cardiac asthenia may in some cases be recovered from, under the influence of cardiac tonics, but in the majority of cases it is a near precursor of the final break-up.

I wish to call the special attention of the meeting to an acute form of albuminuria, which occurs in connection with diabetic coma, and which is of very serious prognosis. In pursuance of a complete examination of the urine of a patient suffering from diabetic coma of the dyspnœic type, I found a considerable quantity of albumen, which had certainly not been present before the coma set in. The patient died, and at the *post mortem* examination there was seen, in well-marked form, the "necrosis" of the epithelium lining the convoluted tubes and Henle's loops, described by Ebstein. Another

patient, under the care of Dr. Morgan in the Manchester Royal Infirmary, showed albuminuria about twenty-four hours before noticeable signs of diabetic coma appeared. I mentioned this in a note to a review in the *Medical Chronicle* for December, 1884, and since then I have never failed to find albumen in the urine of those patients suffering from diabetic coma of the true "Kussmaul's" type, with whom I have met. I have not a large number of cases to record, about eight or nine in all, but I find that Stokvis, of Amsterdam, at the Wiesbaden Congress of this year, has stated as his experience also that albuminuria is of very frequent occurrence in diabetic coma.

A case which came under my notice recently may be mentioned, in that it not only illustrated this point, but was also of medico-legal importance. A gentleman's coachman, who had previously been in apparently good health, although it was afterward elicited that he had been losing flesh for about a year, complained one day of a slight pain and uneasiness in the abdomen. For this, a druggist gave him a bottle of medicine, of which he took one dose, and died comatose four hours afterward.

The medical gentleman who was called in invited me to make the *post-mortem* examination. On opening the skull, a strong sweet smell of aceto-acetic acid was perceived, which became almost overpowering when the thoracic and abdominal cavities were opened. The liver was enlarged and congested, the kidneys large, in color mottled yellow and red, and on section the thorax was found to be greatly increased in extent. A quantity of urine drawn off from the bladder gave the ferric chloride reaction of aceto-acetic acid, contained a large quantity of sugar, and in addition a considerable amount of albumen. A small amount of albumen is frequently found in urine drawn from the bladder after death, but such could not be the origin of the large amount found in the above case. On microscopic examination of the kidneys, I found the glomeruli intact, but the epithelium of the convoluted tubes was greatly swollen, in some parts hyaline, in others appearing as a confused granular mass, which was very difficult to stain, and which showed very few nuclei. In many parts, too, the epithelium was detached from the walls of the tube. This condition of the kidneys was, therefore, the probable cause of the albuminuria. The pathological signs showed that the case was one of diabetic coma, and it was afterward proved that the medicine the man had taken contained nothing harmful.

Recently, in a case of diabetic coma, I analyzed the albumen which was present in the urine, and found that it consisted of two and a half parts of serum-albumen to one part of serum-globulin, a proportion which I have observed to be a common one in severe organic lesions of the kidneys.

The relation of this albuminuria, and its accompanying kidney change, to the diabetic coma, is of great importance, but uncertain. The coma is certainly not uræmic coma, but all the later researches prove that it is due to the circulation of some poisonous matter in the blood, whether this be acetone, aceto-acetic ether, aceto-acetic acid, or oxybutyric acid. Two possibilities seem open: one is that the poisonous matter in the blood irritates the kidneys, and so produces the change in the epithelial cells, which change is quite analogous, so far as the convoluted tubes are concerned, to that produced by a large dose of cantharides. In support of this, it should be noted that, in the experiments in which attempts have been made to produce diabetic coma by injecting into the blood the various substances mentioned above, albumen has occasionally appeared in the urine. The other possibility is that something more than the presence of the poisonous matter in the blood is necessary to produce coma. It may be that this further determining influence is the epithelial change in the kidney, the sign of which is the albuminuria described. It will be remembered in this connection that, in the researches hitherto published, the complete symptomatology of diabetic coma as seen in man has not been produced in animals, by the injection of any poisonous matter into the blood, so long as the kidneys have been intact.—*British Medical Journal*, September 18, 1886.

DISLOCATION OF THE TESTICLE.—DR. SMITH reports, in *The Indian Medical Gazette*, for July, 1886, the case of a soldier who was struck with a rifle-butt in the scrotum. He complained of great pain, and examination showed absence of the left testicle from its normal position, and the presence of a small, rounded tumor, very sensitive on pressure, in the groin about at the internal ring. Nothing was done for the man, except to relieve him of heavy work. Some months later the patient died of beri-beri, and on post-mortem examination the testicle was found lying within the abdominal cavity, where it had contracted some adhesions to the peritoneum. A slit was seen at the internal ring, through which the little finger could be passed into a pouch running toward the scrotum. The man stated that the two testicles had always been present in the scrotum up to the time of the accident.

JEQUIRITY IN TRACHOMA.—DR. W. F. SOUTHARD formulates as follows the results of his experience with jequirity:

1st. The freshly powdered bean acts fully as vehemently as the solution, though in some cases, perhaps, the effects are not felt as quickly.

2d. The croupous membrane is formed fully as rapidly as after using the solution.

3d. The powder clears the cornea of pannus fully as effectively.

4th. The pain may be as severe from the use of the powder as from using the solution.

5th. Should spots of trachoma be left after the first application of the powder, it can be reapplied in from six to twelve days, thus localizing its action.

6th. Its permanent effects are the same as those produced by the solution.

7th. It appears to be much the safer remedy, for it does not seem necessary to limit its use to old trachomas with pannus.

8th. Attention is especially directed to the fact that great caution is necessary in using this remedy, in any form, on account of the unexpected and somewhat alarming constitutional effects sometimes produced.—*Pacific Med. and Surg. Journal*, October, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,

PHILADELPHIA.

SATURDAY, OCTOBER 16, 1886.

THORACENTESIS FOR PLEURITIC EFFUSION.

AMONG the subjects which occupy a sort of middle ground between the general practice of medicine and that of surgery, none is of greater interest or of greater importance than the question of the proper management of serous effusion into the pleural cavity. In regard to the treatment of empyema there is little difference of opinion; but in the treatment of purely serous effusion different practitioners hold diametrically opposite opinions. Some rely almost exclusively upon medicinal remedies, while others believe in early operative interference.

There are two principal reasons assigned for preferring medicinal treatment: First, it is sufficient in the great majority of cases to effect a cure, and it is safe; and, second, operative procedures are not more efficient, while they are dangerous.

In the defence of operative interference these reasons are directly reversed, and puncture of the wall of the thorax is asserted to be the best way of getting rid of the immediate and remote effects of an effusion, while, if properly conducted, it is almost entirely devoid of danger.

To decide which of these opposite opinions is correct, or what mean between them may be adopted, is not an easy task. But something may be gained by examining the grounds upon which they rest.

The efficiency of purely medicinal measures in the treatment of moderate pleural effusions cannot be doubted, nor can the assertion that it has sufficed for very large effusions be denied. To select but a few illustrations of this fact, BARBE, who is not afraid to operate, reports, in the *Archives Générales de Médecine* for May, 1885, a large number of cases cured by the use of iodine externally, and of certain internal remedies. In some of his cases the effusion was estimated at as much as four pints. By the method which Körner, of Graz, first used in 1863—which consists in the withholding of fluids from the patient and in the administration of salt—some remarkable results have been reported. Thus GLAX, in the *Zeitschrift für klinische Medicin.*, Bd. ix. Heft 5, records twelve cases in which the exudate filled or almost filled the pleural cavity, and in which a cure was effected in an average of twenty-two days. Similar results have been reported by other trustworthy observers.

In the face of such facts, and of the opinion of many of the best clinicians, it must be acknowledged that in most cases the medicinal treatment of pleural effusion is entirely efficient, so far as getting rid of the effusion is concerned. Whether or not it is entirely safe, depends somewhat upon the way in which this word is applied. It is safe enough so far as the immediate result is concerned. But is it safe when the ultimate issue of the case is considered? Those who favor puncture of the chest wall assert that there is great danger to the lung from delaying its expansion, danger of adhesion, of consolidation, of retraction of the chest wall, and of permanent dislocation of other organs.

These accusations are somewhat vague, and, so far as we know, are not supported by any carefully prepared statistics. Still they deserve consideration, and the well-recognized fact that attacks of pleurisy often precede the outbreak of phthisis, to which CHAUVET has recently called attention in the *Lyon Médicale*, May 24, 1885, may indicate some imperfection in the method of treating pleurisy. This point, however, should not be strained any more than another, which is made against operative interference, that the outbreak of phthisis which sometimes follows is to be attributed to it.

The negative evidence in favor of the medicinal treatment of pleural effusion lies in the asserted danger of puncturing the pleural cavity. This is said to consist in the risks of septic infection, of converting a serous effusion into an empyema, of arousing into activity a latent tendency to tuberculosis, and a certain danger of wounding the lung. The last of these dangers is hardly of much significance, the next to the last probably owes its terrors to the mistake of taking *post hoc* for *propter hoc*. The danger of septic infection and of converting a serous effusion into an empyema is very real, and there have been only too many exemplifications of it. But it is an error to suppose that the danger is inevitable. With proper antiseptic precautions there is scarcely any reason why tapping the chest should subject the patient to risk of this sort. It is possible, of course, that the aspirating needle or trocar may pass through the

fluid and wound the lung, so that from it a source of putrefaction or of specific disease shall gain access to the cavity of the pleura. But this is very unlikely to happen, and no virulent material ought to come from without if the operation be done correctly. That this, however, does sometimes take place only shows that those who have had such results have something to learn in regard to the principles and practice of asepsis.

It cannot be maintained that there is any considerable danger in the operation of thoracentesis when done carefully, and the choice between it and medicinal treatment must be determined by the estimate of their relative efficiency, and especially by the suitability of either to each particular case.

In some cases the most conservative medical man feels constrained to tap, in others all but extremists would hesitate to do it. Aufrecht, in the *Berliner klinische Wochenschrift*, No. 10, 1886, maintains that small effusions—which may be cured by salicylic acid—should not be tapped, but when the effusion reaches the third intercostal space in front, the fluid should be let out; and this he believes to be a good rule even when the symptoms do not seem to threaten life. But it is not well always to empty completely the pleural cavity. Aufrecht thinks that more than five pints should never be withdrawn at one sitting, and Barbe, in the paper above referred to, is of the opinion that tapping need not be resorted to until the accumulation amounts to about two quarts, and that only half of this should be drawn off at a time. His opinion is founded on an experience of fourteen cases, in which he made twenty-seven punctures, and in which there were no subsequent paroxysms of cough, or serous expectoration. In Aufrecht's experience morphia subdued the paroxysmal cough perfectly.

Very recently Heitler, in a paper in the *Centralblatt für die gesammte Therapie*, for June, 1886, has advocated active interference in pleural effusions. He does not believe that early puncture can abort a pleurisy, and recent French experience has demonstrated that putting such a belief into practice has led to an increased mortality. Aufrecht does not overlook the fact that desperate cases have recovered without tapping. But he regards the presence of either a very large effusion, a rapid rate of effusion, or a long persistence of the effusion as a sufficient indication for operative interference. What he means by long persistence of the effusion may be gathered from the statement that thoracentesis should be practised if the effusion remains stationary for two or three weeks, and shows no tendency to resorption. Stöhr, in an inaugural thesis, Erlangen, 1885, came to much the same conclusion. He analyzed fifteen cases of operation, and considered the proper indications to be urgent symptoms, great effusion, rapid accumulation, and considerable displacement of the viscera.

In all that has been said thus far, it has been assumed that the discussion refers to simple serous effusions. For purulent, ichorous, or hemorrhagic effusions, the propriety of tapping, drainage, and washing-out, seems to be beyond question. But even in deciding what is to be done for an effusion supposed to be purely serous, it must not be forgotten that it cannot always be certainly determined without resort to hypodermatic aspiration. Polain, in the *Gazette des Hôpitaux*, Nos. 38 and 130, 1885, has asserted that there are no certain signs of the nature, nor of the amount of an effusion. This view may be an exaggerated one; but the possibility of error in this respect should not be overlooked.

In conclusion, we think that it may be said that medicinal treatment suffices for the relief of the great majority of cases of serous effusion in the pleural cavity, but that tapping should be resorted to when a rapid accumulation produces dangerous symptoms, or when long persistence of a large effusion makes it likely that this may cause irremediable changes in the lung or chest-wall. The assertion that phthisis may be provoked by a properly conducted tapping is not borne out by a study of a large number of cases, and the risk of converting an innocent effusion into a dangerous one, we believe to be dependent upon circumstances which can be avoided.

THE TREATMENT OF GONORRHŒA.

Those who have the largest experience in the treatment of gonorrhœa disclose the unsatisfactory condition of its therapeutics in the numerous and different plans which they adopt and recommend for its cure, in most of which a certain period of absolute rest seems to be essential. And every practitioner could doubtless testify regarding cases which have refused to get well in the orthodox way, and which have somehow been apparently cured by a druggist's or friend's prescription, while the patient continued to do the very things which his physician had charged him to avoid doing. The discovery of the so-called gonococcus led many to hope that at last the right plan of treatment was clearly indicated, and that the use of a germicide would be sure to effect a cure. Unfortunately in this, as in other connections, the germ theory has proved rather of speculative interest than of practical utility.

The fact remains that anti-bacterial injections cannot be said to be any more efficient in the treatment of gonorrhœa than others which have no such specific action; and their effect may be as fairly attributed to their influence in allaying the inflammation

as to any action they may exert upon its supposed germ.

Nor are injections alone always satisfactory in the treatment of gonorrhœa, for which reason they often may, and sometimes must, be supplemented by internal medication; while sometimes peculiar circumstances make it impossible for injections to be used, and then internal medication must be the sole reliance. The importance of such medication cannot be doubted, and it is worth while to call attention to a recent study of the subject by Posner, in the *Deutsche medicinische Wochenschrift*, of August 26, 1886.

Posner rightly regards gonorrhœa as a cyclic disorder, which, under favorable circumstances, tends to a spontaneous cure, and the requisite time for which may be shortened by judicious treatment. His own experience has led him to think well of the internal administration of the oil of sandalwood for this purpose, which, when he uses it from choice, he supplements with injections of resorcin toward the second or third week. The length of time required for a cure, he finds to be about three or four weeks. He has used internal medication alone in those cases in which all authors agree that injections are to be avoided, such as those in which the gonorrhœa has passed the barrier of the compressor urethræ, and has led to epididymitis, prostatitis, cystitis, or other complications.

The best form of administration of the oil of sandalwood is in the French capsules, containing each five drops; of which he thinks ten or twelve may be given daily. Posner has also given the oil combined with a little oil of peppermint, and Lublinski has ingeniously given it on peppermint drops with satisfactory results.

The use of pure oil of sandalwood is not new, nor are its merits underrated in this country. It is better borne by the stomach than is the oil of copaiba—which is more active—and it undoubtedly relieves tenesmus and strangury while exerting a beneficial influence upon the urethritis. No internal medication, however, can entirely supersede the use of injections, which should be employed whenever circumstances permit, and made of materials suited to the condition of each case. In the stage of acute inflammation the blandest and most soothing injections must be employed, and after this stage is passed there is probably nothing better than sulphate of zinc of the strength of two grains to the ounce of water.

An important point in the use of medicated injections is, not simply to have the urethra washed out by the patient's urine—as is usually prescribed—but to order that the urethra shall be several times syringed out with water as warm as can be comfortably borne. When this is systematically done, injections are most efficient. And when, with the proper use of injections, the administration of oil of sandalwood, or of copaiba is combined, we have what in the present state of our knowledge is the most satisfactory method of treating gonorrhœa.

Physiologists have long maintained that the power of pepsin is limited to the digestion of albuminoids, and this indeed is unquestionably its sole functional significance. An entirely distinct field of observation, however, is opened up in the question of the influence of the digestive ferments upon ingested drugs.

In the *Bollettino della Società tra i cultori delle scienza mediche in Siena*, 1886, No. I., Torsellini describes an interesting series of experiments upon the effect of pepsin upon the solubility of calomel. The observations in question took the form of artificial gastric digestions, and showed that pepsin in the presence of calomel materially increased the solubility of the latter, without the production of corrosive sublimate, in spite of the fact that the solution contained two-tenths of one per cent. of hydrochloric acid. Pepsin alone, in the absence of dilute acid, was, of course, without effect. Control experiments showed that while hydrochloric and lactic acids, in strengths of one-tenth to two-tenths of one per cent., increased the solubility of calomel, this effect was greatly augmented by the addition of pepsin, an effect evidently due to the direct action of the ferment.

At a recent meeting of the Chicago Medical Society, Dr. Schrimer exhibited a case of actinomycosis in a man twenty-five years of age, who had had, for several years, abscesses and fistulæ in the submaxillary regions. In May abscesses were opened in the neck, and the pus contained the characteristic yellow granules. Latterly cough, with symptoms of lung disease, had appeared, and the actinomyces were found in the sputum. This is the first instance of advanced actinomycosis in man which has been described in this country. In Dr. Murphy's cases, also in Chicago, the trouble was confined to the jaws, and readily cured by operation.

Israel has recently reported a case which bears out his views of the origin of the trouble in carious teeth, which form a nidus for the development of the parasite. In an instance of actinomycosis of the lung, there was found, in one of the foci of disease, a small foreign body, which proved to be a fragment of a tooth, which had been aspirated into the lung, and had probably carried with it the germs of the disease.

We have the pleasure of acknowledging the receipt of the following contributions to the fund for the relief of the Charleston Medical College:

Dr. Roberts Bartholow, Philadelphia	$25
Dr. Wharton Sinkler, Philadelphia	10

REVIEWS.

"Haschisch." A novel. By Thorold King. 12mo. pp. 314. Chicago: A. C. McClurg & Co., 1886.

The title and the cover of this book are suggestive, leading its buyer into vistas of pleasure, which, like the dreams of haschisch, are found only a delusion.

The story is one long since stereotyped in fiction. Two brothers love the same girl. One of the brothers, just returned from the diamond fields with abundant wealth, is murdered with chloroform; presumably by a friend, who in a position of trust had, by his carelessness, permitted his employers to be robbed, and had thereby lost his position. This young man, Gordon Wright, is convicted of the crime, and sentenced to imprisonment for life, though the evident intention of the author to have him pardoned in the near future is disclosed by the previous introduction into the story of Philip Arnold, whom the murdered man, the night previous to his death, charged with dishonesty in the management of the affairs of a ward committed to his care.

Madge Irving, Gordon Wright's affianced, of course does not believe in his guilt, and, as the story progresses, the plan to prove him innocent takes shape. Into this Kenneth, the brother of the murdered man enters, but unfortunately falls sick of a fever, which gives Miss Madge opportunity to study the symptoms, and weigh the chances of his recovery with all the zeal of a female devotee to the study of physic, which, indeed, from her success and judgment, in this case, she should have been. Kenneth at last recovers, and after a tedious convalescence, resolves to sail for Europe in search of Philip Arnold, upon whom the reader has long since fastened the crime. The physician who attended him during his illness, was a young man whom he had met abroad, and with whom he was on terms of intimacy. Philip Arnold is finally found, and the labor of proving his crime begun. Kenneth engages himself to the suspected man as a servant, and sends for his friend, the young physician, who, accompanied by a Mr. Smith, sails for Paris, to assist in the business of ferreting out the crime.

Now is the reader introduced to haschisch, by means of which it is proposed to ensnare the villain of the story. A long description of the action of the drug, with its history is given, with the idea of explaining how the culprit is to be caught. By the aid of a French Professor, Arnold is at last duped into partaking of the drug, and under its influence goes through a pantomime in which are enacted the scenes of the murder. On awakening from his haschisch dream, the murderer hastens home, and under the fear that he has disclosed something to his detriment, compels his servant to relate all his actions while under the influence of the drug. This, Kenneth does, and Arnold attempts to murder him at the point of recital where he is charged with the death of Austin Hardy, but foiled in his attempt at this second crime by the appearance of Smith and the young physician, he cuts his throat with a razor which is happily nigh to end the story, which otherwise might have been unduly prolonged through another trial and conviction. Gordon Wright is pardoned and restored to his former position, the crime of the robbery being, like that of the murder, fixed upon Philip Arnold, and everyone but Smith enters into the bliss of matrimony, the wise forethought of the author no doubt leading him to take no further steps for the perpetuation of an already famous name.

The medico-legal aspect of the story, if indeed the author seriously intended there should be any, is without value. The days of inquisition, whether of drugs or torture by wheel and flame, are long since passed. Law does not require a criminal to condemn himself, and the administration of a drug that destroys self-control, and abolishes the will, is lawless even for the ends of justice. As to the use of chloroform for criminal purposes, we may say, it might be so used, though its employment is exceedingly doubtful, and its success uncertain.

A Guide to the Practical Examination of Urine, for the Use of Physicians and Students. By James Tyson, M.D., etc. Fifth edition. Philadelphia: P. Blakiston, Son & Co., 1886.

The several newer tests for sugar, albumen, and the various proteid substances are given much space in the fifth edition of Professor Tyson's "Practical Examination of Urine." The index refers to thirteen tests for the presence of glucose in the urine and seven for albumen. The only fault that can be found with the book is that it gives a superabundance of somewhat complicated tests, many made with chemicals of an uncommon sort, and does not quite sufficiently explain, for a practitioner's handbook, which are the most to be recommended. It seems to us time, for instance, that a process so coarse as Moore's potash test for sugar should be omitted from text-books or the student warned against it, especially as to its behavior with mucin, for when liquor potassæ is boiled with urine containing that substance, the odor and color supposed by Moore to be "characteristic" of grape-sugar result.

And would not one test for indican be enough?

Jaffé's is probably the better of the two given, but it ought to be mentioned that unless the solution of calcic hypochlorite be perfectly fresh the test will fail—and we may add that if the resulting color be red instead of blue, iodides are present in the urine, so that the method may also be made useful in ascertaining their absorption. Lieben's iodoform test for acetone may, it should be said, be used for ordinary clinical purposes, without first distilling the urine.

No one who has used the former editions of Professor Tyson's most valuable little book, can help being grateful to him for so much information gathered into so succinct and convenient a form, and in spite of the small criticisms we have made of minor matters, we are fully sensible of its usefulness and excellence, and hope to see it improving and keeping up to date with annual future editions.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 7, 1886.

The President, A. Jacobi, M.D., in the Chair.

Dr. Julius Althaus, of London, a Corresponding Fellow of the Academy, read a paper on

SOME PHASES OF CEREBRAL SYPHILIS.

(See page 421.)

Dr. R. W. Amidon said that he would like to call attention to one factor in the production of syphilitic coma which the learned author of the paper had not specifically referred to, viz., the factor of a weak heart. Dr. Althaus, he felt sure, however, would be willing to acknowledge its agency, since he had mentioned among the exciting causes over-exertion, anxiety, and alcoholic and sexual excesses, all of which conditions are recognized as conducing to weak heart. He thought that this important factor did not receive sufficient attention from the profession.

The occluding disease of arteries was well understood, but alone he did not think it sufficient to account for the coma. Taken in connection with a weak heart, however, it would satisfactorily account for all the phenomena so graphically described in the paper.

Dr. A. D. Rockwell remarked that as our experience extends in the domain of nervous diseases we must necessarily become more and more impressed with the importance of syphilis in this connection. Patients often state, with honest conviction, that they have never had syphilitic trouble; and yet the subsequent history of their cases proves conclusively that they have. Dr. Rockwell said he had had no personal experience with syphilitic coma, but he thought that perhaps a case which he had had under his care some time ago, might prove of interest in connection with the subject of the paper. It was one of spastic paresis, with some difficulty of utterance. From the beginning there had been a facial paralysis. This had been followed by aphasia and hemiplegia, which afterward disappeared, and then reappeared again. The patient denied that he had ever had syphilis, but a course of antisyphilitic treatment resulted in very marked benefit.

Dr. Robert W. Taylor said that he was in hearty accord with the author of the paper, in much that he had said, but thought that he had scarcely done full justice to certain observers in the historical part of it. It was true that two great pathological epochs in connection with syphilis were inaugurated by Virchow and Hübner; but these were outshone, he believed, by certain clinical epochs. The Strassburg thesis of Hildebrand shows that about 1848 and 1850 there was some professor at that university who had taught a knowledge of cerebral syphilis. The next epoch commenced about 1863, with the writings of Lancereaux, Lamier *fils*, and other French authorities, and these were the text-books from which a vast amount of our knowledge had been obtained. Without detracting from the labors of Hübner, he thought that a word of acknowledgment was due the late Walter Moxon, of London, for his remarkable contributions on syphilitic disease of the arteries, published in the *Guy's Hospital Reports*.

Dr. Althaus's description of syphilitic coma was clear, systematic, and admirable in every way; it was evidently the result of careful bedside study. As regards syphilitic hemiplegia, Drs. Van Buren and Keyes, in this country, had studied the subject very thoroughly, and all the varieties and symptoms described by Dr. Althaus had been noted in the paper which Dr. Keyes wrote a number of years ago, embodying their researches, the main points of which had now been incorporated in several text-books. He believed that certain concomitants, besides syphilis, were necessary to produce these severe neuroses, and among these he would rank as of great importance alcoholic and sexual excess, and unnatural sexual habits.

Dr. Landon Carter Gray, of Brooklyn, said that some questions brought up by the author were, he thought, worthy of some little discussion. The pathology of these cases of syphilitic coma is a subject which still deserves a great deal of study, and personally he was hardly prepared to accept Dr. Althaus's conclusions. The textural changes which took place in the brain itself were out of all proportion to the arterial changes, as was shown in two autopsies which he had had the opportunity of seeing, in cases where the coma was the predominant symptom before death, the paralysis present being secondary. In both cases the presence of arterial disease was evident not only to microscopic inspection, but also to the naked eye. Yet this, so far as he was able to judge, was not sufficient to account for the symptoms noted during life. In one of the cases there were numerous textural changes, including softening amounting to pulpiness, with lepto-meningitis and syphilitic neoplasms. The mere theory of some occlusion of the basilar artery, he thought, was not enough to account for the coma. Again, if the coma were very profound, it might be impossible to say whether any paralysis were present or not.

As to the matter of treatment, he was somewhat surprised to hear the views expressed by Dr. Althaus. He depended apparently entirely on mercurials, and had little or nothing to say in regard to iodide of potassium. As for himself, he had some time since given up the use of mercury entirely in these cases, as he had never seen any beneficial results from it. He had had indubitable evidence in his experience of the superior value of the iodide, and he believed that this was the experience also of the great majority of neurologists in this country.

Dr. Putzel said that he was glad that the question of therapeutics had been taken up, and stated that he agreed entirely with the author of the paper in regard to the superiority of mercury. It was now about six years since he had become convinced that syphilis did not yield, or at least but very slowly, to iodide of potassium. Formerly he employed the bichloride of mercury; but more recently he had found much better results from the use of inunction. It is his custom to employ this until the teeth begin to be touched, and then discontinue it. In connection with this, small doses of iodide of potassium sometimes seem of service.

As to occlusion of the basilar artery, which Dr. Althaus would assign as the direct cause of syphilitic coma, it seemed to him that we were likely to have a number of vessels injured, but not sufficiently to cause occlusion. The blood-supply would be diminished, but this would not be sufficient to cause total occlusion until the end.

CORRESPONDENCE.

THE INTESTINAL SUTURE OF APOLITO; ADDITIONAL REMARKS.

To the Editor of The Medical News,

Sir: In the number of The Medical News for August 28, 1886, I presented an account of this form of

suture, with illustrations, but could not at the time state when the method originated, and presumed that it might have been more recent than it now appears to be. Additional information just received from the same source shows that the suture originated with Dr. Nicola Apolito, of Cagnano, Province of Capitanata, one of the Southern provinces of Italy, and was described in the *Osservatore Medico di Napoli* for July 1, 1841. It is therefore older than that of Gély, and not a modification or simplification of it.

Robert P. Harris, M.D.

Philadelphia, October 12, 1886.

NEWS ITEMS.

A Resignation from the International Medical Congress.—We are informed that Dr. E. Williams, of Cincinnati, has resigned the Presidency of the Section of Ophthalmology in the Washington Congress.

The title of Doctor was invented in the twelfth century, at the first establishment of the universities. William Gordenia was the first person upon whom the title of Doctor of Medicine was bestowed. He received it from the college at Asti in 1329.

Double Embryo in a Single Blastoderm.—Professor Legge, in a communication made to the Eustachian Society of Camerire, states that he has had the good fortune of meeting with, in a fowl's egg, at about the third day of incubation, two embryos in a single blastoderm, joined together at the summit.

Obituary Record.—Died, in New York, on October 7th, in the 89th year of his age, Dr. James Anderson. Notwithstanding his advanced years, he was in his usual health and vigor until two days before his death, when he was attacked with cholera morbus.

Dr. Anderson was born at the Battery on February 21, 1798, and was descended from an old Dutch family. He received his early education in the city schools, and began the study of medicine under Dr. David Hosack. In 1821 he was graduated from the College of Physicians and Surgeons, and began to practise medicine in the city. He still continued his connection with Dr. Hosack, and for a number of years examined all the latter's students. He was one of the early presidents of the New York Academy of Medicine. He was the founder and first President of the Physician's Aid Society, and was prominently identified in an official capacity with the College of Physicians and Surgeons. He was also the consulting physician of the St. Nicholas Society, and was prominently identified with all the old Dutch interests in the city of New York.

Influence of Magnetism on Chemical Reaction.—Mr. E. L. Nichols, in the *Journal of the Chemical Society*, describes a set of experiments with aqua regia, nitric acid, hydrochloric acid, and sulphuric acid, to illustrate the phenomenon that when finely divided iron is placed in a magnetic field of considerable intensity, and exposed to the action of the acid, the chemical reaction differs in several respects from that which occurs under ordinary circumstances. With aqua regia, it was found that the speed of the reaction is greater in the magnetic field than without, and that the heat of chemical union is much greater. With nitric acid, the effect of the magnet was greatly to increase the speed, reducing the average time from eight minutes to less than one minute. With sulphuric acid, the reaction was uniform and complete, and apparently of the same chemical character within and without the field. The magnet was found, however, to increase the speed of reaction, and to decrease the amount of heat produced. A series of measurements was made with nitric acid, in which powdered copper was substituted for iron. The reaction in the field was found to be identical with that which occurred when the magnet was not in action.

Suicidal Mania from High Temperatures.—A case of attempted suicide from acute mania, recently treated in one of the New York hospitals, has served to call renewed attention to the hardships of the life of stokers aboard ocean steamships. A rather intelligent English circus performer, finding himself getting too corpulent for the requirements of his calling and believing that much hard exercise in a very high temperature would rid him of flesh, decided to make the ocean passage as a fireman in a steamship, and obtained the opportunity he desired. The fire-room on a steamer is away below the water line, where ventilation is impossible, or at least not attempted. The temperature ranges from 135° to 175°, and in that atmosphere the men are required to shovel coal eight hours in every day—two stretches of unceasing and heavy work of four hours each in the twenty-four. The man in question was advised that he could not stand the exhaustive labor, but he was not to be dissuaded. Several times he fell fainting on the hot floor of the fire-room, but always insisted on resuming his duty. When within a day of port, in a fit of mania, he rushed from the heat, climbed to the deck, and leaped over the rail into the sea. Sailors rescued him, but he had to be kept manacled during the remainder of the trip.

Dr. George T. Stevens, of New York, has received the prize of the Royal Academy of Medicine of Belgium, for the best essay on "Elucidating the Pathogeny and Therapeutics of the Diseases of the Nervous Centres by Clinical Facts and Experiments." Of all the essays submitted, only his will be published by the Academy.

Dr. Ireland's book, *The Blot upon the Brain*, is to be translated into German. The French translation of this work, which is being prepared by Dr. Edgar Bérillon, of Paris, is nearly finished, and will be published in November. The "Blot" has been prohibited by the ever-vigilant Russian censorship. This is no doubt owing to the chapter on the hereditary insanity of the Romanoffs, and the historical illustrations about the miseries which insane monarchs have caused to their subjects.

Association of the Surgeons of the Pennsylvania Company.—The eighth semi-annual meeting of this Association will be held at the Seventh Avenue Hotel, Pittsburg, Pa., Tuesday, October 19, 1886, commencing at 9 A. M., Eastern time. A number of papers on appropriate subjects are promised.

Paul Revere as a Dentist.—In the *Boston Gazette*, December 19, 1768, appears the following curious advertisement:

Whereas many Perfons are so unfortunate as to lofe their Fore-Teeth by Accident, and otherways, to their great Detriment, not only in looks, but speaking both in Public and Private: This is to inform all fuch, that they may have them replaced with artificial Ones that look as well as the Natural, & anfwers the End of Speaking to all Intents, by PAUL REVERE, Goldsmith, near the Head of Dr. Clarke's Wharf, Bofton.

*** All Persons who have had falfe Teeth fixt by Mr. John Baker, Surgeon-Dentift, and they have got loofe (as they will in Time), may have them fastened by the above, who learnt the method of fixing them from Mr. Baker.

Unusual Cause of Death.—The French public was recently agitated by the discovery of the dead body of a genteel girl in a sequestered street in the suburbs of Paris. There were no marks of violence, but no doubt was entertained, either by the police or the public, that the death was due to crime. For some days the journals were full of wild theories as to the motives which might have prompted the murder. The real circumstances of the case, as now ascertained, are a trifle less romantic, but are sufficiently curious, from several points of view, to merit a passing remark.

At the post-mortem examination, which was made in the usual course of events at the Morgue, it was discovered that death was due to suffocation caused by impaction in the larynx of a collection of the *Ascaris lumbricoides*, which the child had presumably vomited, but not ejected. Not the least remarkable feature in the case is the explanation offered by the parents of their conduct in the matter. Terrified by the sudden death of the child, which nothing had foretold or could explain, they had preferred depositing the body in an unfrequented spot, to risking the malicious remarks and inuendoes of the neighbors and that dread official, the *concierge*. Rather than face this, and a possible trial for manslaughter, they, in a fit of desperation, resorted to the reprehensible plan which excited so lively an interest in French society. The cause of death is one which deserves to be recorded in the annals of legal medicine.

Appointment in Cooper Medical College.—Samuel O. S. Potter, A.M., M.D., has been called to fill the Chair of Theory and Practice of Medicine, in Cooper Medical College, made vacant by the death of Professor Henry Gibbons, Sen.

Beaumont Hospital Medical College.—Under this name a new medical school has been organized in St. Louis.

Free Dispensaries are said to be almost unknown in France, there being only three in Paris. What a paradise for young doctors such a country must be, says the *Maryland Medical Journal*.

Heat Holidays.—A very beneficent action is now required by law in Germany and Switzerland by which holidays are obligatory in all public and private schools when the temperature reaches a certain height. These heat holidays are called "hitzferien," and are worthy of adoption in other schools. In Basle new regulations have just been issued concerning heat holidays. When the temperature rises twenty degrees (Reaumur) in the shade at 10 o'clock in the morning, holiday is to be proclaimed to the scholars until the afternoon. Two such holidays were proclaimed during a recent hot week, to the no small delight of the boys and girls, whose jubilant greeting of the announcement could be heard from the open windows of the gymnasium.

American Pharmaceutical Association.—At the last meeting of this Association the following resolution was adopted.

Resolved, That this Association solicit the aid and coöperation of the American Medical Association, in promoting the prescribing by physicians of officinal medicines only, or such preparations as have published formulas, in preference to others; and that the several State Pharmaceutical Associations make similar requests of their respective State Associations.

Death from Use of Collodion in Smallpox.—A death is reported in France from the application of collodion to the face of a woman suffering from smallpox. The design of the application was to prevent pitting. Suppuration took place under the mask of collodion, and the patient died after great suffering. As the smallpox was discrete and uncomplicated and the autopsy showed no visceral lesions, the fatal termination would seem to have been due to the injury resulting from the collodion.

An Undesirable Experiment.—A recent incident in the Michigan College of Medicine has been a source of much anxiety to more than one of the parties concerned. One of the professors of clinical medicine was giving his final lecture to the class on the subject of venesection. No patient being at hand upon whom the operation could be performed, the lecturer asked for a volunteer. One of the students responded, and was bled. The demonstration was successful; but subsequently inflammation of the wound supervened, followed by abscess, erysipelas, etc., and caused the gravest anxiety to the student, his parents and fellows, and to the operator himself. Fortunately, the patient is convalescent. The incident is one which may well be borne in mind by would-be observers. We are already familiar with experiments on the human subject, which, whatever their value as arguments, have led to more or less serious consequences. The experimenters were in many cases students, and were, therefore, probably undeterred by consideration for their wives and families; but certainly some caution is desirable, since a fatal result would, in all probability, result in a verdict of manslaughter against the victim's accomplices.

A Brutal Physician.—A French journal states that a physician was called in the night to see a woman in childbirth. The labor was complicated, and an operation was necessary, for the performance of which the physician demanded 250 francs in advance. The husband was a laboring man, and had but 100 francs, which

he offered, with promises to pay the balance. The doctor refused in spite of the man's entreaties. Before another physician could be obtained, the woman died in great agony, two lives having thus probably been sacrificed for the paltry sum of thirty dollars.

SIR THOMAS WATSON AND SIR JAMES PAGET.—At the recent banquet of the British Medical Benevolent Fund, Dr. Broadbent, in proposing the health of the Chairman, Sir James Paget, applied to him the words Sir James himself had used of Sir Thomas Watson: "His knowledge was so vast, his goodness so great, and his example so elevating, that we all wished he might spend part of his immortality on earth."

HOPELESS.—Sir Astley Cooper relates the following anecdote of an Irish candidate before the Examining Board of the London College: "What is a simple and what is a compound fracture?" asked the examiner. The reply was: "A simple fracture is when a bone is broke, and a compound fracture when it's all broke." Sir Astley asked him what he meant by "all broke." "I mean," he replied, "broke into smithereens, to be sure." I ventured to ask him what was "smithereens." He turned upon me with an intense expression of sympathy upon his countenance. "You don't know what is smithereens? Then I give you up."—SIR CHARLES A. CAMERON, in *Dublin Journal of Medical Science.*

AMERICAN PUBLIC HEALTH ASSOCIATION.—The concluding session of the American Public Health Association was held on October 8th. The first business, after routine, was the election of officers, which resulted as follows:

President.—Dr. Geo. M. Sternberg, Surgeon U. S. A.

Vice-Presidents.—Prof. Charles N. Hewitt, Secretary State Board of Health, Minnesota; Prof. C. A. Lindsley, Yale College, Connecticut.

Secretary.—Dr. Irving A. Watson, of Concord, N. H., reëlected.

Treasurer.—Dr. J. Berrien Lindsley, of Nashville, Tenn., reëlected.

The Executive Committee is composed of the above officers, Dr. Henry B. Baker, of Lansing, Mich.; Prof. Hosmer A. Johnson, of Chicago, Ill.; Dr. Joseph H. Holt, of New Orleans, La.; Prof. George H. Rohé, of Baltimore, Md.; Col. D. P. Hadden, of Memphis, Tenn.; and the following Vice-Presidents: Dr. H. P. Walcott, of Cambridge, Mass.; Dr. Stephen Smith, of New York City; Dr. Jos. M. Turner, of Washington, D. C.; Dr. Edwin M. Snow, of Providence, R. I.; Dr. John H. Rauch, of Springfield, Ill.; Prof. James L. Cabell, University of Virginia, Va.; Dr. John S. Billings, U. S. A.; Prof. Robt. C. Kedzie, of Lansing, Mich.; Dr. Ezra M. Hunt, of Trenton, N. J.; Dr. Albert L. Gihon, U. S. N.; Dr. James E. Reeves, of Wheeling, W. Va.

Memphis, Tenn., was the place selected for holding the convention of 1887, and the Association adjourned.

AN AFRICAN MEDICAL JOURNAL.—A four-page weekly paper, the *South African Medical Journal*, is published at Cathcart, Cape Colony. Each number opens with an excellent editorial article, followed by a short instalment of a communicated article ("Cases Illustrating the Utility of Iron Salts in Syphilis," by W. Darley-Hartley, M.R.C.S., L.R.C.P., L.M.), and closes with a number of pithy annotations. Mr. Darley-Hartley, the contributor alluded to, seems to be also the editor and proprietor of the journal. Such good work as he is doing in his triple capacity certainly deserves support and coöperation.

NOTES AND QUERIES.

CORRIGENDUM.

To the Editor of THE MEDICAL NEWS.

SIR: In my article on the "Subiodide of Bismuth" (Oct. 9th), the lines, "They simply oxidize the deoxidized pus," etc., should have been omitted, as they were context to matter not printed, and had no reference to iodine or to bismuth.

Respectfully,

A. SIDNEY REYNOLDS.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING OCTOBER 9, 1886.

SUDDARDS, JAMES, *Medical Director U. S. N.*—Will convene Medical Board, October 6, 1886.

BROWNE, J. MILLS, *Medical Director U. S. N.*—Ordered to report to President Medical Board, October 6, 1886.

DEAN, R. C., *Medical Director U. S. N.*—Ordered to report to President Medical Board, October 6, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 5 TO OCTOBER 11, 1886.

MATTHEWS, WASHINGTON, *Captain and Assistant Surgeon.*—Granted leave of absence for one month and twelve days, with permission to go beyond sea.—*S. O. 232, A. G. O.*, October 6, 1886.

FISHER, W. W. R., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 230, A. G. O.*, October 4, 1886.

BORDEN, WM. C., *First Lieutenant and Assistant Surgeon.*—Relieved from temporary duty at Fort Bridger, Wyoming, and ordered to return to his station, Fort Douglas, Utah.—*S. O. 126, Department of the Platte*, October 2, 1886.

HAMMOND, JOHN, F., *Colonel U. S. Army* (retired).—Died at Poughkeepsie, N. Y., September 29, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING OCTOBER 9, 1886.

PECKHAM, C. T., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, to take effect when relieved, October 5, 1886.

KALLOCK, P. C., *Passed Assistant Surgeon.*—Granted leave of absence for twenty-one days, to take effect when relieved, October 5, 1886.

PETTUS, W. J., *Assistant Surgeon.*—To proceed to Evansville, Indiana, for temporary duty, October 8, 1886.

KINYOUN, J. J., *Assistant Surgeon.*—Appointed an Assistant Surgeon, October 4, 1886. Assigned to temporary duty at New York, N. Y., October 5, 1886.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course, not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIX. SATURDAY, OCTOBER 23, 1886. No. 17.

ORIGINAL ARTICLES.

SOME CONSIDERATIONS ON THE CLASSIFICATION, PROGNOSIS, AND TREATMENT OF CERTAIN RENAL DISEASES.[1]

BY THOMAS E. SATTERTHWAITE, M.D.,
PROFESSOR OF PATHOLOGY AND GENERAL MEDICINE IN THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

IN accordance with a happy fashion of the day, that is leading medical men to centralize their attention upon certain of the more important topics in medical practice, I have ventured to contribute my views on some matters relating to renal disease. And I start out with the proposition that physicians will always find it of practical advantage to discover the exact pathological conditions that are associated in any case with renal manifestations; and especially whether they are referable to a primary disorder of the kidneys, or to some systemic dyscrasia.

But I do not urge this discrimination because I believe that a differential diagnosis will always favorably affect our treatment, but rather because I am firmly of the opinion that otherwise the natural course of the disease would be misunderstood, and the prognosis consequently a matter of guesswork.

The present paper is mainly founded upon my personal study of Bright's disease in ninety-six cases selected from a much larger number from my hospital and private records, those only being utilized which had the requisite fulness, in the matters of clinical history and post-mortem findings, to justify me in retaining them for the purposes of study. Though I may err in the interpretation of my data, and I am willing to admit that a larger number of observations may at any rate alter the ratios which I give, I still feel bound to state that, numerically, I believe my cases are entitled to an equal credibility with any similar number of cases observed by trained and educated men under unusual advantages for taking and registering their observations; and I, therefore, hold that the data are adapted to form a basis for clinical study, and hence, for practical inference.

Starting from the standpoint of pathological anatomy, I shall first adopt a classification that recognizes certain known morbid states of the kidney, though upon the matter of nomenclature I may be at variance with some of our pathologists. But each variety of renal disorder that I shall name will represent, with more or less distinctness, a type of Bright's disease, and by that term I refer to a group of clinical symptoms in which we note special urinary phenomena, such as the presence of peculiar cylindrical-bodies (casts), albumen, often an altered volume, sometimes a notable deviation in the specific gravity from a given standard, together with certain gastro-intestinal, nervous or cardio-vascular phenomena that have been taken to characterize a series of closely allied conditions passing under the popular name of "Bright's disease." We shall presently take up these several varieties, and see wherein they are allied, and on what points they differ.

In giving my classification, I may remark that it is broader than one which is purely clinical. But, as the present state of pathological knowledge is far in advance of the clinical, and as the several varieties that I give are matters of easy demonstration, it is natural that pathologists should hold to their data, even if clinicians cannot match them in giving bedside criteria for each pathological change.

Classification on a Pathological Basis.

1. Passive congestion of the kidney.
2. Acute diffuse nephritis.
3. Chronic diffuse nephritis.
   Recognized sub-varieties:
   a. The large kidney.
   b. The kidney of small or medium size.
   c. The small or "little gray kidney."
4. Acute parenchymatous metamorphosis.
5. Chronic parenchymatous metamorphosis.
   Recognized sub-varieties:
   a. The large white kidney.
   b. The medium or small kidney.
6. The sclerotic kidney.
7. The waxy kidney.
8. The gouty kidney.

Adopting, then, for the time being, this classification, and studying the clinical symptoms of each on this basis, I venture the following statements:

1. In any case of ordinary venous congestion of the kidneys, whether from a surgical accident, such as a fracture of the spine, or from a systemic disease, such as purpura hemorrhagica, or local affections, such as hydropericardium, pleurisy with effusion, etc., where the kidneys are found the seat of temporary venous congestion, death is apt to occur by coma, or from pulmonary œdema, with such gastric phenomena as nausea and vomiting. The specific gravity will not, necessarily, be abnormal, but there will usually be albumen, sometimes granular, or even blood casts (these latter we may expect); and the quantity of urine will vary from six ounces per day to the normal. Sometimes, or generally, an infarction of the kidneys, such as may occur during the course of an endocarditis (and it occurs at some time or other in about one-third of them), will not be recognizable by any other than these symptoms, unless we have to do with the suppurative or infective variety of endocarditis in its later stages. And, since the infarct is due to a primary embolus, with secondary and collateral venous stasis, it follows that, at first, certainly, there is localized venous engorgement, and, consequently, such a train of symptoms as it

[1] A portion of this paper was read at a meeting of the Clinical Society of the New York Post-Graduate School, Dec. 5, 1885.

produces; of course, in conjunction with more or less increased vascular tension in the unplugged arterial vessels.

Thus in the case of a patient who died recently at the Post-Graduate Hospital, the urine was scanty, albumen and casts in abundance were present, and the autopsical findings led us to believe that the abnormal condition of the urine was due to a thrombosis of the kidney, secondary to renal embolism, following ulcerative endocarditis of the mitral valve. The patient died in coma, apparently of uræmic origin. And it appears to be a matter of common acceptance that when pressure had been brought to bear upon any of the renal veins (outside of the organ), from any cause, we may find albumen, casts, and a diminished volume of water; all of which facts are perfectly compatible with the laws of urinary pathology. Such symptoms occurred in all cases of venous congestion that have come under my notice.

2. Acute diffuse nephritis appears to be rare, at least as a cause of death. Its frequency in my cases is represented by a percentage of two, and the causes were "catching cold in the loins" and operation for a urethral stricture. Both patients died in uræmic coma, while nausea, vomiting, with frequent attempts at micturition, and œdema of the extremities, were symptoms observed. The sp. gr. of the urine varied from 1.027 to 1.028; albumen was found when looked for; but the urine was either scanty or suppressed. In one of these cases it was observed that the affection was unilateral, and this point leads up to the statement that it is by no means uncommon to find that one organ is far in advance of the other in the degree of its morbid change; and hence comes the natural conclusion, that while one organ is furnishing, through the urine, many of the symptoms from which an unfavorable prognosis may be made—as, for example, an abundance of albumen and casts in variety—the other organ may be doing over-work, and in fact supplying the place of its fellow. This condition is most frequently noticed in the advanced stages of chronic diffuse nephritis.

3. In introducing the topic of chronic diffuse nephritis I find that it constitutes one of the most common forms of nephritic disease, forming about forty per cent. of all the cases commonly classed under the term Bright's, whether acute or chronic. It probably exists under three forms, or to speak more accurately, I find it convenient to distinguish three forms, the distinction being based upon the size of the organ. In the first, the weight and measurements are increased, partly by the swelling of the epithelial elements, and partly by an infiltration of the fibrous tissue. As this fibrous deposit shrinks, the epithelial elements are also necessarily contracted; so that when the process has continued for a time, the kidney has returned to about its normal size, but manifests in a variety of ways the fact that contraction has taken place; later the shrinkage reaches such a point that the organ is permanently diseased in all its parts, and the unhappy bearer stands constantly on the edge of a precipice.

In the large form (3 *a*) I have found as an antecedent condition either inflammatory rheumatism, endocarditis, or phthisis, the latter in about one-half of the cases. Of the usual symptoms, there are apt to be headache, dizziness, vomiting, ascites, or anasarca; the specific gravity of the urine varies from 1.014 to 1.026, while the average is about 1.020. Albumen is present in large amount. The casts are hyaline and granular, large or small. The urine is usually scanty, rarely reaching forty ounces per diem. Death occurs from coma, syncope, or exhaustion. In the medium-sized kidney of chronic diffuse nephritis (3 *b*), rheumatism, endocarditis, or pericarditis preceded the disease in seventy-five per cent. Patients with this kidney have nausea and vomiting; headache, dizziness, dyspnœa, frequent desire to micturate, and swelling of the extremities or general anasarca. The specific gravity will vary from 1.009 to 1.030, with an average of 1.018. Albumen will be present (in quantity from a trace to seventy-five per cent.); there will be granular and hyaline casts; the urine is usually scanty; and death takes place from exhaustion, coma, heart failure, or œdema of the lungs.

In the small variety of chronic diffuse nephritis, the "little gray kidney" (3 *c*), rheumatism of the inflammatory variety was an antecedent condition in sixty per cent.; phthisis in thirty per cent.; carcinoma in twenty per cent.; scarlatina in one per cent., though these precursors were so intermingled with one another as prior conditions, that it was impossible to determine their relative importance as causative factors. Among the symptoms noted were frequent micturition, headache, dizziness, attacks of palpitation, faintness and diarrhœa alternating with constipation. Among the urinary symptoms noted were a comparatively low specific gravity, averaging (in seventy-five per cent. of the cases) below 1.014; frequent absence of albumen and casts, the former exceptionally reaching fifteen per cent. by volume. Death takes place in the customary way, either with profound coma, or by sudden cardiac or respiratory failure.

In gross appearance, this form of kidney is very like the sclerotic kidney (arterio-capillary fibrosis of Gull and Sutton), but it is different in many ways, as we shall see at another place. In the little gray kidney, we note a very regular antecedent condition of systemic disease; among the symptoms more or less œdema of the extremities or anasarca are common occurrences; there is also a moderate but fair amount of albumen in the water, which is apt to be scanty. In the sclerotic form the antecedent conditions are obscure; there is little tendency to dropsy; more or less polyuria; slight albuminuria; but a marked alteration of the vascular system.

Let us now review these three sub-varieties of chronic diffuse nephritis, and observe whether they do or do not bear any intimate relations to one another. First, we revert to former statements that they may, in accordance with the known laws of pathology, bear the relation to one another that has already been drawn; the large, medium, and small kidney, representing the successive stages of one affection. But apart from these considerations let us pass to the clinical symptoms of each.

First of all, we note one constant prior condition

that is not present with any degree of regularity in any other form of renal disease. I refer to acute articular rheumatism, endocarditis, or pericarditis. The other clinical phenomena are best studied by reference to the following table.

especially as in those cases where the skin, lung, liver, and intestines, are unable to do their part. Occasionally the disease appears to be idiopathic, but there can be little question that it is rarely so. We have simply failed to discover the primary cause.

Table I.

Chronic diffuse nephritis.	Gastric symptoms.	Nervous symptoms.	Specific gravity.	Albumen.	Casts.	Amount of urine.	Mode of death.
Kidney of large form,	Present.	Present	1.014–1.026 av. 1.020	None to over 50 per cent.	Hyaline and granular.	Usually scanty.	Usual way.
" " medium size,	Present.	Present.	1.009–1.030 av. 1 018	Trace to about 30 per cent.	Hyaline and granular.	Usually scanty.	Usual way.
" " small size,	Present	Present.	1.010–1028 av. 1.013	Small amount; trace to 10 per ct.	Usually absent.	Scanty or in excess.	Usual way.

It is plain, in the first place, that the symptoms yielded by the large and medium-sized kidney offer small opportunity for a differential diagnosis, the only points of manifest difference being in the quantity of albumen, which in the large variety is abundant, and in the medium kidney of less amount, and in the small of still less, but even on this point there is considerable range; for though in the large kidney, if present, it may average fifty per cent. by volume, it may be absent; in the medium, although, if present, it may average about thirty per cent., it may be reduced to a trace; in the small kidney, if present, it will not average over ten per cent., but may be absent; but such averages are only applicable to a large number of cases taken together where the amount has been estimated a number of times, and then averaged. So of the specific gravity, a single examination in any case would yield little that was valuable, owing to the variations in the specific gravity from day to day through the operation of natural causes. If, on the other hand, we examine the specific gravity of our cases combined, we find that while in the large it is more commonly about 1.020, though averaging from 1.014 to 1.026; in the medium kidney it averages 1.018 with a range of from 1.009 to 1.030; and in the small it is 1.013 with a range from 1.010 to 1.028. And these differences are such as would naturally ensue under the conditions given, the albumen and specific gravity falling contemporaneously and in pretty uniform ratio. In other respects there is no difference in the symptoms more than that as the kidney becomes quite small, the amount of water is apt to increase and casts will usually be absent, two points that apparently need no explanation. From a combined study, therefore, of anatomical, pathological, or clinical facts, our evidence appears to favor the view that these several forms of chronic diffuse nephritis are merely separate stages in one type of the disease.

4. I next take up the subject of acute parenchymatous nephritis. A diagnosis of this variety from a clinical point of view should usually present no difficulties. It is chiefly secondary to scarlatina, diphtheria, measles, pneumonia, typhoid, and typhus, or any condition of the system whereby the kidneys are suddenly called upon to throw off the effete products of the body in an unusually active manner,

In a most marked degree we see acute parenchymatous nephritis in scarlatina, as in the following case, where I made the post-mortem examination at St. Luke's Hospital.

D. S., an American boy, sixteen years old, came to my class at the Demilt Dispensary in 1878. He was then suffering from necrosis of the femur. On April 22d he entered St. Luke's Hospital for surgical treatment. On the 25th he had a slight chill, and within twenty-four hours developed scarlatina. On the night of the 27th his temperature rose to 104°, and pulse to 146. He died in coma, after suppression of the urine had lasted twelve hours.

At post-mortem examination the kidneys were found intensely anæmic; microscopic examination showed that the epithelium throughout the organs was intensely granular, while the Malpighian bodies were infiltrated with leucocytes, the latter condition described by Klebs under the name of glomerulonephritis. Probably the pressure thus brought to bear upon the capillary tufts prevented the excretion of water, and brought on the fatal symptoms.

In a most marked form we notice acute parenchymatous nephritis in pneumonia, whether lobar or lobular, but most distinctively in the former, though it is not uniformly present, probably because some other apparatus of the body has succeeded in relieving the kidneys of the special strain. This complication is of great importance and I have met with several marked instances where the secondary disorder presented a greater menace to life than the primary. Thus in the case of a medical practitioner from Connecticut, who was attending the Post-Graduate School in the winter of 1882, a cold taken in the train by which he came to New York, led to a lobar pneumonia, which was nearly fatal through the renal complications. Coma developing during the first days of the attack, drew the attention of the attending physicians and myself to the probable cause, and inquiry led to the discovery of scanty urine, which was found to contain albumen in large amount, with granular and blood casts. In this case vigorous local treatment and the free use of diffusible stimulants, of which the carbonate and muriate of ammonium proved the most efficient, restored the functional activity of the kidneys, and in due time convalescence was established.

I may say, parenthetically, that in such instances,

especially if the kidneys have been previously damaged, I am chary about using alcoholic stimulants, from fear of the irritation of the renal organs that they sometimes produce, and I rely very largely upon active fomentation, blisters, and revulsives. It is a fortunate circumstance that in such cases external applications can easily be made to act favorably upon both lung and kidney simultaneously.

In acute parenchymatous nephritis the specific gravity is usually within the normal range; thus it will commonly be found between 1.020 and 1.030; in most cases I have found it between 1.020 and 1.022; albumen in large quantity will be a marked feature, often very abundant; and we may confidently look for blood casts, granular casts, and granular matter. There will also generally be decided gastric and nervous phenomena, and death will take place under some one of the many forms that are induced by depression of the nerve centres from the poisoned blood.

But in the majority of instances we have good reason to believe that if the primary disease resolves, the secondary or renal will follow suit. The swollen and granular epithelia will assume their normal characters, and perhaps even the corpuscular infiltrations of the Malpighian bodies may disappear. At any rate, our clinical data lead us to hold that acute nephritis, under the conditions named, will not become chronic in a great number of cases; and we have reason to say, therefore, that the patient has entirely recovered from an attack of acute Bright's disease.[1]

5. Chronic parenchymatous metamorphosis or inflammation, as an uncomplicated affection, is recognized best under two morphological varieties, that of the "large white kidney," and of the medium-sized kidney. This former condition is seen more frequently at post-mortem examinations than any other renal change that can be classed under the general term of Bright's disease. It constitutes about one-third of this class, and for the simple reason that it owes its existence usually to phthisis, which is the most prevalent disease we have to deal with. In fact, where there is the large white kidney we may expect to find pulmonary phthisis in eighty per cent. of the cases. But though to the naked eye the implication of the kidney appears to suggest that we should have very positive renal symptoms, the truth is, *they are rare.* Nausea and vomiting seldom occur. Serous effusions are not very common, and often a slight dropsy may be attributed to the watery condition of the blood, due to the wasting disease. Nor will the specific gravity of the urine give much assistance in the diagnosis. I have found it to vary from 1.010 to 1.028, with a general average of about 1.020; albumen may be abundant or absent; usually casts are entirely absent, though we may occasionally or in some cases find the hyaline or granular variety. There is generally observed a diminution in the amount of water. In fact, the renal complication is fatal, so far as my cases show, in only one case out of five.

5 *b.* The second form of this kidney disease is the precursor of the large white kidney, and may be found after any suppurating or wasting disease has been in existence a few months; when the disease has existed for a year or more, we usually have a kidney of the "large white type." The more advanced the disease, and especially the more extensive the suppuration, the larger the kidney, and the more pronounced the pathological changes.

In the smaller variety severe effusions are comparatively rare; nervous symptoms even less so; the specific gravity varies from 1.012 to 1.024, though 1.016 is not infrequent. Albumen is rarely present in large quantity, usually is absent or represented by a trace. Casts are rarely found. Water is apt to be scanty, as in the "large" variety. Table II. shows the points that offer for a differential diagnosis:

Table II.

Chronic parenchymatous metamorphosis of kidney.	Name and duration of causative disease.	Gastric symptoms.	Nervous symptoms.	Amount of water.	Specific gravity.	Albumen.	Casts.	Cardio-vascular symptoms.
Medium sized kidney,	Phthisis, 80 per ct. 1–3 months,	Rare.	Very rare.	Apt to be scanty.	1.012–1.024 av. 1.016	Commonly absent.	Rare.	Œdema very rare.
Large white kidney,	Phthisis, 80 per ct. 1 yr. or upward.	Rare.	Very rare.	Apt to be scanty.	1.010–1.028 av. 1.020	Abundant or absent.	Generally absent, or hyaline or granular.	Rare.

From a study of it we readily see that a differential diagnosis must be based purely on the fact that in something over three-fourths of all cases of phthisis, where the duration has not exceeded three months, the smaller form of chronic parenchymatous nephritis will be the rule, whereas in something over three-fourths of all the cases of phthisis where the disease has lasted one year or more, the "large white" may be predicated to exist, and especially if the lung disease has been rapidly destructive in its course. But there is some good reason to believe that the changes in the epithelium in these cases are not altogether pathological; at first (we may judge from the analogy of the acute form) the swollen and granular epithelium owes its condition to the proper task it has undertaken to separate from the body an undue amount of unassimilable or effete material that is disturbing the proper equilibrium of the body. It is only after this excrementitious matter has tarried so long in the kidney that the cells become overcharged and poisoned by matters that they would have discharged successfully had they only been burdened with less work. In cases where large masses

[1] I have used the term "parenchymatous nephritis," as the name has met with general acceptance. The term "parenchymatous metamorphosis" I believe to be better, in the present state of our knowledge, there being grounds for believing that parenchymatous changes are not strictly inflammatory.

of fatty and granular débris are thrown off from these organs, it is evident that they have suffered material damage, and we have little reason to suppose that there is any restitution of equivalent tissue.

6. In the so-called little red, granular, contracted, or cirrhotic kidney, which I prefer to call the sclerotic (*skleros*, hard), there appears to be no doubt that we have a disease which has distinctive pathological and clinical features from any of the forms of Bright's disease I have already mentioned. There is a noteworthy thickening of the small renal vessels that is prominent in our minds, since Gull and Sutton, in 1872, called the attention of the profession to the anatomical findings. But it seems probable from the conjoined labors of many pathologists that this "arterio-capillary" fibrosis is a general disease of the vessels, and that all portions of the body may be similarly attacked. The antecedent cause seems to be obscure, but whatever it may be, the blood becomes poisoned and then awakens in the system a condition of arterial tension that later induces thickening of the vascular coats and hypertrophy of the left side of the heart. And these theories are in full accordance with physiological experiments.

Of seven cases in which I have pretty full clinical and post-mortem notes, I find the following antecedent affections: Malarial fever, one; pneumonia, one; typhoid fever, one; progressive muscular atrophy, one; cold caught two years previously, one; syphilis and rheumatism, one; gout, one; and yet we have no reason to say from the above findings that the blood was sufficiently poisoned to produce the disease. There still remains for us to discover the real cause.

And now for the symptoms. Of these, those referable to the gastro-intestinal tract and cerebro-spinal or sympathetic system are mainly the same as are seen in chronic diffuse nephritis. But the specific gravity of the urine is almost always low, ranging from 1.008 to 1.012, with 1.010 as a prominent figure. If albumen is present in any appreciable quantity it is slight. A larger amount never occurs until suppression is setting in. The water will be copious when the disease is at its height, and will diminish, other things being equal, only when dangerous symptoms are at hand. Death may occur from apoplexy, cerebral or meningeal, sometimes from sudden heart or respiratory failure when the patient is apparently in excellent health. Occasionally the final result will be delayed by convulsions, coma; and œdema of the lungs will appear to be the final trouble that closes the drama.

In this form of renal disease casts are infrequent and may be absent for long periods; when present, those of the hyaline variety are most common. Dropsy may be altogether absent. The polyuria, persistent low specific gravity of the water, with slight albuminuria, an occasional cast, but pulse of high arterial tension, and constant headache will direct the physician to the proper diagnosis. This is the cause of death most often in the so-called "heart disease" of the laity. Often both physician and friends may be totally unprepared for the final event, though an occasional examination of the urine would have prepared them for it.

7. The "gouty" kidney. This form of renal disease that has been regarded as so destructive, is in reality nothing but the kidney of chronic diffuse nephritis, in which crystals of sodium urate have lodged. Sometimes the crystals will be found in only one kidney.

8. There is also a waxy kidney, where the walls of arteries and arterioles are infiltrated with waxy or amyloid material. Whatever this material may be, and from whatever source it may be derived, there is no doubt that the change is a consequence of some chronic suppurative process in the body or of a wasting disease, such as syphilis.

Where there is any considerable deposit of waxy matter in the vessels the urine is found to have a low specific gravity, as from 1.006 to 1.010, and the amount of water will be large; albumen will be present in varying amount. Casts will often be absent and the hyaline variety will predominate. The diagnosis is based upon a study of these facts.

It is proper at this point to allude to a form of renal affection that is associated with the pregnant condition. Of this I am not prepared to speak from personal experience. But I am free to say that (contrary to some teachings of comparatively recent date) the presence of albumen and casts in the urine, with scanty excretion, and more or less dropsy, form no necessary bar to the proper performance of natural labor on the woman's part, and that the physician should exercise a wise discretion in countenancing artificial delivery under such circumstances; the facts being that in a large number, perhaps the majority of instances, a condition of more or less pronounced nephritic disorder may prevail during the latter months of pregnancy, and yet the delivery may take place in a natural manner, and at the proper time, with safety both to mother and child.

Having thus reviewed the several varieties of Bright's disease, with reference to morphological changes and symptomatology, we are now confronted with the prognosis in each of them.

First, with reference to nervous congestion due to interference with either venous or arterial circulation, I may repeat that the albumen, casts, and scanty urine will disappear on removal of the cause, if this be possible, as in the case of an enlarged spleen, an ovarian tumor, or renal infarct.

In acute diffuse nephritis, where the cause may have been a blow, exposure to cold, or operation upon some portion of the genito-urinary tract, or extensive burns, etc., local, combined with general treatment will often carry the patient through, and there will be no subacute or chronic condition following. Of course, the disease is a dangerous one.

In chronic diffuse nephritis, the duration of renal symptoms is apt to be long, months or even years, depending in many cases upon the gravity of the antecedent or associated general dyscrasia, such as chronic articular rheumatism or gout, and especially on the activity of its manifestations and its behavior under treatment. But there is reason to suppose that if the systemic disease is held in check, the renal trouble will ameliorate correspondingly.

In acute parenchymatous nephritis we have a disease of greater or less intensity in particular cases. Recognizing as its cause some exanthem, continued fever, or intoxication by animal or mineral poisons, we should turn to the original disease in order to measure the secondary or renal. Yet this rule will not always be practicable. Usually, it may be said, if the prior disease is tractable we need not anticipate uræmic disorders.

In chronic parenchymatous change, when phthisis or some wasting disease is a forerunner, the prognosis is almost uniformly bad for a total disappearance of the symptoms; though it is the primary disease that most often kills.

In that obscure disease that I have called the sclerotic kidney, but which owes its danger mainly to vascular changes, we shall continue to be surprised by its peculiar phenomena, because we do not yet know their cause. There can hardly be any doubt that there is no improvement at any time or under any circumstances in the structural condition of the kidney, but always a gradual progression toward a fatal issue. But that the final event is delayed for years by appropriate treatment, I am firmly convinced.

In the waxy or amyloid kidney we have an affection that is to a great extent an index of other systemic changes. So long as the suppuration or chronic wasting process is going on, there can be no betterment in the diseased vessels. But judging from analogy it is reasonable to suppose that if the primary affection can be subdued so will the secondary. For we are led to believe from clinical experience that where we have a waxy liver, the result of chronic suppuration, the removal of the morbid focus, is at once associated with a decrease in the size of the organ. In both cases it is probable that the vessels only receive the waxy deposit.

In the matter of treatment, if we bear in mind the considerations that have been given, our therapeutic resources may be properly directed.

In cases of venous congestion due to pressure on renal veins it is plain that relief is to be sought in measures that will disembarrass the renal circulation, or, as perhaps in the case of infarction, stimulate the unaffected portions of the kidney to increased work until the uræmic symptoms have gone by.

And so in the acute diffuse variety, we have to recognize the condition and struggle with it as best we may, calling upon the skin, lungs, and intestinal tract to assist with all the power they have at command.

In acute parenchymatous nephritis, an active local treatment is most desirable, and resort may be had to dry cupping, rubefacients, and poultices, but we should also specially direct our measures toward running off the fluids by such tissues as are unaffected; thus in scarlet fever the bowels should be kept open; in pneumonia the skin should be freely exercised. At the same time those drugs that stimulate the renal secretions should be held in high favor.

I am fond of using the spiritus Mindereri in connection with the muriated tincture of iron and Hoffmann's anodyne, and have found this combination to act admirably. Sometimes Rochelle salts will answer as a brisk purgative; of course in some instances, especially in pronounced dropsy, we may have to resort to hydragogues, such as elaterium, in one-quarter grain doses. There is no doubt in my mind that the latter give relief, though I have seldom had occasion to use them. I have also used a well-known elixir purgans[1] with some advantage, in such cases.

In the chronic forms, whether of the parenchymatous or diffuse varieties, we have first to attack the predisposing disease, be it phthisis, the lithic diathesis, or any other dyscrasia, and then finally meet the results of the disease. If, for example, passive effusions are endangering life, either by producing pericardial effusions, and so cardiac embarrassment; or if pulmonary œdema or ascites is making respiration difficult, it may be best so to stimulate the kidneys that they will be induced to take a greater activity. This can be effected in various ways, by diuretics, of which I hold that the muriated tincture of iron holds the first place, or by the hydragogues already mentioned. I give the former in doses varying from fifteen to forty minims, three times a day; or I order large quantities of alkaline waters to be taken, such as Vichy or the alkaline Buffalo lithia water (No. 2). Sometimes Clysmic water, given in amounts averaging about three pints daily, with as much skim-milk, will answer excellently in chronic cases. It is notorious that the kidneys will usually respond. In cases of lithiasis, I find that salicylic acid,[2] given in ten grain doses, both meets the anti-lithic indications and also promotes the flow of water. It may be given advantageously in Poland water, or better still in Clysmic water, but these waters, to be beneficial, should, of course, be taken in some quantity. These chronic cases may be successfully treated for some years in the way I have indicated, though they are prone to acute exacerbations, in which it may be necessary to resort to digitalis infusion in drachm doses, perhaps to fomentations of this drug. After the attack has thus been controlled, the patient may return to the simpler remedies. In most acute attacks in chronic diffuse nephritis, or in the granular (sclerotic) kidney, irregular respiration or cardiac action may seriously threaten life. In such cases, I have been invariably successful in bridging over the early attacks by hypodermatics of brandy. In most instances it is useless to attempt medication by the stomach. The hypodermatics of brandy may then be followed by morphia, and the results have, in my hands, been always good.

Sometimes the most obstinate symptom is nausea or vomiting. It is a question, however, whether the physician should be too anxious to arrest it. It is probably induced by a temporary congestion of the gastric walls, which, for the time being, are subject to a vasomotor neurosis similar to that which attacks other parts under the influence of uræmic poisoning. The fluid is due in great part to exudation from the capillaries, and the stomach is eliminating the poison vicariously. In my experience, the nausea is best

[1] Eli Lilly & Co.

[2] I usually use Frye's granular effervescent salicylic acid.

controlled by such alteratives as hyd. c. creta, given one to three times daily in five grain doses.

In conclusion, it is seen that, so far as the prognosis is concerned, in many cases the manifestations of Bright's disease disappear not to return, certainly those connected with the exanthemas, pneumonia, and typhoid fever, while even in the most common forms of all, the purely parenchymatous metamorphoses—the renal disease plays a comparatively unimportant *rôle*—death being usually due to primary disease of the lungs.

In conclusion, it may be said that of the types of Bright's disease here given, the special form can usually be determined from a history of the case, together with the attendant clinical phenomena, particularly if the patient has been long enough under intelligent observation to determine the range of the urinary symptoms.

251 Madison Avenue.

THE USE OF BORACIC ACID WITH VAGINAL TAMPONS.

By HARRIS A. SLOCUM, M.D.,
of Philadelphia.

In the treatment of the various pelvic troubles where the use of tampons is indicated, one of the disadvantages has been the development of an extremely offensive odor, unpleasant to the physician and distressing to the patient, ordinarily occurring after a retention of the cotton for more than forty-eight hours. Occasions arise when it is inconvenient for the patient to return every two or three days, and it then becomes a matter of importance to adopt some means which will prevent the usual decomposition, and allow her to retain the tampon for a longer period.

To secure this end, a number of expedients have been tried, of which I shall mention but one, viz., the use of boracic acid. From the first trial it has served the desired purpose effectually, and has given decided and striking results. Cases having profuse and offensive leucorrhœa among the Russians, Poles, and negroes of the Philadelphia Dispensary service have been subjected to this treatment, with the unvarying result of entirely preventing the occurrence of the usual unpleasant odor. In several instances the menses have appeared while the tampons were *in situ*, and have, in each case, saturated the cotton, which, upon removal, was found as free from smell as when introduced.

Following is a short description of the mode of application: While using Sims's speculum in either the genupectoral or lateral position, the vagina is cleansed with a piece of wet absorbent cotton held in a pair of uterus forceps, partly withdrawing the speculum to allow of access to the posterior wall. The membrane is then partly dried with a fresh piece of cotton, and several scruples of boracic acid introduced on a spatula, and distributed over the area with a wisp of cotton, or by the aid of the forefinger. The slight moisture permits the powder to adhere, forming a moderately thick coating over the entire wall. In an ointment jar or other convenient receptacle, is placed about an ounce of the acid, and each piece of cotton, held in the forceps, is thoroughly rubbed in it before insertion.

Great care is always necessary in the introduction of tampons, even when they remain but twenty-four hours, to prevent undue pressure upon rectum or urethra. When they are to remain in position a week or longer, greater attention than ever must be paid to these points, on account of the tendency of the cotton to pack, through absorption of moisture and continuous pressure.

Comparing boracic acid with other agents, I have not found one which so completely fulfils its office, without offering objectionable features of its own. With very free or unpleasant discharges a proportionately larger amount of powder must be used.

Whether it affects the vaginal tissues advantageously or otherwise, I am not prepared, at present, to say, though I have frequently noticed after its use, and when that which remained from the old packing had been removed with a piece of wet cotton, that the vagina was much paler than when the tampon was introduced. If, by repeated trials, this observation can be proved correct and constant, it may reasonably form the basis for a series of experiments in the treatment of vaginitis. That the paleness just mentioned is not entirely due to the mere pressure of the cotton, seems evident from the fact that simple cotton tampons are frequently tinged with blood on their surface, although carefully placed and not tightly packed.

Oakum tampons seem particularly apt to irritate the membrane, and cause oozing after forty-eight hours' retention. So decided is this tendency to cause bleeding, that when a case presented where I wished to use oakum, it was not introduced until a layer of cotton had been placed against the vaginal wall, to protect it from the harsh and irritating fibres.

Cotton saturated with boroglyceride is an effectual antiseptic, but will not serve the purpose here. Glycerine produces a copious watery discharge, which, though at times beneficial, is not always desirable, and is ill adapted for long retention, inasmuch as it is diluted and partly removed by the watery discharge it causes.

Notes from a few of the cases treated are appended, in connection with which it should be stated that, before the boracic acid was used, it was a rare circumstance to allow the tampons to be retained longer than three or four days, and when this period was reached, the removal was an operation which anyone would prefer to avoid.

J. B., colored, retroversion with adhesions.

June 16. Tamponed vagina, using boracic acid.

24th. Removed tampon. Slight amount of mucus adhering at position of cervix. No odor. Renewed cotton packing with boracic acid.

July 2. Removed tampon. No odor. Introduced Smith pessary, No. 2.

9th. Removed pessary. Secretion free, but not abundant. Odor decided and characteristic. Washed vagina and renewed cotton, using the acid.

18th. Removed tampon. No odor. Vagina pale.

J. P., white. Patient lives sixty miles from the city, and can conveniently return but once a week. Enlarged, prolapsed, and tender right ovary.

July 2. Used cotton tampon with boracic acid.

12th. Removed tampon. Slight secretion. No smell whatever. Renewed cotton with acid.

19th. Cotton removed. No odor. Vagina pale.

M. H., retroversion with adhesions.

June 15. Tamponed, using boracic acid.

19th. Not the least odor upon the removal of tampon.

A. A., bilateral laceration of cervix, with hypertrophy. Profuse and offensive leucorrhœa.

July 2. Tampon, with boracic acid.

9th. Removed cotton, thoroughly saturated with muco-purulent discharge. Slight odor, not marked.

In this case an odor developed, but was very slight, and resulted from an insufficient amount of the powder being used. If the acid had not been employed, I have every reason to believe that the stench would have been nauseating.

S. U., retroversion.

June 25. Introduced tampon, using boracic acid.

29th. Menses appeared on morning of 26th, and showed at the vulva. Removed cotton, saturated with blood. No odor, not even the characteristic smell of blood.

L. C., September 6th, tampon of boracic acid.

Sept. 12. Removed tampon. No odor whatever.

These few cases will serve to indicate the usefulness of boracic acid in this direction, providing the application is thorough, care being taken to coat the vagina well before introduction, and to treat each piece of cotton thoroughly. The operation is generally completed in three minutes.

1208 Spruce Street.

A PECULIAR GROWTH OF THE OPTIC PAPILLA.

By CHARLES W. KOLLOCK, M.D.,
of Charleston, S. C.

This peculiar growth from the optic nerve was seen in the case of Mrs. M., who sought advice on account of dimness of vision in the right eye and floating bodies in the visual field. When first examined, on the 15th of April last, the vitreous was cloudy, contained floating bodies, and the outlines of the disk were indistinctly visible. No peculiarity of the disk was detected at the examination. Vision $\frac{5}{XV}$ (Oliver's card—or about $\frac{15}{L}$), which was rather surprising, when the cloudiness of the media was taken into consideration. No specific history could be elicited, though she admitted having always been healthy up to the time of her marriage, eight years ago. She had never borne children, and had for some time been under treatment for womb trouble. Iodide of potassium was prescribed in ten grain doses three times a day, to be gradually increased. Two days later a more careful examination was made than the first, when a small bubble-like protuberance was seen upon the disk, covering the point from which the central retinal vessels emerged and entered. Owing to the haziness of the vitreous, nothing more definite concerning the growth could be made out. About this time a patch of retino-choroiditis was discovered to the inner and lower side of the disk, and well forward toward the ciliary body. Under the influence of the iodide, vision and media rapidly improved, the former becoming normal, and the latter perfectly clear, with the exception of one large floating body, which was quite annoying to the patient. The disk was now seen to be inflamed and swollen, but these conditions quickly subsided. The bubble or vesicle-like body could be easily seen capping the central vessels, through which they were indistinctly visible at its edges. While bright and glistening, it was not transparent—a general opacity existing with no distinct nucleus. Later on, as the disk assumed a more natural appearance, a pedicle-like attachment was discovered which seemed to connect the growth with the inner

and lower portion of the physiological cup. By careful examination with the ophthalmoscope there remained no doubt that this was a true pedicle attaching it to the floor of the cup, though there was also some attachment to the vessels, as was proved by the absence of movements except when the eye moved. If there has been any change in the growth since it was first seen, it is a very slight diminution in size and apparent retraction from the superior branch of the vein to the inferior branch of the artery. Its nature must be a matter of most vague supposition. It resembles in some respects a cysticercus, yet it cannot be this, because there has been no increase in size, nor is there any accompanying inflammation of the disk since the subsidence of that connected with the retino-choroiditis. Glioma is uncommon at this age, and its stationary condition would preclude that. Neuroma rarely occurs in connection with cerebral nerves, and is usually without connection with the fibres of the affected nerve. Sarcoma can readily be excluded. Syphilitic growths may be passed by on account of the lack of specific history and symptoms, besides the non-affection of the growth by large doses of the iodide. What then may be the nature of this growth? It may be a hypertrophied nerve fibre, or a fibre which has taken on cystic degeneration. Again, it may be a slowly forming cyst. It cannot be an aneurism, for there are no signs of blood or pulsation in it. Lastly, it may be the swollen end of the hyaloid artery, having perhaps been left congenitally in that condition.

STRANGULATED INGUINAL HERNIA AND EPIPLOCELE; RADICAL OPERATION; EXCISION OF MAJOR PORTION OF OMENTUM; RECOVERY.

By THOMAS S. K. MORTON, M.D.,
SENIOR RESIDENT SURGEON AT THE PENNSYLVANIA HOSPITAL.

F. D., a well-conditioned, muscular negro, æt. twenty-two, was admitted into one of the surgical wards of the Pennsylvania Hospital, on August 27, 1886.

Surgical History.—Ten years ago, he noticed a small lump or kernel in his left groin. It gave him no pain or annoyance, and, but for feeling its presence, he would not have known that anything was amiss. During almost the whole of that time, his work was of the hardest description. Exactly forty-eight hours previous to admission, while loading baskets of peaches upon a steamer, he felt a sudden pain, and a sense of something giving way in that groin, and was compelled immediately to abandon his work. Upon examining the spot, he noticed that a large swelling had appeared. This, as well as the pain, increased greatly; nausea soon set in, and he vomited almost incessantly until admission, for which purpose he walked nearly a mile!

Upon Admission.—He arrived much exhausted by his walk, and vomiting had then ceased. Temp. 102°; pulse rapid, though fair. A large tumor, presenting all signs of strangulated inguinal hernia, was present in the left groin and scrotum. Warm bath, mild narcotism, and ice-bag locally, were employed for an hour, by which time he had reacted from the exhaustion incident to the walk. Anæsthesia to absolute relaxation was then induced, and thorough though ineffectual taxis was made. Everything being in readiness, I at once proceeded to operate.

Operation at 4.30 P.M. The parts, previously well shaved, were washed with ether, then with soap and water, and finally with 1 : 1000 bichloride of mercury solution. A three-inch incision was carried down to the sac, when a stricture at the external ring was discovered and divided. Carrying the finger along the canal, another but tighter, constriction was found at the internal ring, and similarly disposed of. These divisions seeming to make no difference as regards reducibility, the sac was opened to the length of the external incision; it contained no liquid, but was adherent to the contents throughout by easily broken-up lymph. It contained *almost the whole omentum*, and about six inches of small intestine, the former being crowded with small, clotted extravasations of black blood, and had the appearance of beginning gangrene, while the gut, though of an exceedingly dark brown color, had not quite so bad an appearance. A slight thickening and constriction of the sac was found, corresponding to the external ring, while a much more firm narrowing marked the site of the internal ring, the gut between being much swollen and bulbous. Both of these additional constrictions were cut, and the exposed parts covered, for a period of ten minutes, with towels wrung out of 1 : 5000 $HgCl_2$ solution. At the end of that time the gut had begun to assume a beautiful pink tinge at its mesenteric attachment; but the omentum remaining unchanged, its excision was determined upon. For that purpose, it was drawn down until a healthy portion became visible, which was ligated in three portions with "fourteen" day chromicized catgut, the sphacelated portion cut away, and its pedicle returned to the abdomen. Reduction of the bowel was easily accomplished. The retracted sac was then obliterated by deep sutures, the columns of the external ring neatly approximated by four sutures of fourteen-day catgut, and the external incision by interrupted sutures of seven-day catgut, covering in a five-strand drain of the same substance having exit at the inferior extremity of the wound. The dressing consisted of protective, eight thicknesses of moist (1 : 1000) bichloride gauze, thickly powdered upon its wound-surface with iodoform, a large pad of bichloride cotton (dry, but also 1 : 1000), and a double spica of gauze bandage over all.

Progress.—His temperature, after the operation, registered 98°; next morning, 100⅕°, where it remained for one day, and then dropped to 100° for one day more; then to 99°, where it stood for twelve hours, and then permanently regained the norm.

Mild narcotism, and no food for two days, comprised the after-treatment. Bowels moved of their own accord on the seventh day, and continued to do so regularly. No signs of peritonitis at any time showed themselves, and he was without discomfort throughout convalescence.

The dressing was not touched until the tenth day, when, on account of loosening, it was removed, and perfect union found throughout the wound, save a small, superficial ulcer, which marked the former exit of the catgut drain—for both it and the external sutures (buried portions) had been completely absorbed. Except for a few days treatment of this ulcer, no further dressing was employed. He was allowed to get up on that (the tenth) day, and was employed for light work about the wards until September 27th, when he returned to his work. At the time of his discharge, there was no sign of redescent or appearance of the hernia, and he is not even wearing a truss.

For the operation upon, and the privilege of publishing, this case I am indebted to the courtesy of my chief *pro tem.*, Dr. John B. Roberts, acting for Dr. R. J. Levis.

MEDICAL PROGRESS.

Leopold on the Technique of the Sänger Operation.—Leopold formulates the following rules as the result of his experience with the Sänger operation:

1. The patient should be examined and disturbed as little as possible before the operation. The internal and external genitals, however, should be washed with sublimate solution (1 : 2000), or with a three per cent. carbolic acid solution.

2. The operation should be performed as early as possible, at the furthest by the end of the first period of parturition.

3. The operator must be assured of efficient assistants, who have been previously instructed in all the details of the operation.

4. The uterine section should reach only to the movable peritoneum, and ultimately be prolonged to the fundus.

5. After the removal of the child, and before the separation of the placenta, the uterus is removed from the abdominal cavity, and

6, hemorrhage is checked by compression with an elastic ligature, and finally by manual compression.

7. The uterine wound is sutured with silver wire, the decidua being avoided. Coaptation of the muscular surfaces is best effected when, before the sutures are drawn up, the uterus is compressed laterally. The superficial sutures are best made with thin silk.

8. The elastic ligature is now removed, and the further procedures follow the rules of a laparotomy.—*Centralb. f. Gynäkologie*, No. 32, 1886.

The Physiological Treatment of Cholera, after Semmola.—We abstract from a recently published work of Semmola (*Nuove Ricerche Terapeutiche sul Cholera Asiatica*), in which this well-known Italian clinician has laid down the clinical and therapeutic experiences gathered during the recent Italian epidemic of cholera, his views on what the author calls the "physiological treatment of cholera." Semmola holds that no cure can ever be expected from any medication directed specifically against the comma-bacillus, and also warns of too heroic a therapeutic interference with the symptoms of the premonitory and the algid stages.

A physiological treatment, in the judgment of the author, is one which is directed toward raising the vital energy of the body, so as to endow the same with a higher power of resistance against the disease without injuring the entire system by the biochemical action of pharmacal agents.

The main features of this treatment are the following:

1. Absolute rest of the affected organs—viz., the gastro-intestinal tract—by observing a strict fasting on appearance of the first diarrhœa stools. As long as the diarrhœa persists no food whatever is to be taken. Over six thousand clinical observations in Naples have shown that even five or six teaspoonfuls of bouillon given prematurely (*i.e.*, before the stoppage of the diarrhœa), sufficed to reproduce the gravest symptoms, such as algidism and asphyxia. After the disappearance of diarrhœa and vomiting, milk may be given in very small quantities.

2. Timely excitation of the physiological powers by therapeutic, or, rather by physiological means. The best of these are, undoubtedly, repeated warm baths. To prove beneficial the baths must, however, be given in the first period of the disease, before any sign of algidism has set in. The application of the warm bath in cholera has been in vogue also in former times, but never yielded any benefits, as it was only employed in the algid stage of the affection. The warm bath is not alone useful, as was held formerly, on account of the supply of heat to the cold surface of the body—a mere physical process—but also and particularly on account of the physiological influence it exerts on the economy. The warm bath excites the peripheral nervous system, and at the same time, by reflex action, the centre of circulation. The consequence of this excitation is a harmonious restoration of the functional physiological relations between the surface of the body and its internal apparatus, especially those of the digestive tract. True, this biological process can only be realized in the first stage of the disease, when the biological relations between the superficial and internal organs have not yet been essentially altered or broken off altogether.

Through diaphoresis the bath favors besides the elmination of toxic substances from the system, which, by affecting the various nerve-centres, cause ominous alterations in the secretory, vaso-motoric, and general oxidation processes. If necessary, the bath can be repeated every one or two hours. After the bath, the patient is to be wrapped up in woollen blankets, and is to be given warm aromatic and weak alcoholic drinks. It is well to give also small doses of opium (laudanum, liqueur de Batteley, chloridine), in order to render the nervous centres less susceptible to the toxic principles, and in order to reduce the increased intestinal secretion. Opium, given at the proper time, aids and supplements the physiological treatment.—*Therapeutic Gazette*, October 15, 1886.

Syphilis and Gestation.—Hirigoyen makes the following notes as to the influence of syphilis on the pregnant female:

1. In the special maternity service of Bordeaux the proportion of syphilitic women is five per cent.

2. The most frequent complication is a premature termination of the pregnancy, a matter which the duration of the syphilis greatly influences.

3. In eight pregnancies among women syphilitic for a year or more, there were two children born living but very puny.

4. In twelve women attacked with syphilis during the first four months of pregnancy, there were twelve stillbirths.

5. Syphilis acquired during the last three months is very dangerous to the fœtus, at least fifty per cent. being stillborn.

6. Over three-fourths of the infants of all syphilitic women were stillborn.

7. To be efficient, energetic antisyphilitic treatment must begin with pregnancy, and continue throughout its entire duration.—*L'Union Médical du Canada*, October, 1886.

The Physiological Action of Menthol.—Dr. Goldscheider, at a meeting of the Physiological Society of Berlin, discussed the action of menthol on the sensory nerves. It was well known that it produced on the skin a sensation of cold, which was commonly ascribed to evaporation. On the other hand, the same sensation, when produced in the mouth by solutions containing menthol or peppermint, was explained by a supposed astringent effect. Dr. Goldscheider had come to the conclusion that neither of these explanations was correct. He made his experiments with a solution of menthol in lanolin, which he rubbed into circumscribed regions of the skin. After the rubbing, the thermometer showed, in all such places, an increase of temperature to the extent of two degrees C., notwithstanding the marked sense of cold produced. The hypothesis of evaporation was excluded by the fact that the feeling of

cold was no less marked when the part rubbed was covered with a watch-glass, and could, therefore, be produced only by direct stimulation of the nerves of sensation of cold. Again, if of corresponding places on the forehead, where these nerves are most abundant, one were rubbed with the menthol ointment, and the other not, bodies which previously had caused no particular sensation would be felt as cold on the former spot, but not on the latter. Dr. Goldscheider, observing that while some regions, as the forehead, were especially sensitive to cold, others, as the elbow and the volar side of the wrist, were so to heat, found that the inunction of these with menthol produced a sensation of warmth, though less striking than that of cold in the former regions; and he called attention to the recent communication of Professor Herzen on the precisely analogous results of pressure on the nerve-trunks in these regions respectively. He therefore concluded that the sensations, in some places of cold, and in other places of heat, produced by menthol, were purely subjective and consequent on the direct stimulation of the special nerves of temperature, those usually cognizant of cold being far more sensitive to its influence than were those adapted to receive impressions of higher temperatures.—*British Medical Journal*, August 21, 1886.

Acquired Alterations in the Elasticity of the Larger Bloodvessels.—Israel has experimented upon the elasticity of the vessels in health and disease in the following manner: Pieces of the aorta, homologous in size and point of origin, were appropriately suspended, and the degrees of extension produced by the application of given weights were noted.

As the result of the study of fifty such preparations it was seen that the elasticity (or, more strictly speaking, extensibility) was most marked in the vessels of the chlorotic of both sexes, and was less pronounced in nephritics and especially in drunkards. The diminished elasticity of the vessels in the class last named is regarded as explanatory of the not infrequent sudden deaths in this class, with negative results on post-mortem section.—*Centralb. f. klin. Med.*, Sept. 18, 1886.

Posology of some of the Newer Remedies.—The *Rundschau Leitmeritz*, which is, by the way, one of the best of the German pharmaceutical journals, gives the following information concerning the dosage of the remedies which have come into general use since the last edition of the *Pharmacopœia*:

Osmic acid: Best administered in pill form (made up with Armenian bole). The dose is $\frac{1}{60}$th grain, which may be repeated several times a day.

Agaracine: Best administered in combination with Dover's powder. Dose $\frac{1}{12}$th to $\frac{1}{6}$th grain.

Aloin: From $\frac{1}{8}$ of a grain to $3\frac{1}{2}$ grains, in pill form.

Antipyrine: Dose from 75 to 90 grains, divided into 3 portions, one of which is to be taken every hour.

Bismuth salicylate: Dose from 5 to 7 grains, in pill form. In typhoid this dose may be doubled and repeated every hour, up to ten or twelve times.

Canabinone: From $\frac{2}{3}$ to $1\frac{1}{2}$ grains. Best administered mixed with finely ground roasted coffee.

Caffeine: To commence with, the dose should not be over 3 grains, but this may be repeated every hour until four doses are taken, or say 12 grains *per diem*. This may be increased to double the amount mentioned. The *benzoate of sodium and caffeine* is a double salt which contains one-half its weight of pure caffeine. It resembles the *salicylate of sodium and caffeine*, but the latter contains more caffeine (10 parts of caffeine to every 16 parts of the double salt).

Colocynthin: Used subcutaneously. The dose is from $\frac{1}{6}$ to $\frac{1}{3}$ grain. It may also be administered in pill form by the mouth, the requisite dose being from $\frac{1}{3}$ to 1 grain.

Convallamarine: Internally, in pill form. The dose is from $\frac{3}{4}$ to $1\frac{1}{4}$ grains, and it may be repeated every hour, until a total of 15 grains is reached.

Euonymin: Best given in pill form, combined with extract of belladonna or hyoscyamus. The dose is from 3 to 10 grains.

Helleborein: May be given in pill, solution, or in suspension in some mucilaginous vehicle. The dose is from $\frac{1}{6}$ to $\frac{1}{3}$ grain, repeated four or five times in the course of a day.

Tannate of mercury (protoxide) may be given in a wafer. The dose is $1\frac{1}{2}$ grains repeated thrice daily.

Nitroglycerine is best given in alcoholic or oily solution. The dose is from $\frac{1}{333}$th to $\frac{1}{60}$th grain, repeated several times a day. Rossback prefers ether as a solvent. His formula for its use is as follows: Dissolve $1\frac{1}{2}$ grains of nitroglycerine in sufficient ether, and add the solution to a mixture consisting of two ounces of powdered chocolate and one ounce of gum-arabic. Mix very thoroughly and divide into 200 pastilles. Each pastille will thus contain $\frac{1}{333}$d grain of nitroglycerin.

Picrotoxine: In aqueous solution. Dose from $\frac{1}{8}$ to $\frac{1}{6}$ grain.

Sulphate of thalline may be given dissolved in wine or water (with some corrigerant). The dose is from 4 to 8 grains.—*St. Louis Medical and Surgical Journal*, October, 1886.

Thymol as a Tæniafuge.—Dr. Numa Campi records as follows the experience of himself and of Dr. Vanni in the use of thymol or thymic acid as a tæniafuge:

Dr. Vanni, in the first case of tænia treated by thymol, gave three grammes (gr. xlv) in divided doses through the day, and twenty grammes (℥v) of castor oil at night, but succeeded in obtaining only five or six segments of the worm. On the following day, however, he administered six grammes (℥ iss) of thymol, divided into twelve doses, to be taken every fifteen minutes, and at the end of the third hour the entire worm, including the head, was expelled.

I adopted the following method with my first case: In the evening I ordered twenty grammes (℥ v) of castor oil to be taken fasting; in the morning I prescribed eight grammes (℥ ij) of thymol, divided into twelve doses, one to be taken every quarter of an hour; twenty minutes after the last dose had been swallowed, another twenty grammes (℥ v) of castor oil were taken. A few minutes after, a tænia medio-canellata three and a half metres in length was evacuated, the head being dead. To be sure, I had no Shultze's table with me to prove that there was no movement, but I touched the worm repeatedly with a hot coal, and observed no sign of life.

It is very important during the administration of the thymic acid, to give the patient some cordial and stimulant; cognac, or rum, will be found suitable. Thy-

mol is very depressing, according to the experiments of Husemann, and this will explain its action on the nervous system. Even with small doses, the pulse becomes small and frequent, the respiratory movements slow, and the temperature is lowered. These effects, however, are easily and promptly counteracted by the use of stimulants.

I must call attention to another fact. Husemann and Lewin say that thymol should be administered in small doses. On account of its caustic action, they claim that there is danger of producing digestive disturbances and gastro-enteritis. They recommend two or three teaspoonfuls of a one-half per cent. solution during the day. While it is true that we can never be too prudent in the practice of medicine, these doses are too fearfully homœopathic, when we consider that eight grammes of thymic acid may be given in two hours and a half without producing the least gastro-intestinal disturbance.

The use of thymol is advocated for the following reasons:

1. Because this remedy, with the exception of a depressing effect, easily counteracted, produces no disturbance of the stomach or intestines.

2. On account of the rapidity and simplicity of its action, compared with other remedies, which require *courses of treatment*, divided into three periods, the preparatory, the expulsive, and the consecutive.

3. On account of the advantages it offers of being both a tæniacide, and a tæniafuge.

4. Because in case of an error of diagnosis the remedy would produce an efficient purgation and disinfection of the alimentary canal.

5. Because it is reasonable to suppose that since thymic acid succeeds in expelling the tænia medio-canellata, the worm which above all others resists the action of anthelmintics, the same remedy will be of service in expelling all other varieties of flat worms.

6. Because we have, as yet, always been successful with the use of thymic acid, and have probably found a real specific, which, up to the present, did not exist.—*Buffalo Medical and Surgical Journal*, October, 1886.

The Lower Limit of the Pleura.—Mr. W. Arbuthnot Lane presents in *The Journal of Anatomy and Physiology*, April, 1886, an interesting paper upon "Some Variations in the Human Skeleton." Mr. Lane observes that the lower limit of the pleural cavity behind can be determined clinically by measuring the lower ribs, and especially the twelfth. It will be found that if the twelfth ribs are under two inches in length, the pleura may not even reach their upper margin, or, at the most, it may extend but a little way over the inner half of their anterior surface. As the length of this rib increases, the pleura extends still lower down, and in some instances it may reach a point an inch and a half below the lower border of the rib. If the last rib be over two inches in length, the lower limit of pleura crosses it obliquely at its centre, so that it bears a direct relation to the length of the rib. This relationship of the pleura to the length of the last rib shows that there need be no risk of opening this cavity in the ordinary operation of lumbar nephrectomy.

As to the extent of the pleural cavity laterally, Mr. Lane finds—taking the average of a number of cases—that the lower limit of the pleura crossed the seventh costal cartilage obliquely, about three quarters of an inch below its articulation with the rib, then the end of the eighth rib, or the cartilage immediately below it, the ninth rib a quarter of an inch above its extremity, the tenth rib three-quarters of an inch, and the eleventh one and a quarter inches from its outer end. In the axillary line, which is at least sometimes defined as a line passing vertically down from the head of the humerus, Mr. Lane found that in the large majority of cases the lower limit crossed the tenth space or the eleventh rib, not unfrequently lower on one side than on the other, but not much more frequently on one side.

Tetanus Resulting from the Hypodermatic Injection of Quinine.—Rubino records a case of miliary fever in a six year old girl, in which after several days' exhibition of quinine by the mouth and by enemata, he administered the drug subcutaneously. At the end of a month the child was wholly free from fever, but complained of pain in the left arm at the point of introduction of the last injection. Three days later trismus and tetanus appeared. Death on the sixth day.

The author regards the case as essentially one of traumatic tetanus.

Analogous cases of tetanus from the hypodermatic injection of quinine are recorded by Oderaine (*Gazette Hebdomadaire*, 1872), Bortolazzi (*Gazz. degli Ospitali*, 1884, No. 80), and Roberts (*Lancet*, 1876).—*Centralb. f. klin. Med.*, September 18, 1886.

The Analgesic Action of Carbolic Acid and the Cresol Group of Compounds.—Dr. McNeill has made some experiments on himself and others with carbolic acid and the cresols to determine whether their local anæsthetic influence can be utilized. He finds that a mixture of 60 parts of acid and 40 of oil renders the skin of the arm insensitive to pain caused by superficial incisions. It produces, however, a sensation of heat, but this can be removed without any interference with the anæsthesia by the application of glycerine.

A mixture of glycerine and acid will have the same effect as the oil and acid, but only if twenty per cent. stronger. Impure carbolic acid having appeared more effective as a local anæsthetic than the absolute phenol, Dr. McNeill tried the effects of several of the substances allied to carbolic acid which are produced in the distillation of coal. Several of these, as benzol and toluol, had no effect. A mixture of ortho- and para-cresol (sold as cresolene) was found to have a similar effect to carbolic acid, but was not so powerful. Paracresol, on the other hand, acted more powerfully, equal parts of this substance and oil producing anæsthesia.

It is worthy of note that whilst analgesia is produced the sensation of touch remains, and that the deeper parts may be opened painlessly by introducing some of the anæsthetic compound into the tissues laid open.

Dr. McNeill records some cases in which he performed minor operations without pain by the aid of carbolic acid or cresol. No sloughing or other trouble followed their use.

As a mixture of glycerine and carbolic acid is a less powerful corrosive than a mixture of oil and acid, Dr. McNeill suggests that glycerine should be administered in poisoning by carbolic acid instead of oil.—*Med. Chronicle*, July, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, OCTOBER 23, 1886.

PERFORATING APPENDICITIS.

The clinical and pathological studies of the past twenty-five years have led to remarkable improvements in the methods of treating the various affections of the cæcum and appendix; still, the anatomical relations are so uncertain, the symptoms often so complex, and the causation so varied, that the precise localization of the disease may be obscure, and the indications for treatment doubtful. In the *American Journal of the Medical Sciences* for October, 1886, Fitz contributes an exhaustive study of this subject under the title of "Perforating Inflammation of the Vermiform Appendix; with Special Reference to its Early Diagnosis and Treatment;" and his investigations give us a clearer knowledge of the exact relation of inflammation of the cæcum and appendix to peritonitis and perityphlitis.

The term typhlitis is usually employed to designate inflammation of the appendix and of the cæcum; perityphlitis when the peritoneum in the neighborhood of these parts is involved; and paratyphlitis when the connective tissue behind the cæcum is affected. As in the great majority of the cases of fatal typhlitis the appendix is ulcerated and perforated, the term perforating appendicitis is most appropriate. The result may be either a circumscribed peritonitis, or paratyphlitis. The anatomical relations of the part determine which of these conditions will prevail, for the appendix may be either surrounded by peritoneum and free in the cavity, or, as is not infrequent, it may be entirely behind the serous layer, which may, however, be involved by contiguity. Fitz has collected 257 cases of peforating inflammation of the appendix, and has carefully analyzed every symptom. For comparison, he has also collected 209 cases of typhlitis and perityphlitis from other causes.

The well-known etiological importance of inspissated fecal masses and foreign bodies in inflammation of the appendix is borne out by the fact of their presence in three-fifths of the cases. The proportion is doubtless larger, as in many cases the fecal concretion or foreign body is lost in the discharge, or, as in an instance reported in *Revue de Médecine*, for June, the concretion may pass in the feces. Strain, as in lifting, was recorded as preceding the attack in 19 cases. Digestive disturbances—constipation, vomiting, or diarrhœa—were present in 30 cases of appendix inflammation and in 53 of the instances of typhlitis and perityphlitis from other causes. Tuberculous and typhoid ulcers play a less important part in the etiology of perforative disease of the appendix, as there were only 8 instances of the former and 3 of the latter. A percentage of eighty illustrates the special liability of the male sex to this affection, and seventy-six per cent. of the subjects of the entire list were under the age of thirty years.

The recurrence of attacks of appendicitis is well recognized, and eleven per cent. of the cases had presented similar symptoms of greater or less severity before the final attack.

The course and results of the inflammation show remarkable variations. The frequency with which the tube of the appendix is found to be obliterated, in a greater or less extent, points to recovery as a common sequence of appendicitis. When perforation occurs, the result will depend on the position of the tube. A circumscribed peritonitis is probably the most common sequence, and the contents of this peritoneal abscess may become absorbed or may escape into the general peritoneum. Perforation externally, or into the rectum or bladder, may occur, and in one instance the abscess burst into the small intestine, ulcerated an artery, and caused death from hemorrhage. When the appendix lies behind the peritoneum, the inflammation of the connective tissue speedily forms an abscess, which may attain large size and perforate externally in the groin, in the lumbar region, or at the navel. In some of these instances the destruction of tissue is extensive, and the pus may pass downward as in psoas abscess, or upward into the pleural cavity.

The symptoms of the affection have been very carefully analyzed by Fitz. Of these the first and most constant is a sudden, severe abdominal pain, which was present in 84 per cent. of the cases, and in 48 per cent. was localized in the right iliac fossa. This sudden onset may occur in apparently healthy individuals, or may be preceded by diarrhœa. Doubtless, in most instances, it coincides with the perforation, or it may represent the separation of the fresh ad-

hesions of an acute appendicular peritonitis; often it precedes the manifestation of a more general process. In 61 cases, in which it was possible to determine the date of occurrence of this important symptom, it occurred in 67 per cent. on the first day, in 8 per cent. on the second, and in 20 per cent. on the third. Nausea and vomiting are often induced by the great pain; constipation is usually present. Fever very constantly follows, but the range is rarely high. The appearance of a circumscribed swelling is of the utmost value in diagnosis, and it has its usual seat "in the right iliac fossa below a line extending from the anterior superior spine of the ilium to the navel, nearer the former, and two finger-breadths above Poupart's ligament." It represents the accumulation of the exudation, which, at first scanty and fibrinous, may in two or three days form a large purulent deposit. Dulness may be obscured by adherent coils of intestine, or the abscess may be gaseous. The pain on pressure and tenseness of the abdominal muscles may necessitate the use of ether to make a satisfactory examination. Even when a positive tumor is not palpable there is a circumscribed resistance and, later on, a sense of fluctuation. This symptom usually appears so late as to be of very little use in diagnosis. The onset of diffuse peritonitis is indicated by general abdominal pain which, in the largest number of cases, sets in on the second, third, and fourth days. This complication is almost invariably fatal. In 176 cases in which the day of death was noted, 50 per cent. occurred in the first week, 31 per cent. in the second week, and 4 per cent. in the third week.

Perforative appendicitis is most likely to be confounded with stercoral cæcitis, a condition not uncommon as a result of protracted constipation. The pain in this affection is slight, the fever mild and delayed, and the tumor, which can be felt, is an elongated, nodular or doughy mass. Perforating disease of the cæcum is very rare. A careful consideration of the symptoms and mode of onset will usually suffice to make a diagnosis between appendicitis and intestinal obstruction, pelvic peritonitis, and renal or biliary colic.

The termination in resolution of a perforating appendicitis is rare, and we have no evidence of the proportion of cases in which it occurs. In typhlitis and perityphlitis from other causes it is more frequent, and in 180 cases of this kind there terminated by resolution 58, by spontaneous evacuation 33, while 89 cases were opened surgically. The treatment of this affection has been too much in the hands of physicians, and in too many cases there is an unjustifiable delay while waiting for the more definite signs of suppuration. If good is to be gained by an operation the earlier it is done the better chance has the patient for recovery. Fitz very correctly states that if, after the first twenty-four hours from the onset of the severe pain, the peritonitis is evidently spreading and the condition of the patient is grave, the question should be entertained of an immediate operation for exposing the appendix and determining its condition with reference to its removal. The fact that 34 per cent. of the cases died during the first five days justifies operating at the earliest possible period, and of late surgeons have interfered as early as the third day. Laparotomy is called for in a majority of the cases, as by it alone the condition of the parts can be accurately ascertained.

The carefully collected facts in Fitz's article will materially assist in the diagnosis of this grave disease, and will embolden surgeons to practise an early operation which can alone, in many instances, give the patient a chance of recovery.

NOXIOUS OR OFFENSIVE TRADES.

There is a demand for systematic inquiry into dangerous and offensive processes of trade with the view of determining the appropriate means of preventing a nuisance or injury to health therefrom. It is a well-known fact that workmen suffer in their health from a variety of influences connected with their occupations, and we are accustomed to speak, in a general way, of the diseases thus caused as industrial diseases. It is not difficult to prove that the processes of certain trades are offensive and an annoyance to the neighborhood, but it is not so easy to demonstrate that their effects are injurious to health. Nevertheless it may be stated upon general principles that whatever pollutes the air we breathe, or the water we drink, tends to impair health and calls for the intervention of the restraining power of the law.

Sanitary supervision should take cognizance of the health of the workmen and also guard the public from the influences of such industrial processes as interfere with the comfort and tend to jeopardize the health of the community.

In the prevention of diseases arising from industrial labor the coöperation of the employer and employed is indispensable. Both are equally concerned in the labor of prevention, and more can be accomplished by their coöperation than by local authoritative action, though the latter has its salutary influence. The buildings, appliances, and manner of conducting the work should be arranged with the view of affording the greatest possible protection to the workmen. Personal cleanliness and thorough ventilation of the workshops are among the most important measures of safety.

The duty of the employer, however, is only half performed when he has provided means for the protection of his workmen; the obligation also rests upon him of providing the means of preventing the

escape of noxious or offensive fumes or gases into the atmosphere, or the pollution of streams which may be used as the source of water-supply, an obligation which, unfortunately for the public, is oftener violated than fulfilled. Nuisances of this description are frequent and constitute one of the most perplexing subjects with which a health board of a large town has to deal. It is not because the methods of prevention are difficult of discovery and application, for human ingenuity is adequate to the task; but the manufacturers fail to interest themselves in that which concerns them less than the public generally, and object to the expense of apparatus and appliances not essential to their processes of manufacture, though necessary to protect the people in the enjoyment of their right to pure air and uncontaminated water.

Ordinarily, the sanitary law provides the remedy for nuisances of this description which are more or less directly or indirectly injurious to public health, and designates the proceedings to be taken under its provisions; but the administration of the law often fails in the accomplishment of its intended purpose. It frequently happens that when complaint is made against an establishment by reason of the escape of nauseous or injurious vapors or gases, an attempt is made to antagonize interference by the use of petty subterfuges and artful temporizing too well known to the manufacturer. Influence, which has a mighty sway, is made to do valuable service in thwarting any effort made to abate the nuisance.

The suppression of the objectionable processes is construed as a suppression of the business itself, and the effort of the sanitary authorities to correct the evil is paraded as a menace to the trade and business of the town. The result is too often a withdrawal of the proposed corrective measures or the adoption of some temporary expedient savoring of compliance with the law, while the public continue to submit to the evil. The remedy for such abuses lies in adequate laws based upon the results of thorough scientific investigation, and their intelligent, impartial, and resolute enforcement. In framing such laws the interests of the manufacturer as well as of the public should be zealously guarded, so that, while protecting the one, the other shall not be needlessly sacrificed.

TREATMENT OF HERNIA OF A MUSCLE.

This uncommon lesion consists in the protrusion of a portion of muscle through a rupture in its containing fascia. Two cases of this sort having recently come under the care of Giess, and he has made them the subject of an interesting communication in the *Berliner klinische Wochenschrift*, No. 11, 1886. The first case was that of a man who had a hernia of the tibialis anticus muscle caused by a blow with a stone. Palliative treatment by means of strapping and bandaging did no good, and Giess cut down on the hernia and removed the protruding portion of the muscle with scissors. After a few days the hernia had disappeared and suppuration came on. Giess then cauterized the protrusion repeatedly with nitrate of silver. The result was unsatisfactory as the hernia persisted, although it was reduced in size.

In the second case a similar tumor was treated by incision, removal of the protrusion, freshening of the edges of the opening in the fascia, and suturing of the fascia with catgut. The superficial wound was also sutured, and the limb confined in a plaster-of-Paris dressing. The result of this operation was perfectly satisfactory. The wound healed by first intention; the plaster dressing was removed on the sixth day, and on the twenty-first day the patient left his bed with a solid cicatrix, and in a few days had full use of his leg.

The method adopted in this case seems rational, and the success which followed its employment by Giess confirms this impression.

A curious mixture of bad pathology and good surgery is presented by a case reported in the *Virginia Medical Monthly*, for October, by Dr. Wilkerson, under the following startling caption: "Incision into the pelvis of the kidney and treatment topically through the drainage tube, for the cure of Bright's disease." The patient, a man aged thirty, had received an injury of the back, and six months after began to fail in health, became emaciated, had hectic, and passed blood and pus in the urine. Deep palpation on the right side gave an indistinct sense of fluctuation. Lumbar nephrotomy was performed, over a pint of matter was discharged, the sac was swabbed out, and a drainage tube inserted. The man made a good recovery. The case was evidently one of pyelonephrosis, and the treatment pursued most judicious and successful. It is remarkable how deep-rooted is the idea that all affections of the kidney belong to Bright's disease: fortunately for the patient, the doctor's surgery was at least half a century in advance of his pathology, and it is a pity that the report of so interesting a case should be marred by a title both misleading and erroneous.

Last Wednesday week Prof. S. W. Gross, at the Jefferson Medical College Hospital, performed nephrolithotomy upon a man who had for years suffered with pain in the region of the kidney, accompanied by occasional attacks of hæmaturia, and the presence of a few red blood corpuscles, and an abundance of oxalate of lime crystals in the urine, together with strings of mucus and epithelial cells

from the pelvis of the kidney. From a careful study of the symptoms of the patient, Dr. Gross diagnosticated an oxalate of lime calculus in the left kidney, and proceeded to an operation which completely verified his opinion. The calculus was removed through an incision below and parallel to the twelfth rib, and was found to be about the size and shape of a flattened acorn. The patient is now doing well, and there is every prospect of his speedy recovery. We hope, in due time, to present a full report of the case.

REVIEWS.

The Anatomy of the Intestinal Canal and Peritoneum in Man. By Frederick Treves, F.R.C.S. The Hunterian Lectures for 1885. Vellum, 4to. pp. 66, pl. iv. London: H. K. Lewis, 1885.

It is not given to every man in these days to make a study of the gross anatomy of the human body, and yet add materially to our knowledge. But this beautiful edition of Mr. Treves's Hunterian Lectures proves that it will be given to every man who will devote equally patient painstaking labor to his subject. The lectures are based on the dissection of one hundred bodies, in which the abdomen was opened, and every part labelled and drawn, and studied *in situ*, and then after removal. We cannot go over, as we would like to, every error the author points out, and every new fact he states, but can only indicate a few.

The length of the bowel seems independent of height, weight, etc., and, curiously enough, in women it is in the average longer than in men. We have long known that the gentler sex had more "bowels of compassion" than we men, but as to "bowels of digestion and absorption," we should have sworn that we were the better furnished. The holes in the mesentery, he shows are undoubtedly due to atrophy; the pelvis contains not only coils of the ileum, but of the jejunum, and not seldom a portion of the transverse colon; the various forms of cæcum he classifies under four types; the sigmoid flexure he shows to be chiefly pelvic (as indeed also is the cæcum), and omega-shaped; and he explains why in about four per cent. of subjects the surgeon attempting to reach the ascending colon by lumbar colotomy will miss the bowel, because it is not in its accustomed place.

These are but a few points in a hasty *résumé* of the many valuable facts and applications with which the author favors his interested readers.

Mr. Treves writes so well that we shall be disappointed should he find increasing professional work interfere with his literary labors.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Neurology.

Stated Meeting, October 8, 1886.

The Chairman, L. Putzel, M.D., in the Chair.

Dr. Julius Althaus, of London, a Corresponding Fellow of the Academy, read a paper on

some points in the pathology and treatment of paraplegia dependent on pott's disease.

He commenced by relating the detailed history of a case. The patient was a florid-looking girl, of twenty, who lived out at service. She had enjoyed good health from early childhood. She had never had any scrofulous affections of the glands or other parts, and there was no phthisis in her family. Moreover, she had never, so far as she knew, received any injury to the spine. Two years before she came under observation, she suffered from an attack of rheumatic fever; but, on recovering from this, she went back to service. Nine months later, however, she began to suffer from severe pain in the right foot, which was soon followed by marked loss of power in the right leg. Eventually this was followed by pain and paralysis in the left leg also. She then became confined to bed, and for a considerable time was treated in a provincial hospital, without any benefit.

When she came under Dr. Althaus's observation an examination showed that there was almost complete paralysis from the hip-joint down, on the right side, and less marked paralysis in the left limb. On applying the faradic and galvanic currents, responses were obtained with unusual facility. The superficial reflexes were also unusually brisk; and the same was true of the deeper reflexes as well. There was no history whatever of spontaneous cramps or of muscular rigidity. There were more or less coldness, lividity, and clamminess about the foot and instep. The different forms of sensation in the entire limb were perfectly normal. The left side was in all respects less seriously affected than the right.

A distinct prominence of two of the dorsal vertebæ was clearly recognizable. There was no pain in the spine, and no increase of temperature; but the mobility of the spinal cord was much impaired. The commencement of the deformity, it was ascertained, had been coincident with that of the pain and paralysis fifteen months before. The catamenia were regular, and the nutrition of the patient well preserved.

It seemed evident that there was more or less thickening of the spinal dura mater, and that in the cord itself there was interstitial myelitis present. The posterior columns were also implicated, as shown by the neuralgia that had existed so long; but it was probable that the central portion of the spinal cord was normal. She was placed on the iodide of potassium and cod-liver oil, with complete rest and frictions with liniments, etc.; but at the end of three months no improvement whatever was noted. At the request of Dr. Althaus, Mr. Pearce Gould then made an application of the actual cautery to the side of the spine and within a few days the patient was perceptibly better. The application was made four times in all, and the patient continued rapidly to improve. In a short time she was able to walk about as well as ever, and the vasomotor disturbances, shown by the coldness, lividity, and perspiration about the ankle, disappeared. The patient was then discharged practically cured, and entered a convalescent hospital for a time.

Patients suffering from paralysis due to Pott's disease, continued Dr. Althaus, have sometimes recovered by the opening of an abscess, and it cannot be doubted that the powerful counter-irritation resorted to in this

instance had brought about a cure by its effect upon the diseased structures involved. While the pain in the foot and leg had been very marked, there had never been any pain in the back. The former appeared to have resembled the lightning pains observed in progressive locomotor ataxia. He believed that this pain was due not to pressure on nerves or inflammation of the dura mater, but to irritation of the posterior columns of the spinal cord. The symptoms of coldness, lividity, and perspiration of the foot and instep showed that there was present some degree of vasomotor paralysis also. It was plainly caused by central disturbance.

Formerly it was supposed that paralysis occurring in Pott's disease was due to an actual destruction of the substance of the spinal cord; but if this was the case, recovery, which is so often noted, would be impossible. He deprecated the views of Shaw as to the causation of paralysis in these cases. In many cases of Pott's disease the entire cord suffers some amount of pressure, which gives rise to paralysis. Vulpian has shown by experiments on animals that paraplegia can be produced and removed at will by setting up and withdrawing pressure upon the cord, the paralysis being motor in character with no loss of sensation. But this simple form of paralysis is not all. Charcot and others have shown that there is habitually inflammation of the external layers of the spinal cord. Interstitial myelitis seems to be always present also. In the case related there can be little doubt that the coarser pyramidal fibres were affected by either myelitis or degeneration, probably the former.

How, continued Dr. Althaus, shall we explain the fact that while there was almost complete motor paralysis, especially on the right side, there was no loss of sensibility? This is a point which has not been hitherto satisfactorily explained, and is worthy of careful study. There are three different degrees of pressure upon the cord met with in cases of Pott's disease. In the first there is no pressure exerted upon the actual structures themselves. We have all seen cases in which there was considerable deformity, but no paralysis. The reason of this is that the pressure is just sufficient to displace the spinal fluid, but it does not extend to the cord itself.

The second degree is that which existed in the case under consideration. Here there was not only displacement of the spinal fluid, but also interstitial myelitis. In these cases of paralysis resulting from Pott's disease motion is more easily lost than sensation. There is not a single case of Pott's disease on record in which there has been paralysis of sensation without that of motion, while we constantly meet with the reverse of this—paralysis of motion without that of sensation.

The third degree of pressure is met with in those cases in which we have to do with complete transverse myelitis, implicating not only the columns, but the gray matter of the centre of the cord as well. In connection with this, we find anæsthesia and analgesia, with paralysis of the bladder and rectum, and a tendency to bedsores. In such cases, on account of the profound organic changes which have resulted from the pressure, recovery is impossible. It is important, therefore, that we should resort to the actual cautery at an early period in cases of Pott's disease in which paralysis results, in order to prevent the pathological process in the cord from going on to this advanced stage.

The conclusion of the paper was devoted to some consideration of the actual cautery. During the first half of the present century, he said, this means of counter-irritation was universally and indiscriminately used in all forms of spinal disease. During the first twenty years of the second half of the century, however, a reaction set in, and it was employed less frequently and more intelligently. Dr. Althaus said that, personally, he now never thought of resorting to the actual cautery in spastic spinal paralysis, tabes dorsalis, or other diseases of the cord proper, but that he had always found it of the greatest service in disease of the membranes.

Dr. V. P. Gibney said that he had been much pleased with the clinical picture which the distinguished visitor had presented, and also with the admirable manner in which he had connected the various symptoms observed with the pathological conditions undoubtedly present. The case detailed was one of great interest, and he thought that the point in regard to the service rendered by the actual cautery was well taken. This agency, however, is not the only means at our command for securing benefit to the patient. He had seen a large number of similar cases perfectly relieved within a week by the simple application of a jury-mast. Some time ago Dr. Charles J. Poore, of this city, read a paper in which he related a number of cases in which he was able to report very good results in the treatment of Pott's disease by the actual cautery. Afterward, however, he was much disappointed in its use, as the results in other cases were entirely unsatisfactory.

The author of the paper had cited but a single case, and though in this particular instance the method was eminently satisfactory, he did not think this was sufficient to prove its applicability in general. Personally, he believed the actual cautery to be objectionable, and particularly in the case of children. Although it is the present custom to apply it very lightly, as compared with the former practice, it is impossible to persuade patients that it will not hurt, and both the mothers and the children object very strongly to its use. Of course, this objection applies principally to private practice.

He thought, as Dr. Althaus had pointed out, that the cases which improve belonged not to the third stage, but to the neuralgic class of cases. He had a number of times applied the actual cautery in such instances, just as soon as any symptoms of paralysis showed themselves, but without securing any relief. When, however, he had stopped its use, and had resorted to suspension, and the application of a jacket, the patients got well. In these cases he was strongly in favor of giving large doses of iodide of potassium—say sixty, seventy, or eighty grains three times a day to a child. The objections to the use of the iodide in adults did not hold good in regard to children, with whom it almost always seems to agree perfectly, and who often grow fat upon it. With the iodide, and a jacket to support the spine, he had obtained better results than in any other way. The theoretical part of Dr. Althaus's paper he thought admirable.

Dr. Sachs said he agreed with the author of the paper that interference with motion is much more common than with sensibility. With regard to the treatment, he had no doubt that the actual cautery is efficient in certain cases; and yet in the one related by Dr. Althaus, he was inclined to doubt whether the credit for the cure should be given to this procedure entirely. Thus, in

addition, the patient was given complete rest and treated with cod-liver oil and other tonics. He had seen cases cured by complete rest alone. The same was true of many cases of chronic myelitis, and he called to mind particularly one case of post-puerperal paraplegia. He did not wish to discredit the treatment by the actual cautery, but it seemed to him that the other measures adopted were of considerable importance in bringing about the satisfactory result noted.

Dr. L. Putzel said that he had had a few cases in which the results were similar to those obtained by Dr. Althaus in the case reported in the paper. In three instances the improvement was so rapid after the application of the actual cautery that no reasonable doubt could be entertained as to its efficient agency. In the larger number of cases, however, this procedure was entirely without beneficial results. As to large doses of iodide of potassium, as recommended by Dr. Gibney last year, he had found in his experience that these also were without effect. He agreed with the last speaker that, after all, time and rest are the most successful remedies. Good feeding, however, is a matter of great importance also.

With regard to the absence of anæsthesia in these cases, it seemed to him that the explanation presented in the paper was a very plausible one. It certainly seemed to be a fact that there is some quality about sensory fibre which makes it resist pressure much more efficiently than motor fibre.

Dr. Althaus in closing the discussion said that the good effect produced by very large doses of iodide of potassium, as claimed by Dr. Gibney and others, was a very interesting matter, and that on his return to England it would give him great pleasure to test practically the efficacy of the treatment. It had been assumed that the rest and other treatment, beside the application of the actual cautery, had had much to do with securing the good result noted in the case which he had narrated. But this he believed was not the fact. For four months in the provincial hospital, and for three months after, when she came under his own care, the patient had been treated with complete rest in bed, and in addition she had been taking cod-liver oil and iodide of potassium, the latter in thirty grain doses three times a day. And yet no effect whatever was produced—the patient remained in precisely the same condition, without the slightest improvement. As soon, however, as the first application of the actual cautery was made (within less than ten days) a marked improvement in the paralysis commenced; and this rapidly became more and more marked under the repeated use of the cautery. Before resorting to this measure he had wished to give the rest treatment a thorough test, and as it was attended with no improvement, while from the first the improvement was marked under the use of the cautery, he thought that he was fully justified in attributing the cure to this particular method of treatment. There were, no doubt, cases in which the cautery had failed; but it seemed to him that in these instances the disease was probably more advanced. He inquired whether there was not some loss of sensibility, as well as motion in such cases? In conclusion, he said that his reason for bringing this subject before the Section was to induce surgeons to resort to the actual cautery at as early a period as possible.

Dr. Graeme M. Hammond read an elaborate paper on

ATHETOSIS, WITH REMARKS ON ITS PATHOLOGY.

In speaking of the treatment, he said that this affection, being dependent on certain irremediable organic changes in the brain, it was impossible ever to produce a cure. At the same time, there were certain measures which, in some instances at least, had been attended with marked relief, and sometimes had abolished all symptoms of the trouble for a considerable period. He referred in detail to four cases, one of which, reported by Gowers in 1876, had been treated with galvanism, and the remaining three of which had been treated with nerve-stretching. The most interesting of these was the original case of Dr. William A. Hammond, upon which his description of the disease which is mainly characterized by an inability to retain the fingers and toes in any position in which they may be placed, and by their continual motion), published in 1871, was based. This patient was also a confirmed epileptic. In 1882 Dr. G. M. Hammond stretched the median nerve very forcibly; after which both the epilepsy and athetosis disappeared for three months. At the end of five months, however, they were as bad as ever. At the time of the operation the nerve was in an apparently perfectly healthy condition. In 1884 the same operation was repeated, and the nerve still appeared normal. After this the patient remained well for about four months, but in eight months was again as bad as ever.

In 1885 the operation was again repeated, and this time the nerve appeared to have lost its healthy character, and, after the stretching, instead of promptly rebounding to its position, it hung in a loop outside of the wound. The result of the operation, however, has been more satisfactory than either of the others. A year and four months have now elapsed since it was performed, and there has been no return whatever of the athetosis; the muscles of the hand, arm, and foot, all being perfectly under the control of the will. The patient, however, still has an occasional epileptic seizure (perhaps once a month), and he is the subject of that interesting feature sometimes characterizing epilepsy, double consciousness. This state of oblivion to former events sometimes lasts for four days at a time.

Dr. Hammond said that he believed that nerve-stretching yielded better results than electricity, or any other method of treatment in athetosis. He was unable to say precisely how stretching the median nerve of the arm affected the leg also; but such appeared to be the fact. Such a procedure could, of course, have no effect on the organic changes in the brain giving rise to the athetosis; but he thought that it might perhaps have some effect upon the corpus striatum. Dr. Dana had shown that stretching of the sciatic nerve actually stretched the spinal cord as high up as the cervical vertebræ.

Dr. Hammond was able to present the reports of nine autopsies, made by various neurological authorities, in cases in which athetosis had been present during life. In three of these there were well-marked lesions of the corpus striatum; in three, of the optic thalamus; in one or more, of both the corpus striatum and optic thalamus; and in two, of the cortex cerebri. He also referred to a number of authentic autopsies of cases of allied affections, in which the same portions of the brain were the

seat of organic disease. His conclusion was, that athetosis and allied affections are due to lesions of the corpus striatum, optic thalamus, and cortex cerebri, and of those parts alone.

Dr. Birdsall said that in order to show that athetosis and allied clonic movements are dependent alone on lesions of the gray matter of the brain, it is necessary to prove that the internal capsule is not at all affected in the autopsies referred to. Athetosis so frequently follows hemiplegia, and especially in children, that it seems reasonable to suppose that the motor fibres are affected in it.

Dr. Putzel mentioned two autopsies which he had seen, which bore upon the subject, and which went to confirm the position taken by the author of the paper. One was in a very marked case of chorea, of twenty years standing, and the autopsy revealed pronounced atrophy of the central convolutions, with descending degeneration down the cord. The other was in a case of pre-hemiplegic chorea. He was glad to find that the author of the paper had not treated athetosis as a distinct disease, but as an affection allied to chorea, hemichorea, etc.

Dr. Hammond explained that the greater number of the autopsis he had referred to were described with the greatest accuracy, many of them being accompanied with diagrams representing the seat of disease, and that in none of them were the motor fibres implicated in the slightest degree.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting, October 5, 1886.

The President, C. L. Dana, M.D., in the Chair.

CASE OF CONGENITAL ABSENCE OF THE FACULTY OF COÖRDINATION.

Dr. G. M. Hammond presented a boy four years of age, brought to his clinic on account of inability to walk. He was born at full term; labor was natural. He appeared to be perfectly healthy at birth, but shortly afterward he became sick, and continued more or less ill for six months. The attending physician diagnosticated colic. Since recovery from this attack the patient has had no sickness. The special senses were normal. The patient understood as well as other children of his age. Perhaps he did not speak as plainly as he should, but two other children in the family, perfectly healthy, talked in the same manner. There was no history of syphilis. The patient was well formed; the muscles of the limbs were well developed for a child who did not walk; muscular reaction to both electric currents was normal; the reflexes were normal. The only apparent reason for his inability to walk was want of power to retain his equilibrium. He could crawl on his hands and knees perfectly well unless he attempted to go very fast, when he would fall, and he always fell toward the right. He could stand holding to a chair, and walk pretty well if held upright. There was also incoördination in the upper extremities. He widened his base in standing. Dr. Hammond had not decided whether there was congenital absence of sensory tract in the cord or cerebellar disease.

Dr. Julius Rudisch had seen two similar cases, both in girls, one about eight years old and the other about thirteen. The first was seen some years ago, was under observation but a short time, and his recollection of the case was indistinct, but he was impressed with what he took to be muscular weakness, not simply ataxia, but weakness in the back. The child if sustained could walk well; if not sustained, it would fall like the child presented by Dr. Hammond. The older patient could walk, but in a peculiar ataxic way, and in the position of marked lordosis. The legs were well developed, and for that reason he thought the trouble was in the muscles of the back. The cases were not, in his opinion, congenital locomotor ataxia.

Dr. N. E. Brill thought such cases were not uncommon, especially among idiots. The gait of the boy presented reminded him of the swaying motion of a cat sent Dr. Spitzka by Prof. Wilder. Other actions than walking were natural. Rumpf reported a similar case, and found a rudimentary cerebellum. Dr. Spitzka removed the cerebellum of this cat and found it natural. Dr. Brill thought we had to distinguish in these cases between locomotor ataxia and static ataxia. Dr. Hammond's case appeared to be one of static ataxia due to rudimentary cerebellum.

The President had found in his case books one in which a provisional diagnosis of infantile ataxia was recorded. The girl, about two years old, was well nourished, large; could not coördinate the hands or feet. In addition there were some forced movements; the head would suddenly plunge forward.

VESICO-GENITO POST-FEMORAL NEURALGIA AND NEURITIS.

Dr. Landon Carter Gray read a paper in which he described two cases, seen during the year, of a peculiar variety of neuralgia and neuritis that had not, so far as he had been able to ascertain, been hitherto described. The first patient was a man, aged forty, of good general health but marked lithæmic temperament, subject every summer to quasi-malarial attacks. Hitherto his neuralgia had been gastric or intestinal. He escaped his usual attack this year until July, when the temperature fell in one night 4.8° F., and on the second day following when getting out of bed, the patient felt a sharp tingling pain through the buttocks, perineum, scrotum, tip of the penis, and down the back of both thighs to somewhat above the knee. Some slight smarting was felt in urination. Toward the afternoon the pain began to lessen, but became worse again following a Turkish and Russian bath. The cutaneous pains became violent; the urination scalding. The bladder became paretic; the urine had to be forced into the urethra. For four days the temperature was from 100° in the morning to 102° or 103° in the afternoon, the neuralgic symptoms still existing.

The second case was that of a female, aged thirty-five, seen in consultation with Dr. Burge, September 6th. During the past two years the patient had had a good deal of sciatica, otherwise had had good health. In December last she was suddenly attacked with sharp pain in the buttocks, perineum, labia, and down the back part of the thighs to the knee. There was simultaneous retention of urine, requiring the catheter. Several weeks later, Dr. Burge saw the patient, and found tactile anæsthesia of the buttock, perineum, labia, and the back part of the thighs to just above the

knee. Dr. Gray saw the patient nine months after the onset of the trouble. She then had vesical anæsthesia, and voided urine without her knowledge. Over the area just mentioned, except the labia, which he was not allowed to examine, he found impairment of the tactile, temperature, and pain senses, but slightly less marked near the knee than above. There had never been any motor impairment.

These cases had a clinical interest, because a knowledge that such a neuralgia might occur would make us chary about diagnosticating a central affection, as we might well be inclined in the early stage, especially when there was vesical, motor, or sensory paralysis.

Dr. Rudisch asked whether an examination had been made for prostatitis, which caused symptoms in a degree like those described.

Dr. Gray said the area of distribution of the pain was not like that in prostatitis; besides, the second case occurred in a female.

Dr. W. H. Thomson referred to the case of a woman from the country, a locality said by her physician to be free from malaria. After a prolonged convalescence from an attack of pleurisy, she began to suffer severe pain in the anterior part of the left thigh, and from slight trouble with the bladder; the pains coming on certain days of the week, lasting one day and two nights. This continued five months, when she was free until the following fall. The medicine prescribed by Dr. Thomson had not prevented a return of the singular symptoms again the present fall. There was no indication of sciatica.

ON THE USES OF HYOSCYAMINE.

The President stated that there are two preparations of the drug, the crystalline and the amorphous. The former seems to be similar in property to the opiates, while the latter seems to have neurotic properties. He had heard that hyoscyamine was employed in the asylumns for the insane in New York, but not very successfully, whereas in the asylums of Pennsylvania its success had been marked. He had employed hyoscyamine in paralysis agitans, in chorea, and in a few cases as a hypnotic, and it had been employed as a hypnotic to a considerable extent in his service at the Bellevue Hospital. The number of cases of chorea in which he had used it was six; in three it was noted to have been of benefit, or caused very rapid or very marked improvement. One of the cases was marked, and had not yielded to other treatment. In three cases the results were doubtful. He had employed it in four cases of paralysis agitans; in two, he thought, with unquestionable benefit. In two it seemed to produce no benefit. On the whole, he thought that unless given at rather an early stage of paralysis agitans it did no good. The form employed in chorea and paralysis agitans was the crystalline, but he was not sure that the amorphous form would not be the better preparation in such cases. He thought we could get along perhaps as well without as with hyoscyamine.

Dr. B. Sach's experience with hyoscyamine had not been very extensive, but he had employed it in a few cases of paralysis agitans, acute mania, and the insomnia accompanying the neurasthenic condition. He had employed only the crystalline form. In contradistinction to what the President had said, that it was best to give it in the early stage of paralysis agitans, he remembered one case in which every other therapeutic agent had been tried without success, when hyoscyamine was administered in about one one-hundredth of a grain doses twice a day, with the effect of making the patient very much more comfortable, and of diminishing somewhat the annoying movements of the hand. In another chronic case it had been of no benefit. He had obtained no effect from the drug administered to allay the excitement of acute mania. It had also been disappointing in insomnia accompanying neurasthenia. It seemed to be of more value against insomnia from mental restlessness.

Dr. W. M. Lebzynsky said that about eight years ago it was quite fashionable to use hyoscyamine in asylum practice, and he had employed it in chronic mania, acute mania, and epileptic forms of insanity. First he used the amorphous, and later sulphate of hyoscyamine. It was claimed that the latter form was easier absorbed, and produced its effects in smaller doses. The sulphate was also preferred for hypodermatic use, in which manner he had employed it in one-sixtieth of a grain doses. To patients with recurring attacks of maniacal symptoms the drug was given a few days before an expected attack and continued until the attack was aborted.

In a state of exhaustion he would regard hyoscyamine as a dangerous drug to administer, but where there was no objection to its use on that ground he had known it to produce sleep where chloral and morphine had failed. Given to patients subject to epileptiform convulsions before menstruation it seemed to avert the attack. He had given it in small doses in two or three cases of chorea, and thought it produced some benefit.

Dr. L. C. Gray had been using hyoscyamine ever since it had been introduced to the profession, and he must say that for certain purposes there was no drug in the *Pharmacopœia* that he could not better afford to dispense with. The most convenient form was in tablets, each containing one one-hundredth of a grain. In some people hyoscyamine produces serious retention of urine. It might also produce serious results if given to persons whose general strength was below par. In an old gentleman with atheromatous arteries, hypertrophied and feeble heart, one one-hundredth of a grain of hyoscyamine caused a condition of collapse. He knew of one patient suffering from melancholia who was sent to Greenwood by hyoscyamine. He had given it in two cases of chorea, one being an exceedingly violent case, the child finally dying in a convulsion. To that patient he could never give a second dose of hyoscyamine because of the alarming prostration which a first dose would cause. In another case, in which the child had to be held in bed, the drug proved an effective means of restraint, but the child was always found prostrated to a marked degree the next day. In paralysis agitans it had been very useful, and came to be with him a routine treatment. He thought the reason why it had been of more benefit in his practice was that he combined with it some stimulant or tonic to prevent its depressing effect. He gave with it good food, one or two grains of quinine a day, sometimes alcoholic stimulants. He had satisfied himself that it was the hyoscyamine in this treatment that had a restraining effect upon the movements in paralysis agitans.

But it was especially in cases of mental trouble that hyoscyamine was of great benefit. In insanity with symptoms of hallucination, especially in the early stage before the patient could be taken to an asylum, hyoscyamine would do much toward restraining a patient, and, it would seem, aided in cutting short the disease. He was very careful to give no more of the drug than was absolutely necessary, and he combined it with bromide of potassium, which increased its effect. He had never seen hypnotic effect from hyoscyamine.

Dr. W. H. Thomson said that his experience with hyoscyamine almost from the beginning rather prejudiced him against it. One of the first cases in which he employed it was that of a judge troubled with insomnia. The next day he was unable to hold court, had bladder symptoms, etc. He found it useful in asthma with considerable dilatation of the right side of the heart, without bronchitis, but a congested state of the lungs. He had employed it in facial neuralgia, headaches, and various neurasthenic conditions, but had nothing definite to say about its effects. One patient with paralysis agitans was benefited by it among many with whom it was a failure.

Dr. Kellogg had used hyoscyamine in cases of mental excitement. It had not proven the sedative he had supposed it would, but it controlled the muscular excitement. He had failed to get any hypnotic effect from it. He had not been favorably impressed with its after-effects in acute mania.

Dr. H. S. Hinkley had found it serviceable in allaying maniacal excitement. Dr. Waitzfelde, of the Pennsylvania Hospital for the Insane, had used bromide of hyoscyamine, and spoke very highly of it.

Dr. Richards had given five to seven drops of a one per cent. solution in several cases of insomnia without effect.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, October 18, 1886.

The President, Charles A. Leale, M.D., in the Chair.

The President, Dr. Leale, on opening the meeting, made the following remarks:

Our season for professional activity has returned, and the stern realities are before us of busy metropolitan lives. We may congratulate ourselves that much has been done, but must confess that very much has been left undone, and that even the younger generation is quickly passing away. Let us, therefore, fully equip ourselves for our coming duties, ever with the remembrance that we are in the midst of the most vigorous age of the world's history.

Since we last met, one of our most prominent and beloved associates has departed full of glory, after a life of ceaseless toil and beneficence. I refer to Dr. Frank Hastings Hamilton, who so recently addressed us with his usual eloquence. Although severed from us in body he has given us, in his spirit, a most brilliant example worthy of our highest emulation.

THE DEATH OF DR. FRANK H. HAMILTON.

Dr. John Shrady offered the following resolutions, which were unanimously adopted.

Whereas, It has pleased the Almighty Disposer of Events to remove from the sphere of his usefulness our much respected co-worker, Frank Hastings Hamilton, M.D., LL.D., and

Whereas, The New York County Medical Association desires to express a sense of its bereavement, in common with the many organizations with which he was connected, therefore be it

Resolved, That the fulness of his days has been a record of a well-spent life; and that his work has adorned the surgical annals of America, borne his name beyond the borders of a hemisphere, and added to the solid contributions of medical literature.

Resolved, That as a scholar in his chosen science he has won a place among the worthies of all tongues; and that he has conscientiously weighed all his statements, and given to the world the results of a ripe experience and a most painstaking discrimination.

Resolved, That his professional life has been gauged by the strictest regard for the right—that his loyalty, ever unimpeached, was never expended upon the unworthy, nor his unswerving rectitude ever been challenged even by the captious multitude.

Resolved, That the memory of his many virtues will ever linger with us, and that we tender to his family our sympathies; assuring them that his humanity, his sterling merit, and his valued counsels have not been unappreciated by those who had the honor of association with him.

Dr. Frederic S. Dennis read a paper on

SOME POINTS OF SPECIAL INTEREST IN THE TREATMENT OF COMPOUND FRACTURES, INCLUDING A REPORT OF OVER FIVE HUNDRED CONSECUTIVE CASES,

which will appear in full in The Medical News.

Dr. J. W. S. Gouley said that he did not believe there was a surgeon present who would not most heartily endorse all that had been said. He would, however, say a word in regard to one or two of the points referred to. First, in regard to meningeal hemorrhage, he was fully in accord with the author of the paper as to the propriety of performing explorative trephination. The idea was not new, but it was sound. Whenever there was a doubt as to the existence of such hemorrhage, the patient should have the benefit of this doubt; and he would, like Dr. Dennis, remove a sufficient quantity of bone to enable him to reach the wounded artery and secure it. It was a much better plan, he believed, than to perform the graver operation of tying the carotid artery.

As to malignant disease, he had observed not a few such cases. One in particular which now occurred to him was a sarcoma of the instep, which resulted from injury to the bones of the tarsus. He performed amputation at the ankle-joint, and the patient made a good recovery. Excision of portions of the long bones he had performed with much success for a long time. In one case he removed six inches of the tibia, and reproduction of the bone followed. In the case of a soldier during the late war, who received a gunshot injury of the tibia and fibula, he removed four inches of bone, and put on a plaster-of-Paris dressing. In regard to plaster of Paris, he claimed to have introduced it into the United States, having first applied it during the early part of the war (in the spring of 1861). He had recently heard of the soldier referred to, through a pension examining officer,

and learned that he was alive and well. In these cases he made it a point to remove all the damaged portions of bone.

Dr. F. Van Vleet made some

REMARKS ON ABSCESS OF THE BRAIN, WITH ILLUSTRATIVE CASE.

The patient was a child who had for some time been affected with otitis media (for which no treatment was employed), and was attacked with measles in August last. The otitis attracted no attention until the measles developed, when it became greatly aggravated; the discharge being very profuse and very foul. The child made a good recovery from the measles, but the discharge from the ear still continued. It appeared to be in quite good health until the 22d of September, when it complained of pain in the ear at night, and became fretful. There was some vomiting, and then it suddenly died. At the autopsy the auditory canal was found full of fetid and greenish pus. All the organs were normal, except the brain. In the dura mater there was a circumscribed area, which was thickened and covered with exudation; while in the left hemisphere of the cerebellum there was an abscess containing about one ounce of pus.

The point of interest in this case is, that if the ear-trouble had been properly attended to in the beginning, the abscess would probably not have developed, and the child's life would not have thus been needlessly sacrificed. (The specimen was presented.)

CYSTIC TUMOR OF THE LABIUM MAJUS.

Dr. Gouley exhibited a cystic tumor which, he said, he had recently removed from the left labium majus of a woman about thirty years of age. It had been about fifteen years since she first noticed its appearance, though for a long time it remained quite small. Once it was punctured, and once or twice it opened spontaneously, discharging a brownish fluid. Only lately it had so increased in size as to distend the whole labium. It had the characters of what is known as hydrocele of the labium majus, and contained dark mucoid fluid, which led him to infer that there had been hemorrhage into it. The mucous surface presented a trabecular appearance, and he believed that the tumor was an enlarged and dropsical vulvo-vaginal gland; an opinion in which Professor Isaac E. Taylor coincided. It was pyriform in shape, and the lower part extended for a considerable distance underneath the ramus of the ischium. In its extraction he had to divide several branches of the pubic artery, and in consequence of this he decided not to close the wound, as he had at first intended, but to leave it open and allow it to heal by granulation. The operation was a somewhat tedious and difficult one, but the patient did perfectly well afterward.

Dr. A. P. Dudley said that he had met with a number of such cases at the Woman's Hospital. In many there was suppuration, although there was no history of gonorrhœa. In a great many cases, however, there was a history of vulvar inflammation, and gonorrhœa was frequently the cause of the trouble. If any portion of the sac were allowed to remain, it generally filled up again in case the wound were sewed up; and he believed it was, therefore, better to allow the wound to heal by granulation, as Dr. Gouley had done. In one case which he had treated, the cyst filled up three times, as a result of excessive sexual intercourse. In this instance the duct was stopped up; but in most cases the duct presented an irritated appearance.

Dr. Gouley said that in his case the entire cyst was carefully dissected out. There was nothing left, so that any refilling was out of the question. He prided himself on the fact that his knife never once entered the cyst, until after it had burst spontaneously from the pressure upon it. Then he laid it widely open.

Dr. Dudley said he would heartily congratulate Dr. Gouly on the success of his operation.

NEW YORK STATE MEDICAL ASSOCIATION.

Fifth District Branch.

Second Annual Meeting, held at Brooklyn, October 12, 1886.

Morning Session.

After the transaction of some preliminary business,

THE PRESIDENT'S ADDRESS

was delivered by Dr. J. G. Porteous, of Poughkeepsie. In it he congratulated the branch and the parent Association on the flourishing condition of the organization, and paid a tribute to the illustrious dead of the year, Drs. Austin Flint, Frank H. Hamilton, and Desault Guernsey, the latter being President of the Fifth District Branch at the time of his decease.

Dr. Joseph C. Hutchison, of Brooklyn, then read a *Biographical Notice of the late Frank H. Hamilton, M.D., LL.D.*

Dr. Avery Seguin, of Brooklyn, read a paper on *Some Recent Impressions of Medicine in England.*

Afternoon Session.

Dr. H. A. Pooler, of Goshen, Orange County, read a paper on

THE MILK SUPPLY OF LARGE CITIES, AND THE IMPROPER MODE IN WHICH IT IS CONDUCTED.

Having spoken at considerable length of good cows' milk, and in what respects it resembles and differs from human milk, he referred to the abnormal conditions of milk. There is only one period, he said, at which a healthy cow will secrete unwholesome milk, and that is after parturition, when it contains colostrum. Such milk taken by the young or by invalids may produce very harmful results. It is certain that the milk will not be entirely free from colostrum corpuscles ten days after the birth of the calf, but the farmer, not knowing the pathological condition of the milk at such a period, or at least, the length of time that it is affected, usually saves the sixth milking, which occurs only three days after parturition. The milk of the entire dairy may thus be contaminated by the diffusion of the colostrum through it.

In speaking of the adulterations of milk, he said that many foreign substances have been added to it, but by far the most common forms of adulteration are the removal of fat and dilution with water. Pure milk furnishes an indication of the amount of fat required by the human being in the large proportion of butter to

the other solid ingredients which it contains. Besides performing certain purely mechanical offices, fat is essentially concerned in many of the chemical and vital processes of the body. As a heat producer fat stands preëminent, and it is mainly from the fat stored up in the body that sustenance is derived when the supply of food is temporarily cut off or the power of digestion is impaired by sickness. Furthermore, it is believed that nature has especially adapted butter fat to the digestion of infants. Altogether, therefore, it is essential in large quantities to the proper nutrition of young children.

Dr. Pooler then quoted from the report by Dr. C. F. Chandler (made with the assistance of C. E. Munsell, Ph.B.), published in the Second Annual Report of the New York State Board of Health (1881, 1882), as follows: "While a large proportion of the milk sold has been but moderately watered and skimmed, and is still above the standard of the poorest milk (two and a half per cent. of fat), much of the milk has been *extended* and skimmed far below this standard. So openly are these frauds practised that 'creameries' have been established in many localities, the names and locations of seventy-three such establishments being known to the writer; of which sixty-three are known to send skimmed milk to New York City, all of which is sold as whole milk on its arrival."

Later reports of C. E. Munsell, Ph.B., showed, from analysis, that this skimming amounted to from about twenty-nine to seventy-eight per cent. of the fat. Now, it can readily be seen that the mother receives this milk into her home as whole, pure milk, and dilutes it one-half to three-fourths. What then does the child have to live upon, when nature says that infants must have 3.38 per cent. of milk fat for their sustenance and development?

Up to 1883 there was no law in the State prohibiting the shipping and sale of skimmed milk; but the passage of such a law was then secured, and milk inspectors were placed upon the milk trains. Dr. Pooler told the Judiciary Committee of the Legislature that if they would pass the law, he would guarantee to reduce the death-rate of young children in the city of New York at least three thousand, and he was able to keep his promise. In 1879 the mortality in children under five years, was 12,777, or about fifty per cent. of the births of that year. This was before the milk adulterators carried on their work so extensively as afterward. In 1880, however, the mortality in this class increased to 14,650, and while from 1878 to 1879 it increased only 300, the increase in the number of deaths from 1879 to 1880 was 2000. The mortality in 1881 was 17,737, an increase of 3000 over 1880, and about seventy-five per cent. of the births. In 1882 the number of deaths was about the same as in 1881; but if it had not been for the work that was done in the autumn of 1882 the mortality would have reached nearly 20,000; a close watch being then kept on the dealers. In the winter of 1882 and 1883 the skimmed-milk bill was passed and enforced, and, notwithstanding many discouraging circumstances, the mortality was reduced from 17,737 in 1881, and 17,520 in 1882, to 13,856 in 1883, a reduction of some 4000.

But, unfortunately, in 1884 the good work was interfered with by the politicians. Up to that time the labor performed had been almost all voluntary services. An appropriation was, therefore, asked from the Legislature; but while this was granted, a Dairy Commission was also appointed to take charge of it, and this commission was manipulated so as to form a part of the great party "machine." There were other political changes also, and the withdrawal of Professor Chandler from the head of the Metropolitan Health Department was an irreparable loss. Hence the mortality in children under five years increased from 13,865 in 1883, to 15,272 in 1884, an increase of nearly 2000. Dr. Edson, of New York, and Dr. Bartley, of Brooklyn, had, however, done all in their power, with the means at their command, to keep the evil in check, though the small force available for this service was quite inadequate to the demands upon them.

Dr. Pooler spoke next of the adulteration of milk through the cow, by feed and otherwise. The refuse of about nine thousand distilleries, breweries, and malt-houses, in this country, is nearly all sold to feed the cows that produce the milk upon which the infantile portion of the population principally subsist. The natural food of the cow is grass, either green or dried, and when she is fed exclusively upon it, her fresh milk is generally neutral in reaction. On the contrary, the milk of cows fed either wholly or in part upon food other than the natural, is almost invariably acid. Dr. Mayer, of Berlin, found the following results: "Of cows fed with brewers' grains, red potatoes, rye, bran, and wild hay, in five instances the milk was slightly sour, in one very sour.

"Of forty cows fed with potato mash, barley husks, and clover, and barley straw, in ten examined the milk was sour, in three very sour.

"From five cows fed by a cow-feeder on lukewarm bran mash and hay, in four the fresh milk was quite neutral; in one it was decidedly alkaline."

All physicians know how easily affected infants are by acid milk, and Dr. J. Lewis Smith, in his work on diseases of children, says that milk used for children should always be alkaline. If it is acid, as shown by the proper test, it should be rejected. Dr. Hassal, in his standard work on food and its adulterations, says: "As is well known, a very considerable number of the cows which supply London with milk are kept in various confined and unhealthy places in the metropolis. Such cows are seldom turned out to grass; the system adopted being altogether unnatural and artificial. Brewers' grains and distillers' mash form much of their food. These stimulate the animals unnaturally, and under this stimulus large quantities of milk of inferior quality are secreted. The cow quickly becomes worn out and diseased in consequence."

It has been shown also, by experiment, that brewers' grains afford a most favorable soil for the development of the microbe of anthrax, and in 1879 an attack of this disease occurred in England, in a district which had been previously free from it, where it was found upon investigation, that all of the cattle infected had been fed upon grains from one particular brewery. That disease may be transmitted from the lower animals to man, is an undoubted fact; and hence it is of special importance that the cow should be kept in a healthy condition.

The facts show that the action of brewers' grains is to impoverish the milk in its most essential constituents, and largely increase its most objectionable ingredient,

casein. When the fat is not equal to the normal amount, the milk forms a hard curd in its coagulation, which is known to the skimmed-milk cheese-makers as "hickory curd;" the formation of this being directly due to the abstraction of fat. It is the cheapness of the brewers' grains, together with the large amount of milk which the cows give when fed upon them, that induces farmers to purchase this food. The proper food, wheat middlings, or wheat bran, costs twenty dollars a ton, and will yield less milk, though of far better quality, than a ton of brewers' grain, which costs only from four to six dollars.

Dr. Pooler also spoke of the evils resulting from the transportation of milk from long distances.

Dr. Alfred Ludlow Carroll, of New Brighton, Staten Island, read a paper on

LEPTO-MENINGITIS INFANTUM.

The clinical history and pathology of acute hydrocephalus, he said, are involved in considerable obscurity; the symptomatology varying, on the one hand, in cases having a similar morbid origin, or, on the other hand, closely corresponding in instances due to different kinds of lesion. It seems to be the general opinion that recovery from a meningeal attack in childhood precludes the idea of tubercular deposit; but whether non-natal forms of acute hydrocephalus (not secondary to disease elsewhere) are always dependent on inflammation of the pia, or whether there may be other less serious pathogenetic factors, is a question still open to discussion.

Huguenin, in Ziemssen's *Encyclopædia*, affirms that cerebral hyperæmia is the exciting cause in all instances save those occurring in marasmic conditions supervening upon chronic digestive disorders; and in these, forced to admit an anæmic state of the brain, he assumes "partly a hydrocephalus *ex vacuo*, in consequence of the diminution of the brain, partly the result of the long-continued weakness of the heart's action and slowness of the circulation, with greater emptiness of the arteries than of the veins." In the former class of cases he reiterates that we are forced to assume a true inflammatory process as the cause of the effusion into the ventricles, but at the same time states that it is impossible to say, during life, when the hyperæmia ceases and the inflammation begins. But in his description of the pathological anatomy, it is admitted that the pia "contains a moderate amount of blood, or is anæmic; no traces of arterial hyperæmia can be found. We are forced to assume that it disappeared at the moment of death."

J. Lewis Smith, describing tubercular and spinal meningitis conjointly, speaks of the "inflammatory action" as usually confined to the pia mater, and includes purulent meningitis of the convexity, apparently, as a more intense form; adding that serous distention of the lateral ventricles is a common result in either variety of the disease. Vogel, on the contrary, asserts that acute hydrocephalus never occurs in combination with simple meningitis, but invariably supervenes upon tuberculous meningitis.

Other authors either deny a non-tubercular origin of acute hydrops of the ventricles, or, at all events, ignore the affection which Huguenin endeavors to differentiate; an affection of which well-defined examples are not infrequently encountered, but wherein we are asked to "assume" an ante-mortem hyperæmia which suddenly changes to a post-mortem anæmia, and an inflammatory process which does not leave behind it the ordinary traces of inflammation. As regards the first of these assumed phenomena, all pathological investigations go to show that we are much more likely to be misled by a post-mortem fulness of the intracranial vessels where previous anæmia has existed than to fall into the opposite error.

On the other hand, although the mere so-called determination of blood, caused by local irritation, may speedily pass away, the evidences of inflammation are usually regarded as persistent and unmistakable after death. And these evidences lie, not in simple fulness of the larger vessels, but in the crowding of the smaller ramifications with coherent corpuscles, even in an early stage of the inflammatory process; whilst in a more advanced condition exudation products are discoverable. In inflammation of the pia of undoubted character, this membrane is lacerated and infiltrated; the arachnoid thickened and opaque; fibrinous exudation being marked. In the disease described by Huguenin there is no effusion between the dura and pia, nor in the meshes of the latter, the outer surface of which, he says, is usually remarkably dry; there is exudation at the base; the ependyma of the ventricles show no change, macroscopic or microscopic. The only significant morbid appearance is a turgescence of the choroid plexuses, sometimes with punctiform extravasations. In brief, we have to deal with a disorder of which the pathological features are, more or less rapid accumulation of fluid in the ventricles, with a specified morbid condition of the choroid plexuses; its clinical manifestations (by no means uniform) being convulsions, unconsciousness, paralytic symptoms, and disturbances in the tract of the pneumogastric and splanchnic nerves.

The known causes of serous effusions are usually found in anæmic conditions, or in mechanical impediment to the return of venous blood. Within the cranium such stagnation is especially likely to concur with arterial anæmia, since, even allowing for the balance ordinarily maintained by the ebb and flow of the cerebro-spinal fluid, atmospheric pressure tends to retard the egress of venous blood. It has long been known that in animals bled to death the intracranial vessels may retain their contents after all the rest of the system is drained. Meningeal venous turgescence of this kind, "ex vacuo," is familiar as arising from atrophy of the brain, and in other conditions associated with arterial anæmia. Furthermore, the pia gradually diminished in vascularity from the convexity toward the base, until, at the crura and pons, it is almost devoid of vessels. Finally, we have the authority of Nothnagel for doubting whether active hyperæmias can limit themselves to circumscribed regions of the brain; whilst localized ischæmia about the nasal ganglia is a more probable event, originating in arterial spasm, reflected irritation, or insufficient cardiac action.

Having devoted considerable time to the phenomena and mechanism of effusion into the ventricles, Dr. Carroll went on to say that, as to the clinical aspects of acute hydrocephalus, it is well known that convulsions are oftener due to cerebral anæmia, rapidly induced, than to any mechanical alterations of pressure upon the brain. Epilepsy is commonly conceded to be of anæmic origin, and Moxon has observed that in this disease the

convulsive seizure is often preceded by a momentary arrest of the pulse. Niemeyer affirms that the so-called symptoms of pressure in apoplexy, tumors, the various forms of hydrocephalus, and other diseases encroaching on the intracranial space, are not immediately referable to the pressure on the brain-substance, but to the consequent anæmia; and he further points out the false interpretation usually given to increased pulsation of the carotids, which he defines as an essential consequence of cerebral anæmia.

Another common mistake is to regard the vascular appearance of the external surface of the head and face as indicative of the intracranial condition. In states of general anæmia, facial pallor and cerebral anæmia are twin results of the same cause; but when the blood is pumped up toward the head in due amount, a localized ischæmia within the skull is apt to direct an increased flow into the external carotid and those branches of the internal carotid which arise before its entrance into the cranial cavity.

It is extremely difficult to discriminate during life between idiopathic lepto-meningitis, as it may be called, and other meningeal affections of childhood. In early infancy and after exhausting diseases, the secondary "hydrocephalus ex-vacuo" is to be considered rather as a mode of dying from other complaints, and the past history of the case (afterward one of protracted diarrhœa) will afford a clew to its nature. True meningitis, commonly affecting the lateral part of the convexity, arises by traumatism, or extension from adjacent foci, as in internal otitis, caries of the cranial bones, mastoid inflammation, phlebitis sinuum, etc., and although in most examples its diagnosis may be made with some confidence, it is well to know that not a few cases occur in which the symptoms simulate those of acute hydrocephalus.

Having briefly referred to his extensive post-mortem experience, which, he said, had induced him to believe that tubercular meningitis seldom, if ever, occurs except as a part of a more generalized deposit. Dr. Carroll summed up his argument by saying that he was convinced that a malady quite frequently occurring in childhood, and often erroneously reported as tubercular meningitis, characterized by serous distention of the ventricles, and variously described under the names of "simple meningitis," "lepto-meningitis," and "acute hydrocephalus," but by most writers ascribed to hyperæmia and inflammation, is, on the contrary, essentially due to cerebral anæmia; that the principal and most significant morbid factor is a varicosity of the choroid plexuses, sometimes extending to the plexuses of the fourth ventricle, and aggravating the arterial anæmia which gave it birth.

In conclusion, he submitted a microscopic preparation exhibiting the condition of venous and capillary stasis met with in these cases.

NEWS ITEMS.

TORONTO.

(From an Occasional Correspondent.)

The American Public Health Association.—The fourteenth meeting of the American Public Health Association, which was this year, for the first time, held outside of the United States, was one of the most successful in the history of the Association. For the past three years several Canadian medical officers have taken active interest in it, and have given valuable co-operation. It was in response to most urgent solicitation that the body met in Toronto from October 4th to 8th.

The work outlined was carried forward in a business way, and many valuable papers and discussions were presented. There was less of speculation and generalization than usual, and more of experience, not only telling what ought to be done but how to do it. The President, Dr. Henry P. Walcott, of Boston, had for his subject, "The Claims of Preventive Medicine and the Expectations we were Justified in Entertaining as to its Future." His first words were those of caution. He adduced the cessation of the plague, not only in England but throughout Europe, as an illustration of the fact that we cannot always attribute all the good things that happen to this or that sanitary measure. There is enough to do, he said, in the directions where both science and experience have arrived at some definite conclusions, but advance in any quarter must necessarily be slow, made under the guidance of systematic experiments and observations controlled by scientific methods, and not in the pursuit of the speculations of theorizers. The principal object of scientific inquiry in preventive medicine during the past year has been, he said, as in the preceding year, the study of the infectious diseases and the microörganisms associated with them. He went on to review what has been done and what is being done in the study of such diseases as cholera, smallpox, yellow fever, scarlet fever, rabies, and trichinosis. All these were of too much importance to be neglected by the guardians of the public health. To meet the present needs of sanitary science, the President advocated the undertaking by the general Government of scientific investigations of diseases which are so general in their distribution that the whole country is affected by them, or of such a character that the satisfactory inquiry into them would involve expenditures too great for the meagre appropriations of State and local boards of health. Some of the investigations carried on under the direction of the National Board of Health of the United States were of the highest scientific merit, and had an acknowledged authority everywhere. The public burden from the victims of the misuse of alcohol is becoming each day greater and more intolerable.

A portion of a day was devoted to papers and discussions as to the sewage problem for Toronto. Its chief general value consisted in the facts brought out as to the need of a close study of currents, eddies, and all shore changes when seeking an outfall for a sewer, and especially if somewhere from the same body of water the city water-supply is derived. The opinions of such engineers as McAlpin, Galbreath, Waring, and Jordan were drawn out, and the debate was engaged in by physicians, by the Mayor, and by some citizens.

A paper on "The Destruction of Night Soil and Garbage by Fire," and another on "Sanitation in Street Paving," as presented by Dr. Reeve for Dr. Baird, of Wheeling, were of great interest because they gave definite plans and details as to both, illustrated their practical operation by examples, and showed the economy of the

methods. So much interest was elicited that it is probable that several city officers will visit Wheeling to see the workings of the process. The following brief abstract will give some idea of the plan, which embraces the use of a Smith gas furnace for the heating of steel slabs preparatory to being rolled into nail plate. This furnace is much larger than the boiling furnace, and capable of generating a more intense heat than any furnace known. The result was as follows: A barrel of ordinary garbage or slop was burned in four minutes, a barrel of butchers' offal (bones and animal matter) was burned in seven minutes, a barrel of fluid night-soil, thrown into the furnace with buckets, was almost instantly evaporated, and a barrel of solid feces was burned in fifteen minutes.

The solid and impervious pavement was described with equal interest and detail.

Much interest centred about the discussion of the best methods of internotification of disease, as well as in the illustration by examples of its indispensable importance. On the one hand, our Canadian brethern had much to tell us as to their experience in quarantine and with smallpox, while Dr. Holt, of New Orleans, fresh from the contest with the Biloxi authorities, showed that the days of repression and concealment of facts have passed, and that the public health and the check of epidemics depends upon that *confidence* which will lead each board to give full and early notice to all adjacent boards as to cases of yellow fever, cholera, typhus, or other threatened invasion. Several city officers took part in the discussion. It was shown that mercantile and commercial interests cannot be ultimately injured if health authorities are manly and courageous, and deal promptly with the facts under proper sanitary regulation. This is well illustrated by the fact that the entire tendency of good administration is to shorten time of quarantine whether at sea or on land.

No less interesting were the details given by Dr. Thornton, the Health Officer of Memphis, and Col. Haddon, its Mayor, as to "Six Years' Sanitary Work in Memphis." Facts were detailed in a lucid way, tested statistics and death-rates were presented, the errors of their sewer system, its corrections and its value fairly exhibited. There can be no doubt that Memphis can be pointed to as a city which owes its present prosperity chiefly to the vigorous activity of its citizens in sanitary construction and administration.

The paper of Dr. Bell, of New York, on "The Disinfection of Rags," accumulated all possible references which would go to show that either rags or clothing had caused the spread of communicable diseases. It was soon evident that a gauntlet had been thrown down, and health officers from Boston, New York, New Orleans, etc., were on their feet, and efforts were made to suppress the report on the ground that it was partisan in its character. Boston officers denounced the plea for disinfection of foreign rags as special, and denied that any case of infection from rags could be cited from Massachusetts, which alone received one-third of all the rags imported. The debate lasted until after midnight, and while not settling a vexed question, it will put on record many important facts and statements.

The report of the Committee on Disinfectants dealt chiefly with the best apparatus for the use of steam in disinfection. It still inclines to this, nothwithstanding the graphic delineation of the quarantine use of corrosive sublimate by Dr. Holt. It seemed a little odd to some northern health officers that the enormous and novel use of this agent in ship disinfection was emphasized, when at Boston, for instance, it had been used extensively before it was thought of in New Orleans.

In the line of microörganisms, the only important paper was that of Dr. Salmon, of Washington, who, in a paper on "Recent Progress in the Investigation of Hog Cholera," gave the details of many interesting experiments going to determine the specific character of the microphyte of this disease. He also seems to have shown that when the culture fluid of this microbe is subjected to sufficient heat to destroy it, the remaining fluid can be used as a prophylactic and protects against the disease.

A paper on "The Best Methods and Apparatus for Teaching Hygiene in the Public Schools," by Dr. Yeomans, of Ontario, insisted upon specific instruction in hygiene as a part of school discipline, and as distinct from physiology and anatomy. He showed the value of experiments in physics bearing on the subject, and gave many valuable hints.

The Association was favored with the presence of Dr. Russell, the able Health Officer of Glasgow. He read a paper prepared as a result of his attendance. He began by saying that the country districts of Scotland are as benighted about sanitation as are those parts of America. For its eight cities he claimed some valuable advances. There are none of the political complications we have here. He criticised our tendency to be satisfied with a death-rate no larger than that of older countries, and suggested that even a death-rate of fifteen per thousand should not satisfy us in such a country as this, and especially if typhoid fever, diphtheria, scarlet fever, etc., made up much of the record. In his terse and ready style, with precision of statement, he occupied the attention of the Association for a half-hour, and was voted the honor of being its first foreign honorary member.

In a paper on "The Significance of the Decomposition of Albuminoid Substances," Dr. Bryce made the point that we should not judge of the fact or condition of nuisances by odor, but should base our opinion and decision upon their bacterial manifestations.

A valuable paper on "Alcohol" was furnished by Prof. S. E. Chaillé. In view of the absence of its author, and the pressure for time it was read only by title. Our examination of it, however, satisfies us that it will be a very valuable addition to the literature of the subject. It disputes some ordinary conclusions as to the abuse of alcohol being on the increase, and shows that intelligence is confining it more to classes. It takes very strong sanitary grounds, however, against the present system of licensing, and declares that local option is both a social and sanitary necessity.

Other papers of importance might be referred to, but what we have already said will show the type of the meeting, its great value, and its sensible advance. Surgeon Sternberg, U.S.A., was elected President for the ensuing year, and the other offices were worthily filled. The twelfth volume of reports and papers when published will be a very valuable addition to the excellent volumes which have preceded it.

Clinical Society of Maryland.—At a meeting of the Clinical Society of Maryland, held October 1st, the following officers were elected to serve for the ensuing year:

President.—Dr. Randolph Winslow.
Vice-President.—Dr. S. T. Earle.
Recording Secretary.—Dr. A. C. Abbott.
Corresponding Secretary.—Dr. W. J. Jones.
Treasurer.—Dr. R. W. Johnston.
Executive Committee.—Drs. J. W. Chambers, H. Harlan, and B. B. Browne.

The reports of officers and committees showed a very healthy condition of the Society, the treasury having an ample surplus for current expenses, and the membership of the Society having increased to 190 active members. The Society meets on the first and third Fridays of each month at 8.30 P.M., in the hall of the Medical and Chirurgical Faculty of Maryland, northwest corner of St. Paul and Saratoga Streets.

The Johns Hopkins Endowment.—*The Baltimore Sun*, of October 7th, publishes a statement of the financial resources of the Johns Hopkins University. For the year ending August 31, 1886, the income was $225,922.38. The total expenses for the year were $185,020.96; leaving a balance of $40,901.42. Among the receipts $17,804.12 were credited to tuition. Among the expenses $126,828.26 are charged to salaries. The University owns 15,057 shares of B. & O. Railroad stocks, valued at $2,195,400. The remainder of its endowment fund is invested in bonds, stocks, mortgages, real estate, buildings, apparatus, etc. The total endowment is $4,359,350.43. In addition the University owns the Clifton estate of 280 acres, which is valued at $2000 per acre, making the property of the University worth to-day about $5,000,000.

Hudson River State Hospital.—The managers of the Hudson River State Hospital, Poughkeepsie, N. Y., have established a training school for the instruction of those who wish to make a specialty of nursing the insane, either in private houses or public institutions.

Graduates of general hospital training schools will be admitted to the school for the period of one year. Upon passing a satisfactory examination at the close of the twelve months, they will receive diplomas bearing the seal of the hospital and the signatures of the President of the Board of Managers, the Medical Staff, and the Principal of the Training School. They will be paid at the rate of twenty dollars per month during the first six months, and twenty-five dollars per month for the second six months. For those who remain in the service of the hospital after the completion of this term, special rates of remuneration will be arranged.

Women, between the ages of twenty and thirty, who are not graduates of general hospital training schools, will be admitted to the school, and receive a course of instruction covering a period of two years. After a satisfactory examination at the conclusion of this course they will be granted certificates of graduation bearing similar signatures to the diplomas. They will receive from ten to seventeen dollars per month, rated according to proficiency and time and value of service. Special rates will be made for hospital service after graduation.

In connection with the hospital there is a training school for men who are between twenty and thirty years of age. The course of instruction covers two years, at the end of which certificates of graduation are bestowed upon evidence of competency. The men are paid at rates ranging from sixteen to twenty-two dollars per month, according to proficiency and time and value of service. Special rates are arranged with those who remain at the hospital after graduation.

All the pupils and nurses are allowed board, lodging, washing, and medical care if required, free of charge.

Sir Andrew Clarke declares that one-half of the population of London is permanently ill. His definition of health is: That state in which the body is not consciously present to us; that state in which work is easy, and duty not a great trial; the state in which it is a joy to see, to think, to feel, and to be.

Criterion of Good Standing in Illinois Medical Schools.—The following resolution has been adopted by the Illinois State Board of Health:

Whereas, The continuous graduation of forty-five per cent. of the total number of matriculates of a medical college—due allowance being made for the average annual loss—must be accepted as *prima facie* evidence that practically every candidate is graduated without regard to competency or qualification, therefore, be it

Resolved, That no medical college be recognized as in good standing within the meaning and intent of the Act to Regulate the Practice of Medicine in the State of Illinois, the aggregate graduates of which college amount to forty-five per cent. of its aggregate matriculates during the period of five years ending with any session subsequent to the session of 1885–86.

The Pasteur Institute.—The Paris Municipal Council, after a heated discussion, has voted to extend the concession of the site for the proposed Pasteur Institute, in Rue Vauquelin, from thirty to ninety-nine years.

Medical Societies in New York.—New York boasts of thirty-one different medical societies, all of which resume work during the present month. These societies meet monthly and semi-monthly. On an average there are seven or eight meetings every week in the city.

Excision of a Cerebral Tumor.—Another case of excision of a cerebral tumor has terminated successfully. The patient was a man who had been absolutely hemiplegic for a month, and had passed into a semi-comatose condition. Before these symptoms developed, he had endured terrible pain in the head, and had suffered from fits. On Thursday, September 23, Mr. Victor Horsley trephined over the motor region of the right hemisphere, and, after enlarging the aperture made by the trephine, succeeded in removing a large tumor from the brain; the tumor weighed four and a half ounces, was three inches long, two and a half inches broad, and two inches deep. On the day after the operation the patient was perfectly rational, and even amusing in his conversation, and said that he was quite free from pain. On September 27 the wound was entirely healed, and the man had recovered some power in his leg. This is

the fourth case in which Mr. Horsley has operated successfully on the motor area of the cortex of the brain; the three earlier cases were carefully described to the Section of Surgery at the meeting of the Association at Brighton, and the full text of his paper will be shortly published. His results constitute a real triumph for scientific surgery. Not only have the facts upon which the diagnosis of the seat of the lesion in these cases rests been discovered by experiments on lower animals, but the details of treatment have also been worked out in the course of these experiments. The complete success of the surgical method followed is demonstrated by the fact that, in two of the cases, the wound healed in four days; that, in a third, it had healed in a week; and that, in the case which was in this respect the least successful, the whole of the wound, with the exception of one-sixth, healed by first intention. A more complete proof of the validity of well-directed experiments on animals, it would be difficult to imagine; and it is no wonder that the professional agitators, who are beginning to find their supposed grounds of objection one by one swept away, pursue Mr. Horsley with a bitterness which increases as it becomes less reasonable.

A New Medical Society.—The physicians of Brownsville and Matamoras have organized a Medical Society, and elected Dr. C. Macmanus, President, Dr. M. Cicero, Vice-President, and Dr. Valls, Secretary.

Cremation in Germany.—Cremation, it would appear, is making great progress in Germany. There has recently been held at Gotha a "Diet" of delegates from the various cremation societies in Germany, as well as of several other countries, including Italy, Switzerland, Holland, and America, the last being represented by Mr. Storer Cobb, of Boston, who is at present lecturing in Germany on the disposal of the dead by fire. The Diet discussed and approved the statutes of a general association of societies for funeral reform and optional cremation, and this association was joined by the local societies of Berlin, Potsdam, Frankfort, Darmstadt, Liegnitz, Chemnitz, Heidelberg, Dresden, Leipsic, Hamburg, Vienna, etc. These societies have already their journalistic organs in the shape of two magazines, called *Gesundheit* and *Neue Flamme* (Health and New Flame). The delegates inspected the crematorium at work in the churchyard of Gotha, and they were assured by the burgomaster that the repugnance of many to this form of burial had been completely overcome by the sight of the decorous and befitting manner in which bodies are reduced to dust by the rapid action of fire, and then inurned.

Lead-eating Insects.—A French architectural journal recalls an observation made by Viollet-le-Duc, that lead plates for roofing and other purposes are often pierced by insects. He accused the wasps of being the authors of the little holes which he found gnawed in lead roofs, but later observers have discovered that both worms and flies often drill through heavy plates. Some twenty-five years ago it was found that the lead bullets of cartridges, which had been stored in wooden boxes, were badly gnawed, and a number of gall or saw flies were found in the act of working upon them. Why these little creatures should amuse themselves in digging out the tough metal with their jaws, it is hard to say. Both males and females were found at work; and the only suggestion which our Gallic contemporary can make is, that they were, perhaps, sharpening their teeth. The first notice of perforation made by worms seems to have been made by M. Janniard, formerly official architect in charge of churches and public buildings, who observed that the lead covering of the steps on the roof of an old house in Paris was bored through in several places. Only one of the steps was attacked; and, on looking closely, he found that every hole in the lead corresponded to a worm-hole in the oak planking on which it was laid.

NOTES AND QUERIES.

In memory of the late Professor S. D. Gross.

The flowers sometimes whose bloom is paling
Their fragrance still enfold,
And rarest fruit is often gathered
From tree and vine grown old.

'Twas so with him. Some hearts, though beating
The pulse of feeble years,
Are young in age, and often singing
Life's loves and songs through tears.

I knew him in that later ripening,
When russet hues turn white,
And saw the uprising fires of glory
That burned before the night.

. . . .

Fame stopped him at the gates of sunset,
And on his kingly brow
She gently bound her wreaths immortal.
He needs no praises now.

CHRONIC PURULENT OTORRHŒA; ITS NATURE AND TREATMENT.[1]

BY CHARLES H. BURNETT, A.M., M.D.,

PROFESSOR OF OTOLOGY IN THE PHILADELPHIA POLYCLINIC, ETC.

A CHRONIC purulent or mucopurulent discharge from the ear is usually the result of inflammation of the mucous membrane of the middle ear, and, as such, implies the existence of a perforation in the membrana tympani through which the purulent matter escapes into the external auditory canal, and from the meatus externus. The perforation in the membrana tympani is usually in the lower portion, posterior to or beneath the malleus, in that part of the membrane below a line drawn nearly horizontally through the short process of the hammer—*i. e.*, in the so-called membrana vibrans. In some rare, but very important, cases, the perforation is in the flaccid membrane, or the membrane of Shrapnell, which lies above the short process of the malleus. The latter may be the only perforation, or it may exist with one or more perforations in the lower portion, the so-called membrana vibrans, below the line of the short process of the hammer. Although there is no mucous membrane in the external auditory canal, a chronic purulent discharge, in some very rare instances, comes from the cutaneous walls of the canal, the membrana tympani remaining imperforate. These cases are so rare, however, as not to enter into the observation of any one who does not see a great deal of aural disease.

The rule is, that a chronic purulent discharge coming from the external auditory meatus emanates from the mucous membrane of the tympanic cavity, and indicates, therefore, a perforation in the membrana. A discharge from the ear deserves the name of chronic after a duration of two or three weeks. This form of aural disease is both common and important, is met by all practitioners of medicine, and demands, therefore, their careful attention, both on account of the annoyance its presence gives the patient, and the danger to hearing and life which lurks in its persistence in the middle ear.

Chronic purulent otorrhœa generally begins in childhood. Hence cases of this disease in adults are usually very chronic. The original course of otorrhœa is chiefly nasopharyngeal, and Eustachian tubal catarrh, induced by coryza, teething, and the acute exanthemata. Teething, by inducing a reflex irritation in the middle ear, leads practically to catarrhal inflammation of that cavity, perforation of the drum-membrane, and the establishment of a chronic running. Purulent inflammation of the middle ear is almost invariably preceded by pain, and often constitutes the cause of earache in children.

Among the causes producing purulent otorrhœa in adults, must be named swimming and diving in cold water, plunging the head under cold water, washing the head and allowing it to dry in a draught of air, and also the use of cold water in the nasal douche, and the inhalation of the various patent powders, snuffs, and fluid preparations advertised for the cure of nasal catarrh.

Tuberculosis of the lungs is also a cause of subacute and chronic purulent otorrhœa. This form is characterized by little or no pain, by its tendency to affect the posterior and upper parts of the drum-membrane and cavity, and by its resentfulness of all forms of treatment but the mildest. It is supposed to be due to reflex inhibition of vasomotor power in the arterioles of the ear, supplied by the carotids. The irritation which thus acts reflexly is in the diseased lung. The irritation, passing by the pneumogastric to the sympathetic system in the neck, inhibits influence over the carotids. Passive dilatation ensues in the vascular tract, and those parts of the membrana tympani and middle ear supplied by it undergo passive congestion and inflammation of a low form, without much or any pain, the purulent matter ruptures the membrana, and an otorrhœa, chronic from the outset, is established.

The tendency to chronicity in all aural discharges is favored by the difficulty of keeping the ear clean, and by the improper treatment so often instituted. The retention of matter in the fundus of the auditory canal favors decomposition of the pus, and further disease in the ear. The exposure, too, of the mucous lining of the drum-cavity to the atmosphere, by means of the perforation in the membrana, irritates the mucous membrane, and promotes further inflammation. It is to this fact that acute attacks of earache are due, in cases of chronic otorrhœa.

If chronic purulent discharge from the ear is associated with, and kept up by, chronic catarrh in the nasopharynx and the nares, the rhinitis must receive due attention, or the discharge will not, without great difficulty, be checked. Permanent cure of chronic otorrhœa can hardly be expected, if the nasopharynx remain profoundly diseased.

The natural tendency of chronic purulent disease in the drum-cavity is to impair the hearing. The loss of this function, and the disagreeable odor which attends otorrhœa, are the chief early inducements for patients to seek surgical aid. It is at this period of the disease that the surgeon can do the most good. The impairment of the hearing may be due to thickening of either the mucous membrane covering the ossicles and their joints, or of that over the fenestræ of the vestibule and the cochlea. This thickening of the mucous membrane on these parts

[1] Read before the Philadelphia County Medical Society, October 13, 1886.

brings about an ankylosis in the great mechanical means of audition, viz., the chain of the ossicula auditus, and in the membrane of the round window. By means of the latter, a compensatory yielding to the movements of the ossicles is effected in the normal state. Finally, the purulent disease may loosen the joints of the ossicles, or even destroy portions of them, and thus render it impossible to restore the integrity of the auditory chain. In some rare instances, either the foot-plate of the stapes in the oval window, or the membrane of the round window, is eroded, and hearing is hopelessly destroyed in consequence of the invasion of the internal ear and the auditory nerve.

The perforation in the membrana tympani, by relaxing the membrane, and altering the normal position of the ossicles, also aids in producing defective hearing. After the production of so much destruction in the membrana, disorder in the ossicles, impairment of hearing, and the establishment of a chronic purulent otorrhœa, the disease may continue uneventfully on this plane for years.

The patient may or may not undergo any form of treatment, or at most will cleanse the affected ear, in order to abate the odor which comes from it. If the hearing in one ear is good, the bad hearing in the running ear is endured, and the discharge is not thought of, if it is not copious or offensive. These are the neglected cases, and they tend to the development of granulations and polypi *upon the mucous membrane of the cavity of the drum.* As these form in the diseased ear, the discharge increases in quantity, and the hearing grows duller. These latter facts, as well as the greater anxiety about personal defects in early adult life, finally lead the patient to seek aid. Inspection now reveals a polypus, or perhaps two, with distinct pedicles. Or, if these have not yet formed, granulations are seen, which more or less obscure a view of the drum-membrane. Such granulations, if let alone, seem to coalesce and form the solitary polypus, or perhaps two polypi. Aural polypi vary in size, from a buckshot to a large marrowfat pea; or, if old, and sufficiently compressed by the auditory canal, they assume the shape of the latter, and finally extend from the meatus, after attaining a length of one and one-half to two inches.

Instead of the formation of polypi, the purulent disease may be more destructive, and produce death of the mucous-periosteal membrane in the drum-cavity, and of the subjacent bone. This death of osseous tissue in the aural tract may take place in the tegmen tympani, just beneath the brain, or it may ensue in the so-called antrum of the mastoid cells.

When the tendency of this disease has brought about necrosis in the regions named, the affection has assumed a most serious aspect, because a fatal issue may now be induced at any time by either an embolic process in the brain, the lungs, or the liver. Prior to this course, a fatal meningitis may be set up by an extension of the disease through the roof of the drum-cavity, or through the fenestræ, and thus into the labyrinth and brain, or the necrotic disease having passed into the mastoid cells, the lateral or sigmoid sinus may be affected and purulent phlebitis at this point aroused. A clot may then be formed in the sinus, pieces of which enter the circulation, and thus an embolic process established at some vital point.

Time does not permit us now to consider the various phenomena which would enable us to distinguish these manifold results of chronic otorrhœa. It is enough for us to bear in mind that chronic purulent disease of the mucous membrane in the drum-cavity is always competent slowly, or, in some instances, rapidly, to bring about profound disease in the bony box of the ear, situated very near the brain, and that this chronic disease may be prevented, and its fatal results averted, by proper and timely treatment.

In many instances in chronic otorrhœa, before the worst results occur, warnings of the unfavorable advance of the disease are given, in the form of facial paralysis, violent attacks of ear-pain, with fever and delirium, and attacks of inflammation within the mastoid cells. In some cases sequestræ are thrown off from the drum-cavity, from the inner or osseous part of the auditory canal, and from the mastoid cortex.

Facial paralysis indicates an invasion at the upper and back part of the drum-cavity, and that meningitis, from extension of the disease through the tegmen, may ensue. Inflammation of the mastoid cells is more likely to be followed by phlebitis of the lateral sinus, and its consequences.

Cases of chronic otorrhœa with mastoid inflammation, and phlebitis of the lateral sinus, sometimes terminate fatally by embolism in the lung or liver, without any cerebral disease. Not to neglect chronic otorrhœa is the most important lesson the surgeon can learn, for a cure of the very chronic cases, especially when any of the portentous phenomena I have named make their appearance, is nearly impossible. Patients should be encouraged to have aural discharges stopped as soon as possible, whether acute or chronic. It is an injury to them to foster in their minds the idea that discharges will stop of themselves, or, if not, that they had better continue to run. Abnormal discharges from no other part of the body are allowed to run on disregarded, and, surely, discharges from the ear should not be, for they are as amenable to proper treatment as those elsewhere, and, if neglected, may become serious. From the deep and peculiar situation of the drum-cavity, purulent discharges from this part of the head are likely to be retained, and to undergo decomposition. This favors continuation and extension of the disease, and the mucoperiosteal nature of the tissue in which the affection has its seat renders death of the subjacent bone imminent with consequent involvement of the cranial cavity. The patient, therefore, should demand of his physician an intelligent consideration of such a malady.

Treatment.—The first consideration in the treatment of chronic purulent otorrhœa is cleanliness and cleansing. Cleanliness is demanded in order to prevent decomposition of the discharge in the ear, and septic influences from such a nidus. Cleansing the ear is necessary to enable the surgeon to make a diagnosis of the condition of the fundus and the membrana, and in order to prepare the ear for treatment.

Cleansing the ear is best accomplished by the surgeon, and should very rarely, if ever, be entrusted to the patient. It is best effected by syringing with tepid water, either with or without a disinfectant, if the discharge is copious and tenacious. If, however, the discharge is neither copious nor thick, the ear can be cleansed by a small dossil of absorbent cotton on the cotton-holder. Failure in this procedure is often attributable to the use of too thick a pledget of cotton. This should not be more than five centimetres in diameter. If it is larger it gets wedged in the meatus or in the canal, the fundus is not reached, or only with difficulty and after pushing, which is painful to the patient, and may abrade the canal, or even the deeper parts of the fundus and the membrana.

The syringe may be employed without illuminating the ear by the forehead mirror, but the proper and successful employment of cotton on the cotton-holder can be done only under the best illumination of the auditory canal, by the forehead mirror.

In infants and very young children, with very narrow meatuses, cleansing is most conveniently done by syringing with warm water, the return current from the ear being caught in a towel held beneath the auricle. After syringing, the water must be carefully mopped out of the fundus of the canal by absorbent cotton, in order to gain a view of the diseased parts, otherwise the refraction of the water will give a very distorted view of the objects seen through it.

Cleansing the middle ear is furthered by using some form of inflation of the tympana.

After the first cleansing of the external auditory canal and its fundus, the surgeon should find out in what part of the membrana tympani the perforation is. This may be found either above the so-called folds of the membrane, in the membrana flaccida (Shrapnell's membrane), or below the folds, in the membrana vibrans. The first-named part is a very small portion of the entire part of the membrana lying above the short process of the hammer. The latter, that below the folds, constitutes what is generally known as "the drum." In fact, this part has received nearly all the attention from surgeons, as it is by far the most common seat of perforations. Sometimes a perforation exists in both these portions of the membrana tympani at the same time; but this is not common. It is highly important to determine in which of these parts of the drum-membrane the perforation lies, since the treatment must be modified by the position of the perforation.

Let us first consider those cases in which the perforation is large and in the lower part of the membrana, the membrana vibrans. These, as already stated, are the most frequent.

Earache from acute inflammation in the tympanic cavity, in such chronic cases of purulent otorrhœa, must be combated by gentle warm-water syringing or irrigation, and in protecting the inflamed mucous membrane with insufflation of powdered boric acid. These insufflations and all others can be done either with the blow-tube on the principle of the blow-pipe, or by the hand powder-blower.

In those cases of acute inflammation in chronic otorrhœa with large perforations in the membrana, the pain can often be allayed by the use of instillations of cocaine, because the perforation in the membrana permits the entrance of the solution into the drum-cavity, and its ready contact with the mucous membrane.

Cocaine solutions instilled into an ear with imperforate membrana tympani are impotent to quell pain in the ear. They also seem valueless even when the membrana contains a small perforation, because they still seem to fail to reach the inflamed mucous surface.

If coryza is present, as it is apt to be, in these acute attacks in chronic otorrhœas, it, of course, must not be disregarded. The prognosis in these cases is favorable as to restoration to a relatively normal or healthy state, if the subject is in ordinary health.

It is in these cases of purulent otorrhœa with large perforations in the membrana tympani, that preference should be given to the so-called dry treatment. In this form of treatment very little water is used for cleansing, and only when the discharge is thick and copious, and hence not easily removed by absorbent cotton. The reason for this preference of dry treatment is that the use of water favors the continuance of the discharge in many cases, and promotes a tendency to the formation of granulations and polypi. If syringing the ear is to be done, it must be carried out by the surgeon, and not entrusted to the patient. After the ear is cleansed by either of these methods, some form of boric acid, finely powdered, should be employed by insufflation. This enters the tympanic cavity, and hence comes in direct contact with the inflamed mucous membrane. It remains there more readily than fluid preparations and hence acts longer. The beneficial effects are due to the antiseptic properties of the boric acid, and to the protection the layer of powder gives the mucous membrane. Boric acid may be combined with hydrastin, ten grains to the ounce; calendula one part to two of boric acid; resorcin one drachm to the ounce; chinoline thirty grains to the ounce; alum ten grains to the ounce; salicylic acid or iodoform. This treatment can be carried out only by the surgeon, and during the intervals of treatment the patient is to do nothing himself in the way of treatment. It should be performed every day until the discharge begins to lessen; then at increasing intervals of time.

If this dry treatment does not give entire satisfaction, as it may not or will not, if granulations or ulcerations exist beyond the reach of the powder thus blown in, resort may be had to instillations of astringent and antiseptic solutions, as nitrate of silver—not less than forty grains to the fluid-ounce of water; or carbolic acid solutions from three per cent. to five per cent. in strength. These are to be put in the ear after it is cleansed, and followed by a dressing of insufflated boric acid, either in simple or in compound powder.

In cases of chronic purulent discharge from the attic of the tympanic cavity with perforation only in the membrana flaccida, the dry treatment cannot be relied upon, because of the smallness of such perfora-

tions, and the consequent inability of the surgeon to blow the powder into the diseased cavity. In these cases the treatment consists in the application of solutions to the attic through the perforation by means of the tympanic syringe. The long slender nozzle, six centimetres long by one millimetre in diameter, must be conveyed under illumination by the forehead mirror, down the auditory canal to the seat of disease. I have found the best results to follow the use of injections of a three per cent. solution of carbolic acid by this means into the attic cavity of the tympanum after thorough cleansing of the attic by injections of hydrogen dioxide, which thoroughly removes all pus. They do not tolerate nitrate of silver. It is well to follow these applications by insufflations of boric acid into the fundus of the auditory canal. For though they cannot reach the attic unless the perforation be large, they have an antiseptic effect about the perforation and the rest of the outer surface of the membrana tympani and the fundus of the canal.

Cases of chronic purulent disease in the attic are difficult to treat, on account of the bad drainage from those parts above the ossicles, and because of the small perforation usually found in the membrana flaccida. They are also dangerous to the life of the patient, because the disease lies near the tegmen tympani, directly beneath the brain. Natural deficencies in the bone at this point exist so frequently that the meninges and the mucous membrane of the roof of the drum-cavity are often in apposition. The hearing, too, is nearly always impaired when the attic is diseased, because the joints of the ossicles, especially the malleo-incudal joint, are greatly involved, and their vibrations impeded.

In order to facilitate better drainage of purulent secretions from the attic in chronic disease, and more efficient medication, especially by the insufflation of powders, Dr. Sexton has suggested, and frequently performed, when the membrana is largely destroyed, its removal and then that of the mallens and incus, or their remnants. The fundus is then treated with a powder of salicylic acid and boric acid, until a dermoid cicatrization ensues. This operation is applicable to chronic attic disease, *without perforation of the membrana flaccida*, but with large destruction of the membrana vibrans, in which the diseased mallens and incus interfere with drainage of the attic, downward into the atrium.

In every case of chronic purulent otorrhœa, if the nasopharynx and pharynx are markedly affected at the same time as the ear, they must also receive treatment. Some forms of chronic otorrhœa are certainly aggravated in adults, by decayed teeth and diseased gums. For the discharge in such cases, which may have been inveterate, or often recurrent, ceases upon the removal of the diseased teeth, usually some of the molars, and the healing of the gums.

In any case of chronic purulent otorrhœa, so long as we can detect no lesion beyond impaired vibration in the ossicles, with defective hearing, as a consequence of the chronic disease in the mucous membrane, the cure of the affection may be considered as probable, excepting in tubercular cases far advanced in pulmonary disease. By curing the purulent disease of the mucous membrane, the growth of granulations and polypi, and the occurrence of necrosis and caries of the adjacent bone, are prevented.

If, however, the ear has not been treated, or improperly treated, granulations and polypi may be found, with impairment of the hearing. The granulations are best removed by touching them, and only them, with chromic acid, carefully conveyed to their surfaces on a small cotton tuft, not more than two millimetres in diameter, on the cotton-holder, under perfect illumination of the canal and fundus by the forehead-mirror.

If polypi, with distinct pedicles, have grown from the mucous surface of the middle ear, and extend into or from the perforation in the membrane, they must be extracted with the polypus snare, and their pedicles touched every day or two, until they disappear. These are entirely curable, and the discharge from the ear usually ceases after the removal of the polypus and the destruction of its roots, and the hearing improves. The removal of the polypus, without subsequent treatment and destruction of its pedicle, is useless.

Instead of this conservative, hypertrophic action, on the part of the mucous membrane, it may slough, leaving the subjacent bone bare. The latter then dies, either superficially or in its profounder parts, and some of the evils I have sketched are experienced by the patient. If such cases are seen before they have advanced beyond the destruction of the mucous membrane, and properly treated, the mucous membrane may be repaired, and necrosis of bone beneath it averted. In some cases of profound inflammation and ulceration of the mucous membrane of the drum-cavity, denuded bone can be felt with a probe, and crumbs of bone are thrown off with the aural discharge. But with the improvement in the condition of the ear, these particles of dead bone cease to appear, and denuded bone can no longer be felt. In such cases the ear should be syringed once daily, by the surgeon, with tepid water, in which salt or potassium permanganate may be placed. Or the ear may be syringed with weak solutions of corrosive sublimate, 1 : 1000, carbolic acid five per cent., or with undiluted peroxide of hydrogen (Lehn & Fink's, or Schiefflin's). This drug has the great advantage in breaking up and removing all pus, and of informing the surgeon when this is accomplished, by the cessation of foaming which ensues as soon as there is no more pus, with which it makes a frothy reaction. Thereafter the ear is to be dressed with the powder of boric acid already named. Cleanliness and antiseptics, with attention to the general condition, form the guiding motives in the treatment.

If sequestra form, they should be removed if possible. In this way portions of the labyrinth, or the cells and cortex of the mastoid are at times taken from the ear, and the parts of the cranium near it. So long as they remain, as it were, in the aural tract, they are obstacles to cleanliness and points of infection threatening the entire system.

In many cases, indeed I am inclined to say in most cases, of necrosis of the cranial wall from chronic aural purulency, operative interference is well-nigh

useless. Unless it be the mastoid cortex, all other parts of the auro-cranial surface are extremely difficult to operate upon, and surgical interference becomes a dangerous undertaking. Again, when the surgeon is consulted in cases of intracranial disease, a systemic septicæmia, arising from chronic purulent disease and necrosis in or about the ear is established, and the patient is beyond aid. To trephine for cerebral abscess, which has resulted from chronic aural disease, is to operate on a moribund patient, and to hasten surely the fatal issue. The time to aid such a sufferer was when the chronic purulent otorrhœa could have been checked, and before it had induced necrosis of bone or embolism. In my opinion, there never is a moment after the cerebral abscess is formed, that an operation for its relief is justifiable, excepting perhaps in those instances in which a sinus can be found leading to it from the mastoid or squama. In regard to mastoid trephining, for so-called mastoiditis and periphlebitis of the lateral sinus, my opinion is much the same.

The mastoid cortex can be easily perforated and the mastoid cavity opened, the operation in itself being comparatively a simple and safe one. But such an operation is rarely, if ever, needed, because an acute inflammation originating in, or limited to, the mastoid cells, without possibility of other escape, rarely if ever occurs; and for such a disease alone would trepanation of the mastoid cortex be demanded.

I admit that a chronic purulency in the tympanic cavity may gradually and painlessly affect the mastoid antrum, its cells, and its outer cortical as well as its inner wall, which is the outer wall of the lateral sinus. This diseased state in the furrow of the lateral sinus is of the most serious import, but an operation on the mastoid cortex cannot arrest its progress or remedy its effects. Too often when pain in the region of the mastoid is felt, and other well-known symptoms of so called mastoiditis arise, the pain is really due to inflammation in the lateral sinus, or deeper parts from such chronic disease in the bone, and not to matter pent up in the mastoid cells, which a perforation in the mastoid can relieve. I am forced to such conclusions, because fluid matter from the drum-cavity and mastoid antrum can escape, in most cases, from the external ear. Also, because in many cases of pain in and about the mastoid, with symptoms which are supposed to justify trephining its outer cortex, the cavity has not been found filled with fluid matter seeking an escape, but with some inspissated pus at most; while periphlebitis in the lateral sinus has been discovered, having its origin from the neglected tympanic disease, which trephining is powerless to cure.

Even if the mastoid cortex and cavity are found diseased, an operation upon them will do no good if the lateral sinus is diseased, and perhaps the seat of a clot.

When mastoid operations are supposed to have been of value and to have done good, as has sometimes been claimed in acute cases of otitis media, there is ample evidence that they were not really needed.

In many cases of tumefaction behind the ear, in painful acute inflammation in chronic cases, Wilde's incision does give great relief. And in some such cases where this incision has been followed by perforation of the bone, and relief and apparent cure have followed, it has been because there was no disease in the inner mastoid wall and the lateral sinus. In such cases the local depletion gave the relief, and the mastoid perforation was purely gratuitous. The result would have been just as fortunate without the embellishment of the operation of trephining the mastoid. Hence in acute cases of otitis media great care should be taken not to resort precipitately to mastoid trepanation. In chronic cases it is of value in very few instances, and the indications for its employment are not well defined. In many cases the mastoid becomes œdematous, brawny, shining, sensitive to both deep and superficial pressure, and painful to the patient. These are often relieved by poulticing and leeching, without even Wilde's incision. Sometimes if let alone, they undergo speedy resolution.

In any such instance of supposed mastoiditis, consequent upon chronic otorrhœa, the simplest means of treatment at our command should be used. If the lateral sinus has not been invaded, there is no need of haste. If it has been attacked, mastoid trephining will certainly not check it.

It must not be forgotten that many instances of pain and swelling about the mastoid are due to congestion and swelling in its mucous lining, and in that of the middle ear and mastoid antrum. The circulation both within and without the mastoid is then impeded, and swelling, œdema, and tenderness of its outer surface are the result. Hence the relief obtained sometimes by spontaneous resolution, or by artificial depletion over the cortex of the mastoid. As the swelling in the mucous membrane of the middle ear and antrum goes down, relief is given to any matter which may have been dammed up in the mastoid cells, and which now escapes and runs into the external ear, and the mastoid pain and swelling disappear.

ON TETANY AND TETANILLA.[1]

By JULIUS ALTHAUS, M.D., M.R.C.P. Lond.,
corresponding member of the new york academy of medicine, senior physician to the hospital for epilepsy and paralysis, regent's park, london.

Amongst the convulsive diseases of the nervous system which we are in the habit of encountering in the practice of our profession, there are some which have, on account of the extreme severity of their symptoms, engrossed the attention of physicians almost from time immemorial. The principal representative of this class is epilepsy, which was for a long time believed to be a special infliction sent by the wrath of the Almighty, being termed *morbus sacer* by the classical writers. Tetanus arising from injury and exposure to cold, was likewise already well known to Hippocrates and Aretæus, and has, as well as epilepsy and chorea, engaged the attention of innumerable observers, while even at the present day all these diseases offer to those

[1] Read before the New York County Medical Society, October 18, 1886.

who are willing to investigate them patiently, points of interest that are still involved in obscurity. The complaint to which I intend to refer to-night has, no doubt, always existed, like the more formidable diseases which I have just mentioned, but has only been recently recognized as a special entity, partly, no doubt, on account of its symptoms being habitually much less severe, and partly from having been confounded with other diseases, which although they resemble it in some particulars, are nevertheless totally distinct from the same.

Tetany is not frequent, but where it occurs it presents points of considerable physiological and pathological interest, and is occasionally so severe as to lead to a fatal result. It is also practically important for physicians to be familiar with its clinical features and its pathology and treatment.

There is another kindred complaint to which I have for many years past drawn attention at the hospital, and which I have termed tetanilla. I have, however, up to the present time never published my observations on the subject, and was, in 1881, forestalled in this point by the late Prof. Friedreich, of Heidelberg, to whom we owe such excellent work on muscular atrophy and hypertrophy, and who was also, as you know, the first to describe that peculiar and unusual form of locomotor ataxy which runs in families and habitually begins about the age of puberty, and which is now generally designated by the name of Friedreich's disease. This able pathologist, whose premature death from aneurism of the aorta we deplored not many months ago, gave to the complaint which I have just introduced to your notice as tetanilla, the somewhat barbarous name of paramyoclonus multiplex. Löwenfeld and Seeligmüller have more recently described cases of this affection, and I will make use of the opportunity which this meeting affords me to speak of my own experience with regard to it. Of course, I do not in the slightest degree wish to interfere with Friedreich's unquestionable right of christening a disease of which he was the first to record his observations; but I confess that the name tetanilla which I had, as it were, privately given to the affection, sounds to me much more euphonious than paramyoclonus multiplex, while the fact that both appear to be functional disorders of the nervous system, showing their chief symptoms in closely allied muscular disorder, would seem to favor the idea of giving them somewhat analogous names, showing at the same time in the word tetanilla, the less degree of severity which the latter form is apt to assume in practice. It will, however, be for the profession to decide which name shall eventually be adopted.

I think I shall do best if I commence my remarks on tetany, of which I have seen altogether ten cases —four in males and six in females—with a short historical retrospect of the work which has been contributed by various authors who have had opportunities of investigating this complaint. I do so more particularly because recent French writers have claimed it as a peculiarly French disease, and one which has, according to them, "une paternité toute française;" the fact being that the first description was given by a German physician, Steinheim, in 1830, while the first French publication, by Dance, appeared quite a twelvemonth later, viz., in the *Archives Générales de Médecine* for the year 1831. Of course, it is not to be supposed that Dance should have been acquainted with Steinheim's essay at the time he wrote; for the French have only commenced at a very much later period to read German publications; and when Dance wrote they were in the habit of looking upon everything German or English as only fit for barbarians, whose prescriptions might be good enough for horses—"médecine de cheval" being even now a not uncommon term with the French for any foreign system of treatment. At any rate this fact remains, that Steinheim was a year in advance of any other writer on the subject, and it seems, therefore, hardly fair that Delcroix should in his recent thesis on the subject, moved no doubt by the noblest patriotic sentiments, have substituted the year 1830 for 1831, as the date of publication of Dance's paper. I have myself verified the reference; and while I am free to admit that Dance's publication is an unusually able one, I have to state that in point of time it is unquestionably the second, not the first. Dance, who was then physician to the Hotel Dieu, at Paris, has given a detailed description of four cases of the affection, and pointed out with considerable minuteness its difference from simple cramps, muscular rheumatism, tetanus, hysteria, as well as certain affections of the spinal cord, nerves, and muscles. He laid stress on the paroxysmal character of the spasms, and the favorable issue of all cases in spite of occasionally alarming appearances; and believed the disease to be a kind of intermittent and non-pernicious tetanic fever. I may here at once say that, although Dance's paper is more interesting than Steinheim's, nevertheless the French writer's view of the pathology of the complaint—viz., that it is owing to malaria, has not been confirmed by further experience; while the German author's statements that the rheumatic diathesis is at the bottom of the disease, has, at least for a certain number of cases, turned out to be correct.

The name, tetany, which is universally used, originated with Corvisart, in 1851. Trousseau, who in his practice at the Hotel Dieu, in Paris, enjoyed unusual opportunities of studying the complaint, met with it at first only in nursing women, and called it rheumatic contracture of wet-nurses; but he soon perceived that it also arose from other causes than lactation, although he looked upon the latter as the most active and frequent causative influence. The complaint was subsequently studied by Moxon, who termed it remittent tetanus, by Wilks, Riegel, and more especially by Kussmaul (in 1871), whose fine clinical instinct enabled him to draw such a striking picture of the complaint, that he succeeded more than any previous writer in attracting general attention to it. Erb, Chvostek, and Weiss are amongst the later authors who have added their quota to the pathology of this disease.

Tetany consists of a succession of attacks of tonic spasm or rigidity of certain groups of muscles, mostly symmetrical, which follow one another at somewhat

irregular intervals, and are after a variable time followed by relaxation. The attacks are not accompanied with loss of consciousness, but there is throughout the course of the complaint undue mechanical and electrical excitability of the motor nerves and muscles.

The chief causes which appear to give rise to tetany are certain kinds of irritation acting on an otherwise predisposed or enfeebled nervous system. Thus, it occurs after and in consequence of persistent diarrhœa, more especially in the underfed and half-starved children of the poor. Kussmaul has described the case of a boy, aged six, who had been brought up by hand in wretched surroundings, and had lately lived almost exclusively on small beer; indeed during the first few days the little fellow was in the hospital, he refused all food excepting beer, and suffered from incessant diarrhœa. He eventually recovered from the diarrhœa as well as the tetany, but was three months afterward seized with a violent attack of vomiting and purging, after which the tetany reappeared. The same cause I ascertained in the case of a little girl, aged three, whom I saw at the hospital in 1881, and who had been reduced almost to a skeleton by incessant diarrhœa. The attacks came on in her hands and feet every few hours, and lasted about twenty to thirty minutes, during which time she kept yelling in the most fearful manner. Her mother had suffered from hysterical fits, and a sister had had chorea. Obstinate constipation and entozoa in the intestine have likewise acted as exciting causes.

A case is on record in which the ova of tænia medio-canellata and trichocephalus dispar caused tetany, which latter ceased after the parasites had been expelled from the bowels. The irritation of dentition has likewise been assumed to give rise to tetany, although the evidence supporting this point is not strong. Irritation in the sexual sphere of women, and occurring in connection with menstruation, pregnancy, the puerperal state, and lactation is, however, an undoubted factor in the production of the complaint. It also occurs after smallpox, cholera, typhoid fever, and other acute diseases; indeed, Aran has seen it occurring in a dozen convalescents from typhoid fever who were in the hospital at the same time. Bauer has also seen it simultaneously in three women of the same family who had eaten unwholesome bread. This had been procured from a distance on account of its cheapness, and was so mouldy and nasty that the men of the family refused to touch it. None of them had tetany, and the three women recovered after discontinuing to eat of this particular bread. Bauer thinks that it may have contained ergot of rye, but could not procure a sample for analysis.

Another active agent in the production of the complaint, and which was chiefly dwelt upon by Steinheim and Trousseau, is the influence of wet and cold. The latter observer describes the case of a man who was found in the streets of Paris one morning in winter, having passed the night there in a state of intoxication, and being so stiff that he was believed to be in an epileptic fit, yet he had been quite conscious all the time. While under observation in the hospital, he was found to be subject to attacks which lasted from a few minutes to half an hour, and had such good use of his limbs in the intervals as to enable him to attend upon the other patients in the wards. On account of the undoubted influence of cold in its production, tetany has also been called intermittent rheumatic contracture. Sleeping habitually in damp rooms, or working in damp shops, appears to favor an outbreak; and exposure, no doubt, often acts concurrently with other influences. Thus, one of the nursing women in whom Trousseau saw tetany, was found to have got out of bed in the night and gone outside into the yard of the hospital in order to fetch water from a pump in midwinter. She died of asphyxia produced by tetany of the respiratory muscles shortly afterward. In one of the cases which have fallen under my own observation, tetany came on quite suddenly in a young man aged eighteen, who had, while skating in the Regent's Park, in London, broke through the ice and had been nearly five minutes in the water before he was rescued. An emotional influence, however, was probably likewise active in this case in addition to the chill, as the patient being unable to swim, underwent an agony of fear of drowning all the time he was in the water. It is not uncommon that there should be several influences at work in determining an outbreak of a nervous affection; I will only remind you of tabes spinalis, in cases of which we generally find a history of three causes, viz., syphilis, exposure to cold and wet, and over-exertion, whether physical or mental.

An emotional influence was likewise evidently at work in another case of tetany which was under my care in 1879, and which was that of a young lady, aged twenty-one, who had been engaged to be married, and in whom the disease appeared quite suddenly the day after she had had a quarrel with her lover, in consequence of which her engagement had been broken off.

Simon and Regnard have described what they call an epidemic of tetany, which occurred at Gentilly, in France, where it went through a young ladies' school. At first the cases were very few; one girl was affected in July, and another in October; in November, however, quite an epidemic broke out, there being eight new cases on one day, and eleven on the next. The governess at first tried to arrest the progress of the disease amongst the girls, but eventually got it herself. The school was then broken up, and all the girls recovered rapidly. Similar epidemics have been described as having occurred in some prisons and asylums in Belgium. It is, however, quite clear from the description given of the epidemic among the French schoolgirls that there was no real tetany present, but that it amounted to an endemic manifestation of hysteria which, in its symptoms, had a considerable resemblance to tetany. We know that hysteria may mimic most diseases, and need not, therefore, be surprised that it will occasionally mimic tetany. With regard to the cases observed in the public institutions in Belgium, it appears probable that they were in reality such an epidemic of spinal meningitis, as in some of them an inspection was obtained showing the patho-

logical lesions of meningitis; and I shall presently in my remarks about the diagnosis of tetany, refer to the possibility of its being occasionally confounded with that disease. It is, however, a fact that cases of tetany do sometimes occur together; but the explanation of this would seem to be the influence of exposure to unusually severe cold prevalent at the time. Thus, Weiss had twelve cases under his care in the severe winter of 1881, at Vienna, and Chvostek saw seven in the winter of 1880, in Austrian soldiers who, during target practice, suffered considerably from exposure to the intense cold which then prevailed.

In May last, Ord, of London, exhibited at the Medical Society of that city, the case of a woman who showed the usual symptoms of myxœdema, and in addition to them a peculiar symmetrical contracture of the flexor muscles of the hands and legs, strongly resembling tetany. In connection with this case it is interesting to remember that Weiss has seen four cases in which the excision of the enlarged thyroid body, by Prof. Billroth, of Vienna, appeared to give rise to the affection. In one of these cases it appeared on the sixth day after the operation; in a second, on the evening of the same day, and in two other instances immediately afterward. One of these patients eventually died of it. In another case the tetany lasted six days after the operation, then disappeared, but relapsed when an abscess had formed in the neck; it ceased finally after this had been opened and healed. Weiss does not assume any particular relation to the bronchocele, but thinks that it was only the irritation caused by the surgical operation *per se* which caused the tetany; yet it seems a curious coincidence that four cases of tetany should have appeared in connection with thyroidectomy, while it is not known to have occurred after any other surgical operation; and in connection with this, Ord's case which I have just mentioned, is of interest, as raising the question, whether there may not be some more intimate connection between atrophy or absence of the thyroid gland and tetany, than has hitherto been assumed. I would recommend this point to your attention, should similar cases present themselves in your practice.

Tetany has probably no connection at all with certain kinds of occupation, as has been assumed by some writers. Indeed, it has by some been termed cramp of tailors, cobblers, and seamstresses, or professional spasm generally; but the fact that it not uncommonly affects infants, as well as women who have no particular kind of manual labor to perform, and finally in men in all kinds of occupations, speaks strongly against this assumption. The age at which it is most frequent, is the period between one and five years, and again that between fifteen and thirty years. As to the influence of sex, females seem to be rather more liable to it than males.

On reviewing all the different determining influences which I have just mentioned, it is impossible not to be drawn to the conclusion that they can, one and all, only be looked upon as exciting causes; and that constitutional neurotic disposition must be present in patients in order that such causes as cold, diarrhœa, etc., may be effective in leading to the outbreak of tetany. As, however, this point has not as yet been very clearly made out, I have taken some trouble in gaining information upon it in those cases which have happened to come under my care. The result has been that in not a single case was there any direct heredity, for to all my patients and their friends and relations the disease was entirely new, and something they had never known or heard of. In five out of ten cases I have seen, however, such diseases as hysteria, migraine, epilepsy, and chorea had occurred in the parent or other members of the same family. This would already give a proportion of fifty per cent.; but I have to add to this a case of atavism, as the maternal grandfather of one of the patients had died insane; and another case where the parents of the patient were first cousins, and where therefore a neurotic predisposition might be assumed to exist. It is therefore seen that only three cases out of ten were, or appeared to be, entirely free from a neurotic taint, so that my contention of a constitutional tendency being at the base of the complaint, would appear to be well substantiated; more especially when we remember that either through ignorance or carelessness of the persons concerned, the family history given us in such cases is frequently far from complete.

The evolution of the symptoms of tetany may be somewhat rapid or more gradual. In some cases, and, according to my experience, more especially in those where a cause has acted very suddenly, the disease may appear at once fully developed; while in those where the power of resistance of the nervous system appears to have been more gradually undermined by various deteriorating influences, there is a progression in the symptoms which goes from piano through the different degrees of crescendo up to forte, and eventually to fortissimo. Amongst the premonitory symptoms, where such are present, we find more particularly a general feeling of malaise, as of some impending illness, headache, dizziness, specks floating before the eyes, and a feeling of stiffness and awkwardness, or shooting pains in the limbs. Slight temporary rigidity of certain muscles may be combined with this, or there may be a few twitches which subside again presently. These symptoms generally become aggravated, and eventually tetany sets in. Both hands are then seen to have assumed a peculiar position, which is not always the same, but varies according to the several groups of muscles which may happen to be affected. In most instances, it is the muscles supplied by the ulnar nerve which suffer; in some, those under the control of the median nerve, while only very occasionally those which receive their motor impulses through the musculospiral nerve are affected. In accordance with this, it is found that the common position of the hand in tetany is the conical one, resembling that which the accoucheur uses when introducing his hand into the vagina. In this the thumb is forcibly adducted, and the fingers are flexed in the metacarpo-phalangeal joint and pressed against the thumb, while the wrist is bent and turned toward the ulnar side of the arm. The spasm may stop there, or proceed higher up, involving the forearms, which may be bent and

crossed over the epigastrium, and the arms, which may be strongly adducted to the body. In some cases, again, the fingers are so strongly clenched that the nails enter the flesh and produce eschars; the thumb may almost disappear underneath the other fingers, or it is squeezed between the first and second finger so as to show the thumb-nail between their first phalanges. Where the interosseous and lumbrical muscles are rigid, the hand assumes the bird-claw position which was first described by Duchenne. Or there may be spasm in the extensor muscles, the fingers and wrist being stretched out, and unable to be bent, and the fingers being wide apart. A considerable variety of positions may thus be produced, and it is therefore important to remember that the position of the hand which was first mentioned, is not absolutely pathognomonic of the disease. At the same time there is in true cases of tetany, always some degree of rigidity in the muscles supplied by the ulnar nerve, and when this is entirely wanting, the case is most probably not one of tetany.

In the lower limbs the spasm is generally seen to begin in the toes, which are held in plantar flexion, closely pressed against each other, but extended in the metatarso-phalangeal joint. The big toe is adducted and beneath the others, the foot in the varo-equine position, with the heel drawn up, and the tendo Achillis strongly retracted; or, again, the toes may be stretched out, and each one be as wide apart from its neighbors as possible. The feet may be adducted, the knees extended, and the thighs stretched on the pelvis, while in other cases the legs are drawn up to the abdomen. Walking during the attack is thus rendered difficult or impossible; indeed, sometimes there is persistent contraction of the muscles of the calves, so that the patient is quite prevented from moving about, while in other cases the rigidity is so distributed that only the heel touches the ground, and the toes are raised up. The effect of this is the same, viz., to interfere altogether with walking.

In some cases only one side of the body, or only the upper limbs, or only the lower ones are affected, or they may suffer alternately; but mostly there is symmetrical affection in both sides of the body.

In the large majority of cases, only the muscles of the extremities are thus affected; but in some the rigidity also involves those of the head and the body. The head may be pulled down on the chest, and the spine curved; the muscles of the neck may be so rigid as to stand out like tight cords, and to compress the jugular veins; the lips and tongue may be quite rigid; the eyes may be spasmodically closed, and through contraction of one or the other of the ocular muscles, the various forms of strabismus may be produced. The face may be devoid of any mobility of features. The muscles of the lower jaw, and of the pharynx and larynx, likewise do not escape in some cases, and this leads to difficulty in masticating, swallowing, and breathing. In extreme instances there is spasm of the glottis, with great dyspnœa and cyanosis. The diaphragm and the other muscles of inspiration then appear to be fixed, and if this condition is not speedily relieved death from apnœa is the result. Even the bladder may suffer, as shown by retention of the urine, together with frequent desire to micturate. A very bad attack, in which dyspnœa may be so severe as to threaten the life of the patient, sometimes ends with profuse perspiration, and as soon as this is well established, all symptoms are relieved. In one of Dance's cases, perspiration was so abundant as to form a cloud of steam around the patient.

The contraction of the muscles is sometimes very painful, and more especially so in children, who often scream and yell throughout the attack. In other cases there is rather a stiff and bruised feeling than actual pain, together with great tenderness on pressure. The degree of contraction may vary from one minute to another, and this occasionally leads to spasmodic jerkings of the muscles. Where there is much pain, the patient is restless and agitated during the night, and desires constant change of position, while another may lie still in bed like a statue. During the attack the muscles may be entirely withdrawn from the influence of volition; in other cases the rigidity is more moderate, and allows of some degree of movement. Habitually the muscles feel as hard as iron. In a severe case there is so much resistance to passive movements that a great deal of force is required to counteract the rigidity; and the instant we let go, the contraction reasserts itself. Attempts to overcome the rigidity are very painful. Friction often diminishes the rigidity, while pressure may increase it. A sudden impression of cold and heat may also arrest the spasm; thus, if the patient be made to stand with his naked feet on the bare floor, or if his hands be immersed into vessels filled with hot or cold water, the rigidity may relax, but only to reappear again as soon as the influence of these agents is withdrawn. The duration of the attack is variable; it may last only five minutes or as many hours, and may be repeated over and over again; but where the condition appears to have continued for days together, it is probable that, as in certain cases of epileptic fits, the intervals have been short, and remained unnoticed by the attendants. If this should not be the case, then I would say that the case was not one of tetany.

Trousseau was the first to notice that, so long as the diseased condition persists, we may, at a time when the patient is quite free from rigidity, produce it almost immediately by compressing the affected limbs, more especially at points where we can act on large nerves or vessels, so as to interfere with circulation. This discovery was made accidentally. He had ordered a woman suffering from tetany to be bled, and noticed that when the bandage was drawn round the arm, the muscles below tightened. He afterward found that such an affect is produced more especially with the upper limbs, where pressure on the brachial plexus above the collar bone, or the median nerve in the arm, will lead to it. In the lower limbs pressure on the sciatic nerve or the femoral artery may do the same; but here the result is not so quick and certain as in the upper limbs. In one case Trousseau found a very suggestive illustration of the well-known law of reflexes formulated by Pflüger, viz., that the effect of the stimulation is greatest at or near the spot where it is applied, and

that an increase of stimulus is required for affecting more distant parts, which are then acted upon in a certain order. In that case ligature of the right thigh produced first contraction in the toes of the right foot, then in those of the left foot, afterward in both hands, and finally a violent attack of hysteria.

Kussmaul was led by his observations on this symptom to the result that it is pressure on the arteries rather than on the nerves, which causes these effects in the muscles. When he compressed the brachial artery of a patient during a free interval, he noticed that in twenty or thirty seconds the fingers began to twitch; in two or three minutes the flexion appeared to be increasing, and very soon afterward the hand and forearm were spasmodically bent. The proceeding was not painful; when the pressure was withdrawn, the spasm disappeared, and pressure on the nerves did not cause the same effect. My own observations have led me to the result that Trousseau's symptom is produced by pressure both on the nerves and on the bloodvessels, and that complete compression of the latter leads more quickly to the expected result than that of the former. This is more particularly seen in the lower extremities, where compression of the femoral artery in front of the os pubis brings about muscular twitches and rigidity much more rapidly than compression of the sciatic nerve in its notch.

My study of this point has also led me to a very singular observation, which is likely to prove of some importance in the differential diagnosis of tetany from hysterical contracture, as it tends to show that tetany and hysteria are two widely different conditions. I have seen cases of hysterical contracture closely resembling the habitual position of the hand in tetany, where the history of the case was obscure, and it was difficult to make out whether the muscular rigidity was paroxysmal, as it is in tetany, or continuous, as it is in hysteria. In these cases compression of the limbs by Esmarch's bandage enabled me to decide this question; for it appeared that while in tetany pressure increases the rigidity still further, on the contrary, in hysterical contracture the rigidity was relieved, and ceased after the bandage had been applied for some time; to return, however, again almost immediately after the pressure was withdrawn. This singular circumstance seems to show that the arterial anæmia and venous congestion which are produced in a limb by compression, may cause opposite effects according to the condition of the nervous system with which we may have to deal, leading in one case to contraction, and in another to relaxation of the muscles. This is a point which requires further elucidation, and the study of which I would recommend to you in similar cases, as it may eventually throw light on the more intimate nature of the vasomotor disturbance which is present in such conditions as hysteria and tetany, and of which we are as yet in almost complete ignorance.

Another important feature of tetany upon which I must dwell now, is an alteration in the electrical and mechanical excitability of the affected nerves and muscles, which occurs habitually in the cases now under consideration. Indeed, the faradic and galvanic excitability of the affected nerves which was first examined by Benedict, and afterward by Chvostek, Erb, and others, is generally found to be much increased. A feeble constant current causes with the cathode not only the ordinary closing contraction much more readily than in the average healthy subject, but also tetanus of the muscles, which continues for some time; and what is rare in man, although not uncommon in the frog, tetanus with opening at anode, and likewise with opening at cathode. Ready responses are also elicited with a very gentle faradic current; and this ensemble of phenomena constitutes the reaction of convulsibility.

These signs are chiefly marked when the disease is at its acme, become less striking as the patient improves, and disappear altogether when he is well. They occur, however, only in the nerves and muscles which are actually suffering from tetany, not in all the muscles of the body; and this easily explains the apparent discrepancy in the results obtained by the different observers. Erb saw no reaction of convulsibility in the portio dura, while Chvostek found it very marked there in a case in which the muscles of the face were suffering from tetany. The electric tests are not only of diagnostic, but also of prognostic importance, as they sometimes persist when the patient is apparently quite well in other respects. They then show us that the disease, although in abeyance, is not actually conquered, and that there is a liability to a fresh outbreak of the other symptoms. When, on the contrary, the responses have become normal, we may consider with certainty that the patient has recovered. They are, therefore, even a finer test than Trousseau's symptom, which may have disappeared at a time when the electrical reactions are still abnormal.

The mechanical excitability of the nerves and muscles is likewise habitually increased. A tap with the fingers or the percussion hammer on the nerves causes a sudden contraction in the muscles which they supply. This is more particularly noticeable in the sphere of the portio dura, where a slight blow in the region of the stylomastoid foramen, or the pes anserinus, or even the smaller branches of the nerve, effects sudden contractions of the facial muscles; and that not only during the attack, but also in the free intervals. A good way of producing the phenomena in question is that recommended by Schultze, viz., to pass the finger-nail rapidly down one side of the face, from the temple to the cheek and jaw, when all the facial muscles are seen to contract. The reflex excitability of the skin is not exalted, and has indeed nothing to do with the appearances observed; for when the skin is taken up in a fold, and then strongly squeezed or pinched, no effect takes place. This increased mechanical excitability occurs in the portio dura habitually, even where that nerve has otherwise apparently escaped the influence of tetany; and it is, therefore, a very important diagnostic help. We must, however, remember that it is not invariably present. Moreover, I have seen it in recent cases of paralysis of the portio dura, concurrently with the increased voltaic excitability of the muscles; and also in some patients suffering from neurasthenia and hysteria. This shows that it

will not do, in this as in other diseases, to rely on a single symptom for our diagnosis, but that we have to judge from the entire evidence which the aspect of the case offers to us.

Another symptom which exists during the free intervals is a decided loss of coarse muscular power. This can be shown by the dynamometer, which I have found to register habitually thirty or forty degrees less than we should expect from the general build of the patient, and this loss is made up after recovery. There is also subjectively a feeling of lassitude, and fatigue is easily induced by slight muscular exertion.

While, therefore, tetany shows us a great variety of symptoms in the motor sphere, these are much less conspicuous in that of sensibility. I have already stated that much pain is sometimes experienced during the attack, more especially by sensitive children, who are at the same time reduced in their general health, but some patients say that the pain is insignificant. There is, however, generally tenderness to pressure and percussion over the affected nerves and muscles, more especially during the attack, and the same is found in the spine, particularly at that decisive point, the seventh cervical vertebra. Feelings of cold or heat, pins and needles, and other forms of paræsthesia, are occasionally present, but as frequently absent. Sometimes, however, the sense of touch is blunt, so that the patient feels objects as if padded, and imagines that he is walking on a carpet when on a bare floor. The muscular sense is habitually not impaired.

There are few other symptoms to mention. Sometimes there are redness and œdematous swelling, more especially in the smaller joints of the fingers and toes, but also in the wrist and about the ankle, leading us to suspect an attack of acute rheumatism or rheumatic fever. The temperature is mostly normal, but rises to 100° or 101°, and even more in very severe or acute cases, and the pulse is thus accelerated, although habitually normal. There may also be headache, dizziness, flushing of the face, buzzing in the ears, impaired sight, with large and sluggish pupils, rapid breathing, loss of appetite, obstinate constipation and either unnatural dryness of the skin or excessive perspiration. In the majority of cases, however, the secretions do not appear to undergo any morbid change. It is true that Delpech has described albuminuric tetany, but these cases belong to a different class from those we are now considering.

The duration of the individual attack of rigidity varies from a few minutes to half an hour or longer, and the number of attacks during the day is even more variable. Sometimes there are only two or three, at other times there is an almost constant succession of them, reminding one of the status epilepticus, and going on during the night as well as day. The entire duration of the disease is rarely less than a month, and more commonly two or three months.

A few cases of tetany have ended fatally, but, in spite of this, morbid anatomy has not furnished us with precise data concerning the nature of any pathological change. One of Trousseau's patients died eventually of phthisis, and the upper portion of the cord appeared to be somewhat softened.

Kussmaul discovered myelitis in a young man who had been seized with paraplegia some weeks after having recovered from tetany; but the occurrence of paraplegia shows that the case was a complex one, and it therefore proves nothing. Langhans has microscopically examined the cord of a child which had died of tetany. He found the nerve-cells and fibres, as well as the interstitial connective tissue unchanged, but the arterioles showed thickening of the adventitia by deposition of cells, granules, and pigment; and this was in accordance with the symptoms observed during life, more marked in the upper than in the lower region of the cord, and more particularly about the anterior commissure. Such changes, however, which must have had a very gradual origin, cannot account for a complaint which often originates suddenly, and ceases almost as quickly. I fear that just as little can be learned from a case of Weiss's where death took place from œdema of the lungs, following lobular pneumonia at the left base, and in which Zemann found the brain and membranes slightly œdematous, but otherwise normal; the capillaries of the gray centre of the cord appeared distended, and in parts there were very small capillary hemorrhages, while the coats of the bloodvessels appeared normal. Such changes probably are effect rather than cause. In other instances hyperæmia of the dura mater, of the pia on the base of the brain, of the pons, bulb, and upper portion of the spinal cord, and of the peripheral nerves which had more especially suffered during life, have been found; and must likewise be looked upon as secondary rather than primary. Indeed, the great diversity and variety of these changes is in itself a proof that we have not as yet discovered the lesion of tetany; while other considerations lead us to think that, if there is a lesion, it is likely to be molecular rather than coarse, and that tetany belongs indeed to that large class of functional nervous affections which await the application of finer tests than we command at present, before we can have a clear insight into their nature.

Nevertheless some speculation seems to be allowable and even called for, more especially with regard to the localization of the trouble which is present in these cases. That it must be seated in some portion of the motor sphere is quite evident from the symptoms we have to deal with, in which the affection of motility overshadows everything else. We have a large choice from the central convolutions of Rolando at one end of the tract to the striped muscular fibres at the other. Which is primarily affected? De La Berge has pronounced himself for the muscular substance itself; Delpech Hasse and others for the peripheral nerves; Kussmaul, Erb, and Berger, for the spinal cord; Weiss, for the sympathetic nerve, which he believes to be in a state of irritation or disturbance which is constant, but periodically increased, and, while causing irritation of the gray matter of the cord and medulla oblongata, is itself caused by irritation in the bowel, womb, thyroid body, and other viscera. No one seems to have suspected the pons, crura cerebri, the central ganglia,

the white internal capsule, and the central convolutions; and this appears quite intelligible, if we consider that the symptoms are habitually symmetrical, while the usual affections of the parts just named are, on the contrary, unilateral. A great medical philosopher, Hughlings Jackson, considers tetany to be due to perverted cerebellar influence. He looks upon the brain as the centre for the ordinary voluntary movements of the limbs, and the cerebellum as the centre for continuous or automatic movements in the body. Now supposing the cerebral influence to be temporarily removed, the cerebellar influence would be unimpeded, and lead to rigidity of those muscles which during health are chiefly innervated by the cerebrum. I confess that this theory seems to me very far-fetched. Most physiologists consider not the cerebellum, but the medulla oblongata and the pons Varolii to be the centres for automatic movements, while the cerebellum is credited chiefly with being the centre for the equilibration of the body. This latter function is, however, in no way disturbed in tetany, and this appears to me a sufficient reason for rejecting Jackson's hypothesis.

It appears to me that some light may be gained by comparing tetany with another disease, in which we have likewise hardly any symptoms excepting in the muscles, and of which we know by dissection the true morbid anatomy. This is infantile paralysis, as caused by poliomyelitis of the anterior gray matter of the cord. In such cases we have not infrequently symmetrical paralysis of certain groups of muscles, just as in tetany we have the opposite condition, viz., rigidity which is most frequently symmetrical, and which affects by preference certain groups of muscles, leaving others intact. In infantile paralysis, which is a structural disease, we have chiefly paralysis of extensors and abductors; while in tetany, which I believe to be a functional disease, we have rather an affection of the flexors and adductors. The nutritive centres of these groups of muscles we know to be large cells in the anterior cornua of the cord; and it is to an undue and exalted state of excitability of these cells that it seems to me most reasonable to refer the symptoms of tetany, just as we refer to destruction of these cells the opposite symptoms of paralysis in the group of muscles for which we know them to be the centres. The localization of the trouble in the gray cells of the anterior cornua would then have to be sought in the lumbar, dorsal, or cervical region of the cord, or in the motor nuclei of the medulla oblongata, in accordance with the localization of the symptoms in the muscles of the lower extremities, the body, the upper extremities, the neck, head, face, eyes, pharynx, and larynx. I confess that this seems to me the most natural explanation of the symptoms of tetany as they are seen clinically. Why irritation should in these cases affect more particularly the anterior gray cells of the cord and bulb, is, of course, quite as inexplicable as why it should affect certain gray centres in the brain in cases of epilepsy; but for the present all these final reasons altogether escape our grasp.

The *diagnosis* of tetany is not always easy, except in very pronounced or typical cases. Buzzard, a careful observer, has recorded a case as one of tetany, which was evidently, from his own description, one of hysterical contracture. The patient was a Jewish girl, aged ten, who had suffered for three weeks from persistent tonic contraction of the flexor muscles of the upper and lower extremity; there was some œdematous swelling, and over the knuckles a slight flush of redness, which made the case look like one of acute rheumatism. No intermission of symptoms was observed, nor did the muscles become relaxed during sleep. In a day or two, however, she began to improve, and had no return of the spasm. The chief feature of tetany therefore, viz., the intermittent or paroxysmal nature of the muscular spasm, was absent, and the case cannot, therefore, be said to have been one of tetany. We have, indeed, in the diagnosis of this disease, to rely chiefly upon the paroxysmal occurrence of the spasms, the peculiarity that they spread in a direction from the periphery to the centre, on Trousseau's symptom of potentiality of spasm, which is elicited by compression, and on the electrical and mechanical convulsibility of the nerves and the muscles.

It is not likely that tetany should ever be confounded with epilepsy, as there is never any loss of consciousness in the former, and the whole group of symptoms of the epileptic fit is totally different from that of tetany. In Jacksonian epilepsy the symptoms are likewise widely different, and I should not refer to it if I had not known of a case in which this mistake was made by a practitioner. I will, therefore, say that in Jacksonian epilepsy there are tonic or clonic spasms, which generally affect, not symmetrical parts, but one upper, or one lower extremity; that they begin most frequently in the fingers, and travel from there upward to the face, and sometimes end in general convulsions; that after the fit there is paresis in those parts which have been convulsed, and that this paresis eventually merges into paralysis; that, where general convulsions occur, consciousness is lost; and that after the parts have become paralyzed, they are still liable to be convulsed. In addition to these symptoms we generally find also headache, optic neuritis, and vomiting, pointing to the formation of a tumor in the brain, or some allied structural disease of the organ.

Spinal meningitis has also been occasionally mistaken for tetany; yet the difference between the two conditions is likewise very striking. In meningitis we have fever, severe pains in the back; no such periodical remissions of the muscular spasms as in tetany; no Trousseau's symptom; and no increased excitability of the nerves to electrical or mechanical tests; and frequently headache, vomiting, and a small and often slow pulse. Some forms of *acute rheumatism* have been confounded with tetany, but attention to the points which I have repeatedly named as characteristic of tetany will always settle the question. In some forms of *ergotism* spasms have been observed which resemble those of tetany; but ergotism is habitually endemic; it is generally connected with symptoms of spinal degeneration, such as loss of knee-jerk, lightning pains, impaired coördination, and not unfrequently with epileptiform convulsions. Localized convulsions, such as histri-

onic spasm, torticollis, and convulsions in some individual muscles of the extremities, have also been occasionally described as tetany, but only from ignorance. Lastly, *tetanus* affects more especially the muscles of the jaw, tongue, pharynx, larynx, the neck, body, and the abdomen; reflex excitability is increased throughout the system; when the extremities are affected, it is chiefly the extensors; and the fingers and hands, which suffer more particularly in tetany, are spared in tetanus.

This seems to be the most fitting opportunity to speak of tetanilla, or Friedreich's paramyoclonus multiplex, as another form of muscular spasm which is not very uncommon in practice. I have seen the complaint especially in neurotic subjects, frequently with a history of masturbation and inherited nervous affections; and between the ages of fourteen and fifty-four. All the patients were males, and no particular exciting cause could be discovered. It differs from tetany chiefly by the convulsions being clonic, and by the absence of prolonged muscular rigidity, and of Trousseau's symptom. The convulsions are, moreover, generally symmetrical; they cease during sleep, and do not impair motive power or coördination. The nutrition and electrical reactions of the muscles are normal, but their reflex excitability is increased, the knee-jerk more especially being greatly exaggerated.

The degree of spasm varies considerably, being in some cases slight, and in others of considerable severity; in some temporary and in others almost incessant. All the muscles of the body may be affected, either simultaneously or successively. The spasm very commonly affects the adductor of the thumb and the interosseous of the first finger, so that a movement as that of holding the pen for writing is produced, and the bellies of these two muscles are distinctly seen to contract under the skin. Each contraction lasts five or six seconds, is entirely painless, and is presently succeeded by a variable number of other contractions, of which, however, there are rarely more than six or seven. After this there is an interval of rest, and then a further similar set of contractions. Other muscles which suffer frequently are the deltoid, the rectus femoris, the flexor muscles of the legs, the orbicularis of the lips and eyes. Of the latter muscles, generally only small portions are affected; for instance, the parts immediately adjoining the commissure of the lips, which are spasmodically contracted for a few seconds, then relax and repeat this performance five or six times consecutively, after which the muscle is quiet for a few minutes, and then begins to play again.

In other cases the spasm is much more violent, and spreads over a much larger number of muscles. There may be a more or less constant clonic convulsion in the muscles of the face, neck, chest, and abdomen, as well as of the limbs, and which is occasionally intensified by more powerful contractions of individual muscles, by which the head may be suddenly pulled to the side or backward, the eyelids closed, a sudden inspiration like singultus may be caused, and arms and legs thrown about. Perfect rest generally eases the spasms, while walking, using the hands, etc., is apt to increase them; and the patient may, therefore, be more or less disabled from following his occupation.

In one of my cases, that of a cabinetmaker, aged twenty-six, the right upper extremity was the exclusive seat of these clonic convulsions, which were quite sufficiently strong to throw the limb about in all directions, generally lasted two or three minutes at a time, were succeeded by four or five minutes' rest, and then began again. This man was utterly unable to earn his living through this most annoying affection. But it is chiefly the influence which the recurrence of such symptoms has on the mind of the sufferer that is of importance. One of my patients, who suffered in this way, had been told that it was a sign of beginning progressive muscular atrophy; and as he had suffered from syphilis, and was in a low state of health, this prediction made him quite hypochondriacal. Another patient, a medical man, who had read about Jacksonian epilepsy without having seen a case of it, believed that these clonic spasms were the first symptom of tumor of the brain, and that he was on the high road to become blind, epileptic, and imbecile. A third patient, likewise a medical man, had given up a large practice on this account, and gone abroad, being convinced that he was suffering from brain disease.

It is, therefore, important to know the differences which exist between the muscular twitches seen in progressive muscular atrophy, the spasms observed in Jacksonian epilepsy, and the clonic spasms of tetanilla or paramyoclonus multiplex.

The twitches or fibrillary motions of muscular fibres which are seen in patients suffering from progressive muscular atrophy, are generally of a sluggish and worm-like description. There is nothing sudden or actually spasmodic about them, and as they affect more or less individual fibres only, they are not in general sufficiently powerful to cause movements of the limbs or any parts of them. They come and go, are easily excited by passing the finger-nail over the affected limb, or by exposure to cold, and are essentially diffuse in character. They must be considered as a sign that degeneration has been set up in the muscular fibres, and have in general a bad prognostic significance showing that the disease is progressing. I need not further dilate upon the complete difference which exists between them, Jacksonian epilepsy, and tetanilla. The spasms of the latter are certainly not forerunners of any serious cerebral or spinal disease, for in one case which I have seen, they first occurred at sixteen years of age and subsequently at various times; at fifty-four years, however, the patient was still in good health, although occasionally subject to attacks of this kind, which sometimes lasted for a few weeks, and then ceased. All my other cases have recovered. These spasms, I believe, to be owing to a similar, although much slighter degree of irritation in the giant cells of the anterior gray matter of the cord than those of tetany.

The *prognosis* of tetany is generally not serious, except in very young children who have no power of resistance, and where spasm of the glottis or general convulsions are often so easily induced. It is also not favorable in persons who are extremely cachectic, and reduced in strength. In most cases,

however, tetany is not a dangerous complaint, and the patients recover in two or three months, more especially if placed in favorable circumstances.

For the *treatment* of tetany, Trousseau recommended bleeding and cupping of the spine; yet he mentions a case in which, by bleeding, the affection was made much worse and more general. At first the patient only suffered in his hands, so that the fingers were clenched and useless; but after the bleeding, the other parts of the limbs as well as the muscles of the body became affected, so that he sat quite motionless, and could hardly speak or breathe. In the present day bleeding is not likely to be resorted to, more especially as the patients are habitually in a state of exhaustion, through persistent diarrhœa, or when convalescent from acute disease. Just on the contrary it should be our endeavor to build up the constitution of the patient, by removing him, if possible, from his habitual injurious surroundings, by giving him nutritious and easily digested food, and such remedies as cod-liver oil, phosphorus, and arsenic. In recent cases in which exposure to cold and wet appears to have been the cause, the Turkish bath or a wet-pack, ammonia and opium should be used. Where diarrhœa is present, astringents, more especially opium and aromatic sulphuric acid, are to be given. Where worms are suspected, the usual anthelminthic remedies find their appropriate sphere of action.

As direct sedatives, hydrate of chloral and urethan act better than hypodermatic injections of morphia. Those highly popular remedies, iodide and bromide of potassium, have also been called to our aid, and have proved useful in some cases. Electricity has frequently been employed without success, when applied to the affected nerves and muscles; while the application of a large anode to the spine with the cathode at a distance, seems to be much more useful as having a sedative effect on the unduly excitable gray cells. For cutting short an individual attack of tetany, which threatens life through involving the larynx and diaphragm, I know nothing equal to a subcutaneous injection of pilocarpine, which seems to act like magic. As soon as profuse perspiration is established, the spasm ceases, and the patient is rendered comfortable.

The treatment of tetanilla should be chiefly mental. The patient must be assured that there is nothing serious the matter with him, and that his brain is unaffected. Electricity, used in the way just described, and Paquelin's cautery are other appropriate remedies, and rarely fail to cure an affection which, while it is apparently insignificant, yet suffices to make life utterly wretched for these patients, and has driven some of them close to committing suicide. Indeed, there is nothing really insignificant in the practice of our profession, as slight causes may lead to grave results, often through the agency of the imagination.

COCAINE IN OBSTETRICS.

By BARTON C. HIRST, M.D.,
ONE OF THE VISITING PHYSICIANS TO THE MATERNITY HOSPITAL.

In the wards of the Maternity Hospital I have had an opportunity of using cocaine in a sufficiently large number of cases to convince myself of its efficiency in alleviating, if not entirely annulling, the pain of the second stage of labor, especially in its latter part, when the child's head begins to distend the lower portion of the vagina and the perineum. To still the cramp-like pain of the first stage of labor, I believe chloroform will still be found to be best.

From the notes of a number of cases, I select the two following:

Case I.—A. B., primipara, æt. twenty-two; labor began at 3 A.M. July 27, 1886. As the cervix was being dilated, and the head began to descend, the woman showed signs of great suffering, threw herself about the bed, became livid in the face; at 5 P.M. the first application was made; almost immediately the patient became quiet, and remained so till the birth of the child, of which she said she was hardly conscious; in all, there were four applications made from 5 P.M. to 8 P.M., the hour of the birth.

Case II.—Mrs. D., æt. twenty-four, primipara; labor began at 6 P.M. August 9, 1886. Os fully dilated at 1 A.M. August 10th. Child delivered at 5.55 A.M. As the head began to descend, and from then till the birth of the child, cocaine was applied every half-hour; for that length of time the woman, who was quite intelligent, said that the local anæsthesia was almost complete; at the end of that time, however, the effect of the drug seemed to wear off. The preparation used was an ointment of the strength of four per cent., applied with the finger, as evenly as possible, to the mucous lining of the vagina and to the skin of the perineum.

TWO CASES OF HEMORRHOIDS CURED BY INJECTIONS OF CARBOLIC ACID.

By GEORGE E. READING, M.D.,
OF WOODBURY, N. J.

My first experience with this treatment was a little more than one year ago, when a patient, Mr. H. V. R., presented himself to me with the statement that he had long been a sufferer from internal piles, and that while spending some time in Denver, Colorado, the previous winter, he had been operated upon by a surgeon, who injected something into the piles which made them grow smaller. Being summoned home suddenly, he came to me to have the treatment finished.

Upon looking up the method of treatment in Gross's *Surgery*, I found that it is passed by with the slight mention that it consists in injecting six or eight drops of the pure liquefied acid. I accordingly did this with the effect of causing great swelling with subsequent sloughing of the tumor and the formation of an ulcer, which, however, healed kindly in about a week.

The patient said that he experienced much more pain from the injection, which I practised, than from those used by his physician in Denver during his treatment there.

This was the state of my knowledge of this treatment until I saw, in the *American Journal of the Medical Sciences* for July, 1885, an article entitled "The Treatment of Hemorrhoids by Injection," by Charles B. Kelsey, M.D., of New York.

From that I found that my mistake had been in using too strong an injection, and that, for soft internal piles, such as my first case, solutions of the acid of from fifteen to thirty per cent. were quite sufficient, and would cause much less pain and swelling.

My next case was one which gave this treatment as severe a test as it will often be subjected to.

Mrs. M. E. H., aged 35, widow, consulted me on May 12, 1886, with this history. She had suffered from piles as long as she could remember, having frequent attacks of inflammation, during which she suffered intense pain while walking or at defecation.

Upon examination I found a tumor the size of a shelled walnut protruding from the anus. The patient stated that it had not been returnable for several years. The tumor had evidently undergone fibrous change, and was very hard and firm.

I made an injection of six minims of the pure liquefied carbolic acid, choosing this because of the great firmness of the tumor. At the end of four days I made another similar injection, and upon making my third visit, one week after the first, I found that the tumor had markedly decreased in size and had become much softer.

I now began the use of a fifty per cent. solution, and made two injections per week for three weeks (making eight injections in all), when the tumor had entirely disappeared; and this had occurred without confining the patient to bed for more than an hour or two after each injection, and throughout she had been enabled to attend to her household duties, including the care of two children. The patient voluntarily stated that she had actually suffered less during the four weeks which the treatment lasted, than she had the preceding four.

For the details of this method of treatment I refer the reader to Dr. Kelsey's article.

MEDICAL PROGRESS.

Chorea cured by Gymnastic Exercises during Hypnotism.—Dr. Riccardo Pari (*Lo Sperimentale*, July, 1886) gives a very careful and detailed account of a case of chorea in an Italian girl æt twelve. When it came under his notice it was not otherwise remarkable except that it had lasted for four years. It came on after a sharp attack of scarlet fever, and there was no accompanying rheumatism or hysteria of any sort. Careful hygiene had been kept up, and treatment by electricity, tonics and arsenic, fully tried. When examined in October, 1885, there was no anæmia, no cardiac abnormality, or other morbid physical signs beyond moderately severe bilateral chorea. In recent medicine there are some cases of chorea cured by suggestion in hypnotism, and this was first tried by Dr. Pari. The girl was hypnotized by making her gaze fixedly at something in her hand, and it was strongly urged upon her when she was in the hypnotic condition that she should have no more chorea. Two such attempts had no success, which was ascribed partly to her distrust in all methods of cure after her long experience. Then it was remembered how useful gymnastics had been in the cases of Hasse, and at the third hypnotic sitting this idea was taken up, and she was ordered to hold out her arm and keep it still. There was slight tremor after six or seven minutes (when the muscles in a normal state generally begin to grow exhausted), but she was ordered to keep it still, and succeeded in doing so for much longer. In subsequent sittings, she obeyed orders to keep both arms outstretched for a quarter of an hour without tremor, to walk quietly, to stand still in all varieties of positions, first on one leg, then on the other, etc. Between the sittings there was gradual improvement, and after twenty of them she was quite well.—*The Practitioner*, October, 1886.

Use of Cold Inhalations in Fever.—Woitkewitsch records the treatment of fifteen fever patients by inhalations of cold air. Eleven of the patients suffered with typhoid fever, one with pleuritis, and one with pneumonia. The observations were seventy-one in number. The air respired was cooled by a special apparatus to temperature from 25° to 31° F. The duration of each application of the treatment was from fifteen minutes to three-quarters of an hour. The author's conclusions are as follows:

1. The patients' temperature was diminished but little by this treatment, and only for a short time.

2. The frequency of the pulse and respiration is notably diminished.

3. The general condition and sleep are temporarily improved.

4. The symptoms of bronchial catarrh were diminished to a remarkable degree.

5. No harmful results of this treatment were noted in any case.—*Centralblatt f. d. gesammte Therapie*, Aug. 1886.

The Decomposition of Ergotine Solutions.—As the result of elaborate bacteriological studies, Engelmann, of Kreuznach, presents the following conclusions:

1. Pure ergotine, unmixed, and dispensed in sterilized glass, may be preserved almost indefinitely.

2. Aqueous solutions of ergotine undergo a more or less speedy decomposition. This is due to the action of microörganisms.

3. Such solutions, when introduced subcutaneously, induce varying degrees of inflammation.

4. The addition of antiseptic agents to such solutions, as ordinarily practised, only delays the decomposition.

5. In order completely to prevent the development of living ferments, the antiseptic must be added in quantities which are directly irritating, and which, in frequent use, are not indifferent in their action upon the organism of the patient.

6. Ergotine solutions may be quite far advanced in decomposition before the eye can detect such change.

7. Ergotine may be most advantageously administered subcutaneously, when dissolved in water previously sterilized by a half hour's boiling.

8. The solution may be best effected in the syringe itself.

9. The distilled water of the apothecaries usually contains bacteria, often to such an extent that from a single drop there may be cultivated upon the gelatine plate many thousands of colonies.

10. In all solutions of drugs to be used subcutaneously,

it is therefore advisable that the water should be sterilized by prolonged boiling just previous to its use.

11. The decomposition of pure ergotine has been found to be due to bacterial impurities on the glass vessels used. A large number of microörganisms cause decomposition in the solutions; the ordinary bacteria of decomposition, however, are the most active.—*Deutsche medicinische Wochenschrift*, Sept. 30, 1886.

THE DIETETICS OF PULMONARY PHTHISIS. — DR. ALFRED L. LOOMIS writes as follows in the *Journal of Reconstructives* for October, 1886:

Some of the most important rules which govern the dietetics of phthisis may be formulated as follows:

1. Every phthisical patient should take food not less than six times in the twenty-four hours. The three full meals may be at intervals of six hours, with light lunches between.

2. No more food should be taken at any one time than can be digested easily and fully in the time allowed.

3. Food should never be taken when the patient is suffering from bodily fatigue, mental worry, or nervous excitement. For this reason, midday naps should be taken before, not after, eating. Twenty to thirty minutes' rest in the recumbent posture, even if sleep is not obtained, will often prove of more value as an adjuvant to digestion than pharmaceutical preparations.

4. So far as possible, each meal should consist of such articles as require about the same time for digestion, or, better still, of a single article.

5. Within reasonable limits the articles of any one meal should be such as are digested in either the stomach or intestine alone—*i.e.*, the fats, starches, and sugars should not be mixed with the albuminoids, and the meals should alternate in this respect.

6. In the earlier stages the amount of fluid taken with the meals should be small, and later the use of some solid food is to be continued as long as possible.

7. When the pressure of food in the stomach excites cough, or when paroxysms of coughing have induced vomiting, the ingestion of food must be delayed until the cough ceases, or an appropriate sedative may be employed. In those extreme cases where every attempt at eating excites nausea, vomiting, and spasmodic cough, excellent results are attained by artificial feeding through the soft rubber stomach tube.

8. So long as the strength will permit, assimilation and excretion must be stimulated by systematic exercise, and when this is no longer possible, the nutritive process may be aided by passive exercise at regular intervals.

The following may serve as a sample menu for a day in the earlier stage. The meat soup is made by digesting finely chopped beef (1 lb.) in water (Oj) and hydrochloric acid (5 ℥) and straining through cheese cloth.

Menu.

On waking.—One-half pint equal parts hot milk and vichy, taken at intervals through half an hour.

8 A.M.—Oatmeal with abundance of cream, little sugar; rare steak or loin chops with fat, cream potatoes; soft-boiled eggs, cream toast; small cup of coffee, two glasses of milk.

9 A.M.—Half ounce cod-liver oil, or one ounce peptonized cod-liver oil and milk.

10 A.M.—Half pint raw meat soup; thin slice stale bread.

11–12.—Sleep.

12.30 P.M.—Some white fish; very little rice; broiled or stewed chicken; cauliflower; stale bread and plenty of butter; baked apples and cream; milk, Kumyss or Matzoon, two glasses.

2 P.M.—Half ounce cod-liver oil, or one ounce peptonized cod-liver oil and milk.

4 P.M.—Bottle Kumyss or Matzoon; raw scraped beef sandwich.

5.30–6 P.M.—Rest or sleep.

6 P.M.—Some thick meat or fish soup; rare roast beef or mutton; spinach; slice stale bread; custard pudding; ice cream.

8 P.M.—Half ounce cod-liver oil, or one ounce peptonized cod-liver oil and milk.

9–10 P.M.—Pint iced-milk; cup meat soup.

1–2 A.M.—Glass milk, if awake.

ACORN COCOA IN THE TREATMENT OF DIARRHŒA AND VOMITING IN CHILDREN.—Acorn cocoa is a preparation of ordinary cocoa powdered and freed from fat, to which are added the soluble parts of roasted acorns without cellulose, and a little sugar and roasted flour. Liebreich suggested this combination, and that it should be tried in the treatment of diarrhœa and vomiting of children, and it was found that of one hundred and two cases of diarrhœa with vomiting only six died, and the remainder recovered in from one to eight days. This combination is now manufactured as a substitute for tea coffee, or cocoa, and is refreshing, tasty, and nutritive even for adults. DR. F. W. ELSNER (*Australasian Med. Gazette*, June, 1886) has also had a considerable experience with this remedy in this class of cases, and has obtained marked success by its use. His mode of administration was to mix a teaspoonful of it with cold water in a small cup, and then to boil it, constantly stirring, and this quantity is administered thrice daily by means of a spoon or feeding-cup. All other food and medicine is prohibited, and the quantity may be gradually reduced. Dr. Elsner has notes of twenty cases of continuous and exhausting diarrhœa with persistent vomiting, which had continued for three weeks in two cases, and for shorter periods in the others. In half the cases various remedies had been employed before the acorn cocoa was administered; in the others, however, it was the first drug given, and its effect was rapid and complete in each instance, and it never took more than two days to bring about improvement, while twelve days was the outside limit of time in which a complete cure was effected.

SOLANINE.—GENEUIL has made an elaborate study of the physiological effects and therapeutic applications of solanine, and arrives at the following conclusions:

1. Solanine is a poison to the terminal plates of motor nerves. Its action is narcotic upon the medulla, cord, and trunks of both sensory and motor nerves.

2. Solanine may be prescribed without danger in relatively large doses. Its action is not cumulative.

3. It causes no cerebral congestion, even in the aged.

4. Its use is indicated in all diseases in which there is to be combated excitement, pain, or spasm. It has been employed with success in various forms of rheumatism, asthma, sciatica, and various neuralgias. The aggregate daily dose is from one to seven grains, by the mouth or hypodermatically.—*Bulletin Général de Thérapeutique*, September 30, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 30, 1886.

THE BILOXI FEVER.

THE difficulty which exists in forming a judgment as to the precise nature of a fever which seems to have been prevailing in Biloxi, Mississippi, for the last two months; and the controversy which has occurred about it, illustrate phases of human nature with which sanitary officials of practical experience soon become familiar. Biloxi is a small town on the Gulf Coast, on the Mobile and New Orleans Railroad, lying nearly opposite to Ship Island. About the end of August last several cases of fever occurred there, with two or three deaths, and it was rumored that these were cases of yellow fever. An investigation was made by members of the Louisiana Board of Health, resulting in a decision that it was sufficiently probable that the disease was yellow fever to warrant the establishment of non-intercourse with the town. The local physicians, however, maintained that it was not yellow fever, and in this opinion Dr. Godfrey, of the Marine-Hospital Service, concurred, after a visit to the place. This opinion of Dr. Godfrey was accepted as final, the quarantine was raised, and the inhabitants of Biloxi were highly indignant at what they claimed was the entirely unnecessary injury which had been inflicted on the business interests of the town. For about a month nothing more was heard of the matter; but, within the last ten days, startling rumors began to appear in the press, to the effect that the fever had spread so as to affect nearly all the inhabitants of the town, that there were many deaths, that the dead were being buried at night for purposes of concealment, etc. It was also reported that the local physicians were divided in opinion as to the nature of the disease. Upon this the Louisiana Board of Health again declared quarantine against Biloxi.

Subsequent reports indicate that there has been much exaggeration in the recent rumors about the Biloxi fever, and, with our present knowledge, its precise nature must be considered as uncertain. Now, why is this? What is the reason that in the presence of over fifty cases of fever which has produced fifteen or twenty deaths, physicians should find themselves unable to agree as to whether the disease is specific yellow fever or not? and why is it that there is such general distrust of the opinions of local physicians, when these take the ground that the disease is not yellow fever? It would seem that one great reason for this uncertainty is the lack of complete and reliable clinical records, and of post-mortem examinations. If the physicians of Biloxi have kept proper temperature records, and records of the condition of the urine as regards albumen, there should be little room for difference of opinion after comparing such records of thirty or forty cases, and their publication would be the most satisfactory means of settling the question. That the decision as to the nature of a suspicious outbreak of fever at any point on the Gulf Coast must turn very largely on such records is well known to physicians in that locality, and hence the neglect to publish them when disquieting rumors arose, is in itself a suspicious circumstance.

It must be remembered that the inhabitants of a town thus affected, and the health authorities of neighboring towns and States look at the matter from almost totally opposite points of view. The first say, "You have no business to interfere with our commerce until you can prove that this is yellow fever." The second say, "It is our duty to act as if this is yellow fever, until you prove that it is not." Really the interests of both parties are one and the same, and demand the fullest publicity of details in such cases as this. The publication of mere opinions, that Dr. A. thinks it is malarial fever, and Dr. B. is sure that it is not yellow fever, have little effect in quieting apprehension, not nearly so much as the publication of the temperature records of three or four cases would do.

Fortunately it is now so late in the season that there is little reason to fear serious spread of the Biloxi fever, even if it be true yellow fever. Whether it be merely malarial fever or true yellow fever, the people and physicians of Biloxi would have done well to furnish full and accurate information to the public as to the nature and progress of the disease from the very commencement of the appearance of disquieting rumors.

TUBAL PREGNANCY.

IT must be admitted that our knowledge of the determining causes and of the diagnostic signs of tubal pregnancy is still far from complete; we are

prepared, therefore, to welcome any additional information that may be gained from a study of these cases. A valuable addition to the literature of this subject is made by Dr. Wyder, of Berlin, in the *Archiv für Gynäkologie*, Heft iii. Band xxviii. It is based upon a most exhaustive study of five cases, each presenting many interesting features, which have been minutely observed and carefully recorded. Indeed, the report might serve as a model to those members of the profession who, having an opportunity of seeing such cases, should wish to publish the results of their observation. Thorough reports, of single cases, although not conclusive in themselves, would, when taken in conjunction with many others, soon give us a mass of material from which we could formulate definite laws in regard to the etiology, diagnosis, and treatment of a condition as yet not fully understood, although its results are usually so disastrous, and the necessity for active interference on the part of the physician is often so urgent.

The fact that the profession is not yet in a position to diagnosticate extrauterine pregnancy with certainty, is well illustrated by five cases reported by Dr. Wyder Three were falsely diagnosticated, one, it is true, by a student; but his mistake was natural: there was a history of cessation of the menses for two months, an enlarged uterus, considerable hemorrhage, and a mass, which subsequently proved to be the decidua, was projecting from the external os. While waiting for the further progress of what was thought to be a case of abortion, the woman suddenly exhibited all the symptoms of internal hemorrhage and shock, and in a few minutes was dead. The post-mortem examination showed that there had been a tubal pregnancy, with rupture of the sac and escape of a large quantity of blood into the peritoneal cavity. A more careful examination during life would have revealed, of course, a tumor in the immediate neighborhood of the uterus, but to have differentiated this from a small cyst of the ovary, or from a simple collection of fluid in the tube, would have been difficult. Had the diagnosis been made, however, and had it been followed immediately by an operation for the removal of the tube, the woman's life would probably have been saved. As soon as the sac had ruptured, with the ensuing symptoms of internal hemorrhage and collapse, the diagnosis should have been made with some degree of certainty, and immediate laparotomy would have been the only measure offering much hope of relief. Of the two other cases in which the tubal pregnancy was overlooked, one was declared by staff-surgeon Bungeroth, of the Charité, to be an ovarian cyst, while the other in the clinic of Professor Winckel, then of Dresden, was diagnosticated, simply, as retrouterine hæmatocele.

Of these five cases, three recovered, one owing to an operation performed for what was supposed to be an ovarian cyst. The tumor removed from this last case, and the preparations from the two fatal cases, revealed some very interesting pathological conditions. In one case there had been undoubtedly an "outer migration" of the ovule from the right ovary through the abdominal cavity to the left tube; while in one of the others there had been an "inner migration" of the ovule from the left ovary through the left tube, across the cavity of the uterus, and into the right tube, where it had become impregnated. Only two well-authenticated cases of this kind have been reported,—one by Schultze, in the *Würzburger medicinische Zeitschrift*, 1863, Band iii., the other by Hassfurther, in his inaugural dissertation at the University of Jena.

Dr. Wyder's theory that the uterus is the "meeting place" of ovule and spermatozoa is opposed to the opinion held by the majority of the present school of German gynecologists, but he certainly presents strong arguments for his view of the case. The appearance of the cilia on the uterine mucous membrane at puberty, and their action from without inward, would seem to indicate that they are intended to assist the progress of the spermatozoa, while they prevent the too rapid descent of the ovule toward the cervix. On the other hand, the cilia of the tubes, which are present from birth, act in the opposite direction—that is, from the ovary toward the uterus—and this, in conjunction with the sinuosity of the passage and the peristaltic movements of the tubes toward the uterus, would seriously retard the progress of the spermatozoa, in spite of their inherent power of motion. Moreover, coitus usually taking place after, and not during menstruation, the spermatozoa will find the ovule already in the uterus, for it can be pretty clearly shown that the passage through the tubes by the ovules is accomplished within four or five days, while ovulation, as is generally admitted, occurs at the beginning of menstruation.

The well-known fact that coitus at any time may be followed by pregnancy, can be explained in two ways: either that the ovum, having reached the uterus, retains its vitality during a whole intermenstrual period; or that the spermatozoa retain their power of impregnating the ovule for some time after being deposited in the uterus. In this connection, Hausmann (*Ueber das Verhalten der Samenfäden in den Geschlechtsorganen des Weibes*) reports a case in which the spermatozoa were found in full activity eight days after the last coition. This subject is an interesting one, and presents a fine field for further investigation, which may, perhaps, prove that Dr. Wyder's theory is more nearly correct than the belief, at present prevalent, that the ovule becomes impregnated before reaching the uterus.

THE CREMATION OF TOWN REFUSE.

The satisfactory removal of town refuse would appear to be a problem most difficult of solution, if we may judge from the experience of American cities. And yet there is no valid reason why success in this important branch of civic sanitation should not be achieved, if proper skill and the necessary resources were devoted to the accomplishment of this object. Feasible plans embracing schemes for the inoffensive utilization or destruction by fire of these waste matters have been proposed, and, in some instances, have been adopted on a small scale, with a show of success, but no large city has hitherto ventured upon the experiment.

Under the present methods no satisfactory means exist by which dry refuse can be immediately and safely disposed of, and consequently our suburbs are burdened with deposits of decaying and fermenting matters which pollute the air with their foul odors, and otherwise give rise to grave complaints. Very recently public attention has been directed to this subject by the disgusting nuisance created in the outskirts of a prominent city by the improper disposal of kitchen refuse, and fresh interest has been imparted to the question of disposal by fire.

If sufficient revenue can be derived from the products of cremation to reduce the cost of this method within reasonable limits, the chances of its adoption will be greatly improved. There can be no doubt as to its superior advantages from a sanitary standpoint. The effort now being made on a large scale at Pittsburg, Pa., to test the practicability and advantages of cremating the entire refuse of a town, will be watched with intense interest, as the results of the experiment, if successful, will go a great way toward inaugurating a reform in methods which have hitherto been the opprobrium of the sanitary management of every city in the land.

POISONING BY OYSTERS.

A very interesting account of several cases of poisoning in which the results were directly traceable to the ingestion of stale oysters, is given by Dr. Bardet, in the October number of *Les Nouveaux Remèdes*.

On the first of last September, a vender of oysters passed through a small town in Brittany, and emptied his basket in selling to eight families. The first two families, who received oysters taken from the top of the basket, and presumably fresher than the others, suffered no harm. In each of the remaining six families, from one to four members were taken violently ill, in from fifteen to twenty-two hours, with colic, intense vomiting, and purging. The matters vomited contained bile but no food, showing that gastric digestion of two meals had been completed before the attack. Despite active treatment intense depression and atrocious colic persisted for several days. It seems clearly shown that the trouble was not due to putridity of the oysters themselves, for they were observed to be alive and apparently in good condition, though not of entirely agreeable taste.

The theory that these cases of poisoning were due to some alkaloid of decomposition, would seem to be negatived by the length of the interval between ingestion and illness. This point is one which clearly separates these cases from those of poisoning by mussels. The history, indeed, leads one to suspect the presence of some acute infection of bacterial origin, the incubation period of which would correspond with the interval referred to. Unfortunately, none of the toxic material was retained for study, and a clear field remains open for a most interesting series of experiments and observations upon the etiology of poisoning by oysters.

A REMARKABLE CIRCULAR.

A number of physicians in this city have recently received a circular signed by an "M.D.," as the director of a "maternity home" in New York, which seems to call for some public comment. This institution, of the existence of which we were not before aware, is one in which women, who are about to become mothers of illegitimate children, may get rid of all the inconveniences and responsibilities of motherhood for something more than $100; that is to say for an "entrance fee" of $75, and board at the rate of $10 a week. For the additional sum of $25 the "staff," who are said to be members of the County Medical Society and connected with the colleges and other public medical institutions of the city of New York, undertake to "remove" a child immediately after its birth, so that the mother "need not see it again." In addition to this tempting offer to those who are threatened with becoming the parents of illegitimate children, this circular contains the statement that "uterine cases" will be received at the rate of $25 a week, and that "a special fee will only be required for *capital operations*." To facilitate the complete and quiet accomplishment of the objects of this interesting institution, the circular states: "We are ready at all hours to send one of our physicians or nurses to any railroad depot or steamboat landing, or to *any* place in *any* State, to meet a person coming to our house; also to take charge of a child for adoption, upon receipt of the necessary expenses." These inducements are specifically offered to "unmarried females of respectable family," who are assured that their cases will be managed with perfect secrecy.

The thought which naturally arises after reading

this singular circular is simply this: If it does not propose the most cowardly crimes of this generation, namely, abortion and infanticide, it is very unfortunately worded; while, if this is what it is meant to do, we hope there is law enough, and decency enough, in New York city to break up such an abominable concern. We would also suggest to the New York County Medical Society that its friends would be pleased to hear that it is impossible that any of its members should actually be connected with the so-called "staff" of this institution.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Conversational Meeting, October 13, 1886.

Dr. Charles H. Burnett read a paper on

CHRONIC PURULENT OTORRHŒA: ITS NATURE AND TREATMENT.

(See page 477.)

Dr. Samuel Sexton, of New York, was introduced to the Society. He regretted that the instructive paper of Dr. Burnett could not allow us to go back a little and discuss some of the acute processes which precede chronic disease of the ear. He might perhaps be allowed to make one remark with reference to that matter. In all the cases of inflammation of the ear where we can look into the tympanic cavity and see the seat of the disease, we are generally looking upon a comparatively simple case, which heals rapidly if not too much interfered with by treatment. Where the atrium is thus affected alone, the inflammation usually heals rapidly, but this is not the case in those cases in which the attic of the tympanum is principally affected, where the seat of disease is almost entirely out of the range of view on looking into the ear. It is under such circumstances that we so often have a serious case to deal with, both in acute and chronic inflammations. In those cases where the attic is considerably inflamed, it will be found on looking into the external auditory canal, that the membrana flaccida is red and bulging, and that there is tumefaction of the superior and posterior wall adjacent, sometimes with effusion sufficient entirely to close the canal. It is in these acute cases that, if we make a free incision into the walls of the canal, and into the attic, we shall establish free drainage, and avoid a chronic case. This at least has been his experience. Where there is a run-down condition of the system the result may, of course, be somewhat different.

Dr. Burnett had gone over the subject so thoroughly that he should confine his remarks more particularly to the treatment of inflammation of the attic. The attic and the upper cellules constitute a portion of the upper air tract, and are very liable to inflammation. In the treatment of chronic purulent inflammation, which we have under consideration, the trouble lies with drainage, as it does in the management of a great majority of surgical affections. The compartment above the atrium, and behind the membrana flaccida, which is almost as large as the atrium itself, is cut off by the swelling of the lining membrane of the attic, and drainage cannot take place except through the Eustachian tube; and it is in these cases that we have the periodical gathering and breaking which is so common in protracted cases of middle ear disease. Every time the patient takes a head "cold," the membrane lining the parts is liable to become inflamed, and the space between the ossicles and the inner wall of the tympanum becomes closed, and secretions from above cannot escape. In studying these cases of incurable inflammation of the upper ear tract, he thought that benefit might be derived from an operation, and, six or eight months ago, he began performing this operation, which may be described as follows: In the first place he might say that we should not attempt this operation where the membrana tympanum remains to a sufficient extent to respond to aërial vibrations of sound in any effective manner. In these old cases, however, it will usually be found that the major portion of the membrana vibrans has been destroyed, so that there is no danger of injuring the hearing power of the patient. In these cases the membrana flaccida is usually considerably thickened, and the handle of the malleus is retracted against the inner wall of the drum-head, or, perhaps, partially, or entirely lost from caries. In the majority of cases, the stapes is detached from the long process of the incus. In these cases no harm can be done by excision of the ossicles, and much benefit may be derived by the operation. The first procedure then, consists in detaching the portion of membrana flaccida which remains, from that portion of the tympanic ring formed by the margin of the auditory plate. This is done with a knife that is so placed on the handle that it may be passed around close to the auditory plate with ease. Passing the knife further back, the chorda tympani may be detached on each side. Where the tensor tympani muscle remains, it may be readily divided. Although this step of the operation is simple, it is liable to be accompanied with considerable bleeding. Where there are many granulations in the tympanum, it is well sometimes to postpone the operation until they have been removed to a certain extent by treatment. In order to remove the malleus, he had an instrument made which answers very well. This is passed from behind over the ossicles, and they are drawn downward. When they come into view, they are seized with forceps and easily detached. Having removed these portions, it is well to scrape the attic thoroughly, and remove all carious bone. It will be found that mucous membrane remains on the inner side of the attic. This should be removed with a scraper of another kind, which is a modified form of that often used by dermatologists. Care is to be taken not to injure the oval or round windows while scraping. In these cases, the stapes is rarely found present, except so far as its base is concerned. At first he employed insufflations of salicylic acid after the operation, but he now makes no applications, simply keeping the parts clean. In one or two weeks the parts begin to clean up, and usually before three weeks have elapsed the part is completely covered with a sort of dermoid dry membrane. Where any diseased bone or polypoid tissue remains, as sometimes occurs in the antrum, it must, of course, be removed.

The hemorrhage is at times troublesome, but it is never of a serious nature, and is easily arrested by cotton tampons or by the use of very hot water. In regard to injury of the chorda tympani nerve, it may be said that

there is nearly always more or less disturbance of the function of taste, but in the course of a few weeks this disappears. In one or two cases there has apparently been a descending neuritis which has manifested itself by slight pain in the mastoid cellules extending into the face.

With regard to the treatment of attic cases where the membrana vibrans remains, we frequently meet with cases where the membrana flaccida alone is perforated and perhaps with a polypus presenting at this opening. These cases usually occur between the ages of twenty and forty. They seem to be a continuation of a chronic process in the attic where nature has done a great deal toward healing the parts. Where a polypus presents, the speaker has usually used the biting forceps and removed it, and followed this by the introduction of pure salicylic acid. He sometimes uses it dissolved in ether and applied on a cotton-wool carrier. This will often destroy the base of the polypus. In this way these cases may often be kept in abeyance, and sometimes entirely cured.

In reference to the dry treatment, he thinks that perhaps this has been carried too far. Where boracic acid is allowed to remain in the ear for a length of time it may become a source of irritation. He does not use this remedy as frequently as he formerly did.

These chronic cases, in his experience, are rarely attended with pain, and for that reason are more apt to be neglected. It is only when there is an exacerbation of the inflammation that attention is called to them. Sometimes a polypus becomes inflamed and may cause serious symptoms from pressure. He has seen facial paralysis caused in this way, as well as certain vertiginous symptoms which are quite alarming. Generally, on the removal of the polypus these symptoms disappear.

The question is often asked as to the advisability of leaving cotton in the canal in cases of chronic purulent inflammation of the middle ear. As a rule, he thinks that it is better omitted. So long as there is any hope of healing a perforation it is quite a different matter.

The use of cocaine has not been of as much service in otology as in other departments of medicine. He has tried it for the relief of pain in many operations without success. He has, however, used it with advantage after the removal of a polypus, or after the excision of the ossicles.

In closing his remarks, Dr. Sexton called attention to an instrument which he applied for operation in acute cases of periostitis of the canal and attic. The instruments usually employed are too small and not sufficiently strong to make the required incision. With this knife the incision can be readily made in the walls of the canal and through the membrana flaccida into the attic, thus establishing drainage in these acute cases. It is here that he thinks that the surgery of the future in otology lies. If we can make early incisions and give vent to the pus, we shall have few serious cases. He cannot recall the occurrence of a single case of mastoid disease, so called, where this treatment has been promptly adopted. We have been able to treat these cases much more satisfactorily since the introduction of the electric light. It is a difficult matter always to obtain proper illumination with the ordinary light.

Dr. Harrison Allen suggested that attention be given to that phase of the affection which pertain to a desquamative catarrh which simulates the purulent discharge from an old bone-fistule. When the low degree of vascularity of the temporal bone and all its belongings is considered, it becomes a matter of no surprise to find that the necrotic variety of chronic otorrhœa is probably more frequent than is generally supposed, for it is evident that a discharge may be necrotic without the presence of a tangible sequestrum. Should not the treatment of the discharge, he asked, be based upon the methods employed by the general surgeon in the case of ordinary bone-fistule? Practitioners, he thought, should be less timid in proposing incision of the mastoid region. Dr Sexton has shown the safety of ablation of the ossicles under circumstances which prove that broadly conceived plans of surgical interference are tenable in treating these and analogous conditions directly within the external meatus and its associated approaches to deeper structures.

The term "tubercular catarrh" is a misnomer, unless tubercle can be detected in the middle ear. He might be corrected by Dr. Burnett, but he ventured to say that no deposits of tubercle have yet been demonstrated in the mucous lining of the tympanic chamber. The presence of a purulent discharge from the middle ear of a tubercular subject, is a sign of impending dissolution.

Dr. George C. Harlan said that the plan of treatment which he had adopted in these cases was substantially that recommended by Dr. Burnett. He derived a little more assistance from the patients and their friends than Dr. Burnett is inclined to do. It is often inconvenient to see a chronic case of this kind every day. In the intervals between the patient's visits, he sometimes allows him or his friend to inject with a small syringe, a solution of borax, or boracic acid, or of chloride of zinc. This latter he frequently uses in the proportion of two to five grains to the ounce.

The treatment of those cases to which Dr. Sexton had alluded, has been extremely unsatisfactory. The operation proposed by Dr. Sexton seems to have a sound basis, and to offer some hope of a good result in this class of cases.

With reference to the so-called dry treatment, his experience has been much like that of Dr. Sexton. We should have a definite idea as to the class of cases in which this plan of treatment is to be adopted. He thinks that it is of doubtful utility where there is a considerable portion of membrane left. In such cases the powder cannot reach the seat of disease, and may occlude the opening, preventing the escape of discharge. Nor is it applicable where the discharge is thick or at all profuse.

Some years ago he reported two cases in which death was due to long-standing, uncomplicated, purulent aural catarrh. In one case the pus reached the brain through destruction of the roof of the tympanum, and there was an abscess of the cerebrum. In the other case, it passed through the internal auditory meatus, and produced an abscess of the cerebellum.

Dr. Samuel D. Risley had had no experience with the method of operation proposed by Dr. Sexton, but when a suitable opportunity presents itself, feels disposed to try it. These chronic discharges are not always due to pent-up discharges in the attic, but may be due to damming up of the secretions by the presence of granulation masses blocking up the narrow space between the

tympanic wall and the remaining rim of the tympanic membrane, which it is frequently found necessary to remove by the dry treatment, alcohol, or other applications, so that the pent-up secretions can escape into the external meatus.

The dry treatment still serves him a good purpose. It does not work well in all cases, but he considers it a great advance on former methods of treatment. He still feels disposed to use a pledget of well-selected cotton in the canal. It should not be thrust to the bottom of the meatus except when intended to act as a wick for the removal of the discharge. Properly used it prevents the entrance of dust, foreign bodies, and floating germs.

He wished to allude to the important relation which exists between these chronic discharges and the constitutional troubles from which the patient is suffering. He has a number of cases in which he can find none of the local conditions referred to. There is probably no special attic disease, but these patients suffer from lithæmia. In one instance there is pronounced gout. This patient will get entirely well, and then will have a recurrence of the swollen, tender joints. This will be followed by a discharge from the ears, preceded by the well-known pharyngeal conditions long recognized as associated with lithæmia. This will get better after an immense deposit of uric acid in the urine, or possibly an attack of indigestion. We have of late years come to recognize this relation in the etiology of pharyngeal disease. He is convinced that the disease of the middle ear in these cases of lithæmia, is intimately connected with the general dyscrasia.

Dr. Ralph W. Seiss said that it might be of interest, in reference to the prognosis of purulent otorrhœa to notice some experiments which Dr. Chrystie and himself had made on dogs. The operation consisted in making an incision behind the auricle, then an incision in the membrana tympani, and scratching the membrane of the middle ear, and rubbing into the scratch a small drop of chloroform. This set up a purulent otitis, which was allowed to continue from one to four or five weeks, when the dogs were killed. Some five or six dogs were operated upon. Of this number he thought four had ascending neuritis—having lost his notes, he could not speak positively.

Clinically, there seems but little to add. Sufficient stress has not been laid on the importance of treating the nose in these cases. Many cases occurring in children with a marked nasal catarrh, may be treated indefinitely with remedies directed to the otorrhœa, and receive no benefit. If, however, the affection of the nasopharynx is removed, the otorrhœa will often disappear without special treatment.

Dr. Charles S. Turnbull agreed with the author in nearly all that he had said. His experience had been the same with the dry treatment (boracic acid powder, etc). He agreed with him in his objections to the use of the syringe by the patient or his friends. There is danger even in permitting them to use instillations. He was pleased to learn that there is a chance for some surgery in otology, especially if it be of benefit in these cases. At the same time, he thought there was much guesswork about it. It looks all very well in a diagram, but he was sure that it cannot be performed with ease, or without risk. He considered the procedure heroic.

He has been successful in treating several cases of chronic inflammation of the "attic," by applying a saturated solution of nitrate of silver or carbolic acid to the attic on a cotton carrier, the extremity of which had been bent at a right angle.

With reference to pledgets of cotton or wool in the ear, he thinks that they do more harm than good. The small amount of dust, or other foreign material, kept out, does not overbalance the danger from corking up a pus-secreting cavity.

Those tuberculous cases in which the membrane "melts down," he has felt at a loss to explain, pathologically; but, nevertheless, as Dr. H. Allen has said, he feels that it seals the fate of the patient. In a paper before the State Medical Society, two years ago, he stated that he considered tubercular otitis to be incurable. He recently saw in a medical journal a short article referring to a unique case of exclusion of tuberculous ulceration of the mouth, gums, and lips, under the observation of Dr. J. Solis Cohen. He thought that this might possibly help to explain the manner in which the membrana tympani "melted down" so rapidly in these cases of tuberculous disease—*i. e.*, by similar extension through the Eustachian tube.

Dr. Louis J. Lautenbach said that in the treatment of these cases of ear disease he had employed two drugs which are comparatively new, one of which—the peroxide of hydrogen—was referred to to-night. This may be employed in connection with either wet or dry cleansing and can be used alone or with the dry treatment. It seems to be particularly valuable in cases where the discharge is loaded with pus and when the discharge is thick and ropy. In these cases its use, after water cleansing, is to decompose the adhering discharges, giving a clean surface upon which to apply a remedial agent. In cases of thin, watery, or mucous discharge, the peroxide occasionally cures. This remedy is to be used alone only when the ordinary treatment fails, its chief value being evident when used as a cleanser, preparing the parts for treatment.

In acute exacerbations of chronic purulent disease, as well as in acute cases, he had found osmic acid of great value for the relief of the excessive pain which so frequently is present. He had used this since the 30th of April. At that time he was treating a case of threatening mastoid disease. The man had been suffering with excessive ear pain for more than six weeks, blisters and leeching giving but temporary relief. The pain was excessive; no sleep night or day. Everything seemed without avail; aconite, atropia, cannabis indica, chloral, morphia were used in immense doses without result. Osmic acid having been referred to in a medical journal as having relieved the severe pains of sciatica, was used as a forlorn hope. At 2 P.M. he was given, hypodermatically, directly above the auricle, one-fifth of a grain, and at 4 P.M. the pain was gone. When he saw him in the morning he was astonished to find him without pain, and yet more surprised at the promptness of the drug's action. Since then he has used it upon five cases in doses of one-tenth to one-twentieth of a grain, and has found it to give relief. He had not found it necessary to give more than two injections to any patient.

In some cases of chronic suppuration he has found a small suction apparatus of value. He uses it only

when other treatment seems to fail to arrest the discharge. Apparently it is of no value except as a more perfect method of cleansing, exhausting the ear cavity of any moisture that may remain after the ordinary cleansing.

Dr. Samuel Sexton desired to say one word in reference to the criticism concerning the difficulty of this operation for the removal of the ossicles. Of course, it is not a very simple and easy operation, but it is entirely practicable, and anyone who is familiar with the anatomy of the parts may perform it safely. Very often the handle of the malleus, or long process of the incus, will be found lying on the inner wall of the tympanum, making it difficult to get the instrument behind them. But often by a little manipulation an experienced operator may succeed. He has performed it in over a score of cases, and in not one has there been reason to think that any harm was done. The cases have to be selected. If there is much vascularity, some of the work, of course, has to be done slowly, or the case may require two operations. The operation often requires from one-half to three-quarters of an hour for its performance.

There is one point to which he did not refer, namely, after excision of the ossicles the drum-head is not reproduced. In cases where the drum-head has been destroyed by sulphuric acid or other agents, there has, in some cases, been a complete return of the structure in the course of a few weeks.

In reference to a point mentioned by Dr. Allen, he would say that he had recently a case resulting fatally in which tubercles were found in the temporal and occipital bones. The middle ear was not examined.

Dr. Burnett did not wish his position with reference to operations on the mastoid to be misunderstood. If the cortex is diseased he thinks that it is perfectly proper to remove such diseased bone, but unless it can be shown that to operate upon a healthy cortex will prevent the advance of caries upon the inner wall, he would say that he does not know when trepanation of the mastoid should be performed. It remains to be shown that an advance of necrosis on the inner wall and into the lateral sinus can be prevented by such an operation. If pachymeningitis has ensued an operation on the mastoid is useless.

In regard to tympanic disease occurring in tubercular cases, he would simply refer to a paragraph which, for the sake of brevity, he intentionally omitted in reading the paper.

In using the dry treatment he had not met with any of the objections to which Dr. Harlan had referred. He has yet to see a case of mechanical blocking of the canal by the dry treatment. We must combine the dry treatment with some moist treatment. He never said anywhere that it should be relied upon wholly. There are cases where the syringe must be used, but it should be done by the surgeon. If the treatment is given into the hands of the patient, it will be much protracted.

With reference to the instrumental removal of granulations, he would say that he has never seen good results from this practice. If a granulation is snared off, it will return in a few hours. The granulations must be cauterized with chromic acid or dried up by the dry treatment, or by means of alcohol, which, by its affinity for water, squeezes the life out of the granulation. Cotton may be worn in dry ears but not in running ears.

The constitutional treatment of these cases goes without saying. He has not seen the cases referred to by Dr. Risley in which it was possible to connect so closely the gouty tendency with the aural trouble, as Dr. Risley appears to have been able to do.

He would be unwilling to rely on applications made with a bent probe in the treatment of attic disease. It would be difficult thoroughly to apply the treatment through a small perforation by such means.

He has employed the peroxide of hydrogen for several years. It simply breaks up the pus and is a great cleanser, and is of great service to the aurist on account of the tortuous passages which he must cleanse in order to treat the tympanum. Aspiration is he thinks unnecessary after the use of the peroxide, and if applied under such circumstances it practically amounts to cupping the ear.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 21, 1886.

The President, A. Jacobi, M.D., in the Chair.

GIFTS TO THE ACADEMY.

Dr. George A. Peters, Secretary of the Board of Trustees, announced that $5000, a portion of the sum of $20,000, the bequest of the late Dr. Beadle, which the Academy would ultimately receive, had now been paid.

He also announced that Mrs. Anna Woerishoffer, the widow of the late Mr. Charles F. Woerishoffer, had donated to the Academy the sum of $25,000; this being one-fourth of a memorial fund, in honor of her husband, which she proposed to devote to certain scientific and charitable objects. Dr. Peters read the letter which Mrs. Woerishoffer had sent accompanying the check for $25,000, and also the letter of acknowledgment which had been sent in reply.

Dr. Fordyce Barker offered a series of resolutions, thanking Mrs. Woerishoffer for her munificent gift, and making Mr. and Mrs. Woerishoffer Permanent Benefactors of the Academy, which was unanimously adopted. In offering these resolutions, Dr. Barker remarked that before very long he hoped to see the Academy in possession of a fund of not less than one million dollars, a fund which it needs to place it in the position which the scientific demands of the times require of it.

Dr. Francis Delafield read a paper on

PULMONARY EMPHYSEMA.

He commenced by giving a *résumé* of the varieties, causes, symptoms, physical signs, favorable prognosis, and treatment of emphysema usually given in the text-books; in which it is stated that those suffering from this affection are but little liable to become the victims of phthisis and pneumonia. He then remarked that the student when he got into practice for himself was often surprised to find that the characteristics of the affection, as it actually occurred, according to his observation, did not correspond at all with those set down for it by the great mass of authorities. He would find that it did not necessarily arise in connection with bronchitis, and that playing on wind instruments was not a common cause of emphysema. He would find

that the immunity from phthisis and pneumonia was open to question, and that barrel-shaped chests are not so frequently met with as he had been led to suppose. Moreover, if he made autopsies, he would find that the dilatation of the air-spaces or air-vesicles was by no means always proportionate to the severity of the symptoms that had been present during life.

It is true that chronic bronchitis and attacks of asthma are frequent enough; yet there are other cases in which such conditions are entirely absent, and substantive emphysema is essentially different from what the classical descriptions of it would lead us to suppose. It is, therefore, important to decide what we really do know, and what we do not know, about the disease. It is well, on the whole, to divide the varieties of emphysema, according to the recognized classification, into the interlobular or interstitial and the vesicular forms, and to divide the latter into senile, lobular, and substantive.

Senile emphysema is due simply to a senile change in the parenchyma of the lung, and when it is present there is no obstruction to the passage of blood through the lungs, and no dilatation or hypertrophy of the right side of the heart. Chronic bronchitis is often present, but the affection is not severe, and of no very grave import. In some instances substantive emphysema commences in the earlier portion of life, and as the patient grows older, senile emphysema occurs also. It is not always easy to distinguish between the two, and yet the distinction is very important; for, while substantive emphysema is a very serious affection, the senile variety, as had been mentioned, is not.

Dr. Delafield then went on to say that substantive emphysema is in reality a form of pneumonia. It is, in fact, an inflammation of the same type as that which so often attacks the endocardium, the inner coat of the arteries, the kidneys, and the liver. The walls of the ventricles are first attacked, and while some of them become thickened, others become thin. The dilatation, both of the vesicles and the air-spaces, varies in different cases, and is by no means proportionate in many instances to the severity of the symptoms present. In fact, many of the cases are overlooked at autopsies, because there is no dilatation of the air-spaces visible to the naked eye.

Later on, the emphysema spreads, and attacks other parts of the lungs, including the epithelial cells lining the air-spaces and the mucous membrane of the bronchi. The pleura also becomes thickened, numerous pleuritic adhesions form, and the whole condition is, in short, that of interstitial pneumonia. In the milder cases there is but little disturbance of the circulation of the blood; but in the severe cases this gives rise to the worst symptoms. The right ventricle of the heart becomes hypertrophied and dilated, and venous congestion and dropsy follow. The secondary symptoms are, indeed, the same as those of valvular cardiac disease.

Having referred to the various complications liable to arise, he stated that this affection is one that is very frequently met with in New York; coming on, as a rule, in individuals from forty to forty-five years of age. Hereditary influences are marked. The same causes are active in producing it as in the case of chronic endocarditis, chronic arteritis, chronic nephritis, etc. It is of more importance to recognize the cases of moderate severity than the very bad ones, because in the latter comparatively little can be done in the way of treatment. In the moderate cases there is no change in the shape of the thorax; though in old and aggravated cases the barrel-shaped chest is not infrequently present. The pulmonary resonance may remain unaltered for a considerable time.

Having spoken in detail of the physical signs present, Dr. Delafield said that the emphysema may continue for years without giving rise to any rational symptoms. The condition, however, can be generally recognized by taking into consideration the age and general condition and tendencies of the patient. There are other cases in which the presence of Bright's disease or cardiac trouble causes the emphysema to be lost sight of. The dyspnœa at its worst is constant and extremely distressing. In the bad cases there are also more cough and venous congestion, followed by general dropsy.

The disease may pursue a number of different courses. In the first place, a patient who has suffered a long time from winter cough and is always a little short of breath on making exertion, will at length develop spasmodic asthma. There will follow increasing dyspnœa, loss of flesh and strength, venous congestion, dropsy, and death. Another class of patients will be apparently entirely well, except when they have an attack of acute bronchitis. After a time, however, venous congestion, albuminuria, and dropsy will ensue, as in the preceding variety. Still another class will suffer for years from spasmodic asthma before the evidences of emphysema show themselves. Finally, there is a class of cases in which the symptoms are very slight for a long time; when venous congestion and the other grave symptoms will suddenly become developed. The behavior of the affection is, therefore, on the whole, very like that of the atrophic form of chronic Bright's disease.

In speaking of the treatment, he said that the same general rules, as regards hygienic surroundings, climate, mode of life, etc., which had a favorable effect on the progress of other affections of the same class, such as chronic Bright's disease, etc., are applicable in emphysema. It is a question of some importance whether the dyspnœa and asthmatic attacks which so frequently characterize it, are not due in reality to a contraction of the arteries and capillaries, since it is found by experience that many of the drugs which are the most serviceable in relieving these conditions, are those the physiological effect of which is to produce a relaxation of the walls of these vessels.

The conclusions arrived at by Dr. Delafield were somewhat as follows: Emphysema is not a local chronic disease due to excess of inspired air over expired air, or to fatty degeneration, but a chronic inflammation of the lungs; nor is the dilatation of the air-cells and air-spaces an essential part of the affection. The result of this inflammation is such an irregular thickening and thinning of the walls of the air-spaces as would naturally occasion the dilatation of some of them. The dyspnœa and general venous congestion are not due simply to the dilatation, but to the contraction of the pulmonary blood-vessels. Excessive bodily exertion is not the cause of emphysema. In the treatment the indications are to delay the progress of the chronic inflammation and to

overcome the contraction of the bloodvessels present. Chronic bronchitis is, of course, to receive proper attention.

[At the conclusion of the paper, Dr. Delafield exhibited, by the aid of a magic-lantern, a number of sections of lungs taken from different patients, illustrating the points referred to.]

Dr. E. Darwin Hudson, Jr., said that the author of the paper had given his ideas of emphysema from a pathological point of view. Personally he was more accustomed to regard it from its clinical aspect, particularly in connection with the physical signs to which it gives rise; although he had had the opportunity of studying the disease to a considerable extent in the deadhouse also. This post-mortem experience, however, was, of course, limited when compared with that of Dr. Delafield. He has always looked upon the account of emphysema of the lungs given by Waters, of Liverpool, as affording a very definite and accurate idea of the affection. In the paper of the evening Dr. Delafield had described other diseases, more particularly interstitial pneumonia, with emphysema. He (Dr. Hudson) was still of the opinion, however, that we had to take emphysema as a distinct type, and that it consists essentially in rarefaction of the pulmonary structure, as described in Reynolds's *Practice*, and other standard works. The clinical history of the disease has to be taken into consideration, as well as the pathological conditions found after death. It is very common for women at the climacteric period to become obese and develop emphysema, with the barrel-shaped chest so often described as characteristic of the affection. Here the condition could hardly be due to alteration in the anatomical structure of the lung; though no doubt this was the case in other instances. The results obtained from Voldenberg's apparatus, and more recently from Ketcham's pneumatic cabinet, throw considerable light on the nature of emphysema; which was shown to be a disease in a large number of cases in which there is a loss of elasticity and resiliency on the part of the air tubes and vesicles.

No disease is more perplexing to the practitioner than emphysema. It is too apt to be the case, as Dr. Delafield had remarked, that the student expects to find a uniform character in all the cases; while in reality there is great difference in different cases. For instance, in some the pitch of the resonance is high, while in others it is low.

It is, no doubt, true that in a certain number of the cases of emphysema the gouty diathesis is present, with interstitial disease of the kidneys, or other characteristic lesions; but there are a large number of other cases in which the affection is purely mechanical.

Dr. Charles Heitzman said it was some fifty years since Rokitansky gave to the world an accurate knowledge of emphysema, and that ever since then its pathological and clinical characteristics had been well known. It seemed to him that Dr. Delafield either had not seen a pure case of the affection, or had not demonstrated one. The sections which he had exhibited this evening were certainly not specimens from simple emphysema. As Dr. Hudson had stated, they were emphysema combined with interstitial pneumonia. It was, indeed, not a primary disease, but a secondary one. He had in his possession an ample number of specimens taken from cases of pure emphysema, and they were altogether different from those which Dr. Delafield had shown. His own father, who was now eighty-two years of age, was a good example of typical emphysema. As to the pathology of the affection, as interpreted by Dr. Delafield, viz., that it is due to contraction of the bloodvessels, he did not see why we should go to something which we could not prove for an explanation of the trouble. For himself, he was content to believe in the old view of the affection. As he had said before, the specimens shown were not examples of pure emphysema.

Dr. Delafield said that he was sorry that it had been supposed that he looked at the subject solely from a pathological point of view. He had intended the paper to have a clinical as well as a pathological bearing; and the ideas which he had tried to set forth in it were those which he had formed from a somewhat extended study of the disease, both during life and after death. It was hardly possible to dissociate the two sets of facts, and he did not know that he had anything more to add to what he had already said in the paper. The treatment which was found most effectual in emphysema was certainly fully compatible with the views which he had advanced.

Dr. Van Santvoord said that he had at present under observation two advanced cases of emphysema, which seemed to him to bear out the statement of the author of the paper that the affection is of great gravity in many cases; and since he had been in practice he had found out that many of the teachings in regard to emphysema, which he had heard when a student, are not born out by the facts. He then spoke of the great value, according to his experience, which caffeine had as a cardiac stimulant in these cases. The right heart is frequently embarrassed, and venous congestion is apt to occur long before it could be caused by tricuspid regurgitation, or at least before any tricuspid regurgitation could be recognized by the physical signs. He would like to ask Dr. Delafield his opinion in regard to the value of caffeine.

Dr. Delafield said that he thought caffeine a useful drug. It appears to stimulate the right side more than the left side of the heart, and the same is true of convallaria. Just as is the case in pneumonia, it is, therefore, indicated to stimulate the right heart in emphysema.

The President said that, according to the views which Dr. Delafield had expressed, the iodides which, as is well known, are in common use in this affection, are theoretically indicated in all those cases which occur in connection with chronic inflammation. The benefit which is afforded in chronic asthma, peri-bronchitis, etc., could only be explained on the ground that these agents act as absorbents. He would like to ask, therefore, whether, in every case of emphysema, iodide of potassium ought to do good, because it acts as an absorbent? Also whether all cases of emphysema are of the same character? There are some cases in which the affection comes on very suddenly, as, for instance, in connection with whooping-cough. To some extent the trouble is transient, and to some extent it becomes permanent, and the inflammatory element is not the prominent one.

Dr. Delafield explained that he referred only to chronic emphysema.

Dr. F. H. Castle said that of late calcium chloride,

which had been proposed a long time since in this connection, had been steadily growing in favor for the purpose of causing absorption of connective tissue products. He referred to the value in emphysema of remedies which relax the muscular coats of the bloodvessels, and said that he thought this had a direct bearing on the subject of the paper. For instance, the prompt relief afforded by nitrite of amyl would seem to indicate that the seat of the trouble is in the bloodvessels; for if the dyspnœa is due simply to dilatation, or to the presence of mucus in the air-vesicles, we can hardly account for the favorable action of this remedy.

Dr. Delafield said that he agreed with the President, that the iodide of potassium is one of the most valuable of our drugs in emphysema, and its action may well be supposed to be due to its effect on the bloodvessels, because it is a recognized fact that one of the effects of the iodides is to relax the smaller bloodvessels. Thus it is given in cardiac disease for its effect on the small arteries and capillaries. Another drug of the same class which is of great value is chloral hydrate, which acts in a similar manner. Large doses of chloral are extremely useful in acute attacks of dyspnœa, and small doses in chronic dyspnœa.

A PROPOSED BUILDING FUND.

Dr. C. R. Agnew gave notice of a proposed amendment to the By-laws establishing a building fund for the Academy.

NEWS ITEMS.

MONTREAL.

(From our Special Correspondent.)

Medico-Chirurgical Society.—At the annual meeting held October 8th, the following officers were elected:

President.—Dr. James C. Cameron.

Vice-Presidents.—Dr. George Wilkins, Dr. T. Johnson Alloway.

Secretary.—Dr. R. F. Rutlan.

Treasurer.—Dr. A. Lapthorn Smith.

Librarian—Dr. T. D. Reed.

College of Physicians and Surgeons of Quebec.—At a recent meeting of the Council of the College it was decided to increase the scope of the preliminary examination for admission to the study of medicine. The following compulsory subjects have been added to the already very extended list: elementary chemistry, mental and moral philosophy, and rhetoric. It is felt by the English-speaking members of the profession that the preliminary examination is already stringent enough, as evidenced by the great number of rejections, sometimes as high as sixty per cent. However, their French colleagues think that it is a step in advance and that it will reduce the number of entrances into the profession and so lessen competition. Philosophy being a subject taught in all the French schools and not in the English ones, it is considered by the English minority that the French majority are acting in rather an arbitrary and unjust way, but it appears that the Church demands the change in order to counteract the materialistic doctrines which are being taught in a certain powerful and well-equipped medical school; in this way they hope to protect their flock from that "horrible belief which is now so prevalent in old France and, in fact, throughout Europe," and which the teachers in the aforementioned school acquire when they go abroad to England, Germany, and elsewhere to qualify themselves more thoroughly for the positions they occupy.

After next year every person before being allowed to practise will be obliged to pass an examination in all branches of medical study before an examining board of the College of Physicians and Surgeons. No degree from a reputable British or Colonial university will, as heretofore, be accepted. This new regulation is to be enforced in order to weed out one or two weak colleges which have been granting degrees to irregulars and others throughout the province.

The Fever at Biloxi.—A press dispatch from New Orleans states that the excitement which followed the establishing of quarantine against Biloxi has died out, and the fears that were entertained that yellow fever would be brought to New Orleans from the infected town have passed away. Biloxi is still shut off from the world, and the quarantine against her will be maintained at all places until a heavy frost does away with all danger. The situation in the town is unknown. The telegraph lines have been working uninterruptedly and every newspaper in New Orleans has a correspondent in the place, yet not a word regarding the fever has any paper been able to get for several days. No doubt is entertained that the correspondents, who are residents of the town, have been terrorized and compelled to stop giving out reports.

An Epidemic of Pleuro-pneumonia in Chicago Cattle.—Dr. Salmon, Chief of the Bureau of Animal Industry, in his official report upon the outbreak of pleuro-pneumonia at Chicago, says:

On September 22 I visited the Phœnix and Shufeldt distillery stables in company with the State Live Stock Commissioners and the State Veterinarian. Post-mortem examinations were made on the carcasses of four animals, and in every case lesions were revealed which are considered by the veterinary profession the world over to be typical and characteristic of contagious pleuro-pneumonia. On several subsequent occasions I visited these same stables and witnessed the examination of other carcasses which presented equally plain evidences of the same disease. . . . The milkmen at first stoutly denied the existence of any disease among their cattle, but when the evidence became too strong to be longer contested, it was admitted that they had recognized the appearance of a lung disease in 1884. They at first attributed it to chemicals used in the mash by the distillers, also to feeding the slop too hot, but had finally concluded it was contagious pleuro-pneumonia and had been practising inoculation to lessen the mortality. It was soon ascertained that cattle had been removed from the infected distillery stables, driven over the streets of Chicago and allowed to pasture on the commons. . . . The inspection of city and suburban herds brought out the fact that the contagion had been widely disseminated, that diseased cattle had been running upon lots where many cattle grazed, and that practically we must consider all of the unfenced pastures and vacant lots on the west and south sides of

Chicago as infected, and all the cattle running at large as exposed. Most of the cases of disease found were chronic, and some of the herds presented plain evidence of having been inoculated. The inoculation, which has been extensively resorted to in Chicago, while it has lessened the losses, appears to be one of the means by which the contagion has been so widely spread. . . . With contagious pleuro-pneumonia prevalent in the neighborhood of Chicago—the great live stock centre of the country, from which cattle are constantly moving in all directions—it may be truly said that the cattle industry of this country has reached a crisis. It may be still rescued from this scourge if Congress at the coming session can be made to realize the necessities of the situation.

An Egyptian Medical Journal.—*El thifaa* ("the cure") is the name of the only medical journal published in Egypt. It is printed in Arabic, and published monthly. Its price is thirty-five cents a number. The principal contributors are Egyptians and Syrians. It has proved in every way a success.

Respiration at High Altitudes.—The August number of the *Alpine Journal* contains a statement of the results obtained by Dr. Marcet from many experiments on breathing while climbing at high altitudes. He first shows by experiments at ordinary altitudes and in a state of rest that some persons make much better use than others of the air they inhale, inasmuch as their exhalation is very rich in carbonic acid: this may be expressed by measuring the volume (at sea-level pressure and freezing temperature) of air inhaled to produce one grain weight of carbonic acid. Dr. Marcet himself had to breathe 15.5 litres of air, while two younger men needed only 13.7 and 10.8 litres respectively: the latter had a remarkable power of keeping his breath under water, and was little troubled in mountain ascents. Further experiments, conducted at various altitudes up to 13,600 feet, show, that, as a person ascends, he breathes fifteen to twenty-five per cent. less air (reduced, as above, to standard pressure and temperature) to produce a given weight of carbonic acid: the action of air on the blood in the lungs seems, therefore, to be facilitated with decreasing density. It is evident that this will materially diminish the quickness of breathing that would otherwise be required in rarefied air.

European Precautions Against Rabies.—An English Order in Council has been issued, under the Contagious Diseases (Animals) Act, dealing with the regulation and control of dogs. The order, which is cited as "The Rabies Order of 1886," provides for the extension of the Acts of 1878 to 1886, so that "dogs shall be animals and rabies shall be a disease" for the purposes of those Acts. The duty of the police on notice of rabies is defined, and special regulations are laid down for the guidance of local authorities as to the muzzling of dogs and the disposal of stray dogs, and as to the movement of dogs affected with or suspected of rabies. The order extends to England, Wales, and Scotland, and came into operation on October 1st. The following note on the steps taken in continental countries for the extermination of hydrophobia, has been sent by a correspondent to a contemporary, and will be read with interest. Writing from Geneva, he says: "The outcry against the order of Sir Charles Warren, with reference to the control of dogs in the British metropolis, is causing some little astonishment, in this as well as in other continental countries. The law relating to dog-muzzling which is periodically enforced over here is not unpopular, and statistics seem to show that in most cases it has considerably lessened the terrible disease of hydrophobia, and in some it has stamped it out altogether—notably in Norway. There, a few years ago, there was an outbreak of rabies; but as it was not considered serious, the law was not exercised, and the disease seemed to die out. The following year, however, there was a serious recrudescence, and an order was at once issued, that all dogs were to be securely muzzled, that no dogs would be allowed to be imported until they had been officially certified as being free from disease, and that any dog found without a muzzle would be instantly killed. This order was put into execution with an iron hand, and was kept in force for a whole year. The result is, I believe, that there has not been a case of hydrophobia or rabies in the country since. In Italy, a still more summary mode of procedure is in force. An edict goes forth that dogs are to be kept under control, which there means that they are not to be allowed out at all unless led by the owner. There is no ambiguity as to what 'proper control' signifies. In all towns and villages men go about with a cart covered with a net. The men are armed with long sticks, to which a formidable knife is attached. If a dog is met 'not under control,' he is instantly seized and pitched into the cart, the net holding him prisoner. If the wretched animal attempts to bolt he is pursued, the long sticks and knives are brought into play, and, in nine cases out of ten, the hacked and mutilated carcass of the poor animal is tossed into the cart, and as more frequently than not the creature is not killed outright, its suffering may be imagined. To all travellers and residents in Italy these ghastly loads are common and painful sights. When the cart is full it is taken to a specially appointed place, and the animals are despatched. This mode of stamping out hydrophobia is revolting, but it is certainly effectual, since the disease is very rare in Italy. In France and Germany periodical muzzling is also strictly enforced, and very little mercy is shown to animals found without the muzzle. In Switzerland, where there is a perfect craze for keeping dogs, every canton can issue an order at any moment, compelling owners to muzzle their dogs; and the instant rabies is suspected, the law is rigorously put in force—often on very insufficient grounds, and it is no uncommon thing for dogs to remain muzzled in some cantons for six months out of every twelve. During the time the order is in force, spies are specially employed to keep a lookout for unmuzzled curs, and every dog so found, no matter what his value may be, is seized, kept for a few hours, and if not then claimed, is despatched; while every gendarme and garde de la paix is empowered to kill a dog instantly, wherever it may be, if it shows the slightest signs of madness. Though the law might unquestionably be more humanely carried out, it must be confessed that hydrophobia has become very rare in this country."

Medical Women in India.—A meeting of the National Association for Supplying Medical Aid to the Women of India was held at Simla on Sept. 29, Lady

Dufferin presiding. The reports received from the various provinces were highly satisfactory. The main object now was to establish the association on a permanent footing, for which purpose further funds were required. The estimate for next year's work showed a surplus: but, before the financial condition of the undertaking could be called thoroughly satisfactory, it required a lakh and a quarter more capital. Sir C. Aitchison gave an account of the work done in the Punjab. He said that the province was not rich. The few wealthy men had given what they could, and the movement was spreading among other classes.

A Defence of Tea.—An article which appeared in our columns some weeks ago, says the *Lancet*, condemning the excessive use of tea as injurious, has come under the observation of the Chinese at Shanghi, and a recent copy of the *Shên Pao*, a local native paper, contains a leading article which is evidently founded upon a misconception of the tenor of our remarks. The writer states that for several hundred years no one has heard that the habit of tea drinking is an injurious one. Why should it suddenly become so to-day? Moreover, tea has been drunk in China for thousands of years without any apparent ill effects. Our contemporary then proceeds gravely to discuss the various sources from which this imagined danger may arise. The water cannot, it argues, be injurious, for it has been boiled, and as adulteration of the leaves has practically ceased, how can the pure article be injurious when the adulterated article which was exported and consumed for years had no evil effects? Another reason for the appearance of the article condemning tea has been suggested to the contributor to our contemporary, and although in his opinion it is not deserving of immediate and implicit belief, yet, looking at all sides of the question, he would not venture positively to state that it is devoid of truth. "It is said that a foreign doctor discovered a spring of water possessing valuable medicinal properties, and that after mixing some kind of preparation with it he put it up in bottles, like the lemonade and soda water used by foreigners here; that as the demand was not very brisk, he originated this story about the injurious properties of tea, with a view of increasing the sale of his preparation." Despite, however, such a low estimate of the honor of foreign medical men, the writer concludes with the expression of high admiration for their professional skill, which he contrasts with that possessed by the native faculty, much to the latter's disadvantage.

The Teeth from a Medico-legal Aspect.—The identification of dead bodies and criminals is sometimes a matter of much perplexity. For instance: the features of a dead body may be distorted or destroyed; the clothes changed or unrecognizable; and no ordinary circumstances left to make identification clear. Some such a case occurred in Michigan. A man was found in a lake murdered. As the coroner was about dismissing the case as "unidentified," the neighboring dentist had the curiosity to look into the mouth. In a moment he said: "I have a chart of that mouth in my office," and though he could not then remember the name, he soon found it by referring to his chart book. It resulted in tracing the murderer.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 19 TO OCTOBER 25, 1886.

Webster, Warren, *Major and Surgeon.*—Leave of absence on account of sickness further extended one year, on account of sickness.—*S. O. 244, A. G. O.*, October 20, 1886.

Billings, J. S., *Major and Surgeon.*—Granted leave of absence for eight days.—*S. O. 246, A. G. O.*, October 22, 1886.

Corson, Jos. K., *Captain and Assistant Surgeon.*—Granted leave of absence for one month, to take effect when his services can be spared.—*S. O. 246, A. G. O.*, October 22, 1886.

Weisel, Daniel, *Captain and Assistant Surgeon.*—Relieved from duty at Fort Fred Steele, Wyoming, and ordered to proceed to and take station at Fort McKinney, Wyoming, reporting to the commanding officer of that post for duty.—*S. O. 135, Department of the Platte*, October 15, 1886.

Moseley, E. B., *Captain and Assistant Surgeon.*—Relieved from duty in the Department of the Columbia, and ordered to report in person at headquarters, Division of the Pacific, for assignment to duty.—*S. O. 87, Division of the Pacific*, October 16, 1886.

Taylor, B. D., *Captain and Assistant Surgeon.*—From the Department of the East to Columbia Barracks, Ohio.—*S. O. 244, A. G. O.*, October 20, 1886.

Tesson, L. S., *Captain and Assistant Surgeon* —From the Department of Texas to the Department of the East.—*S. O. 244, A. G. O.*, October 20, 1886.

Barrows, C. C., *First Lieutenant and Assistant Surgeon.*—From the Department of Arizona to the Department of the East.—*S. O. 244, A. G. O.*, October 20, 1886.

Egan, P. R., *First Lieutenant and Assistant Surgeon.*—From the Department of Arizona to the Department of Texas.—*S. O. 244, A. G. O.*, October 20, 1886.

Walker, F. V., *First Lieutenant and Assistant Surgeon.*—From the Department of the East to the Department of Texas.—*S. O. 244, A. G. O.*, October 20, 1886.

Carter, E. C., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for six months, with permission to apply for an extension, and to go beyond the sea, to take effect when his services can be spared.—*S. O. 244, A. G. O.*, October 20, 1886.

Edie, Guy L., *First Lieutenant and Assistant Surgeon.*—Having returned from detached service in the Department of Arizona, will join his station at Fort McIntosh, Texas.—*S. O. 144, Department of Texas*, October 13, 1886.

Chapin, Alonzo R., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Laramie, Wyoming, and ordered to Fort Washakie, Wyoming.—*S. O. 137, Department of the Platte*, October 19, 1886.

Black, Chas. S., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, on a surgeon's certificate of disability, to take effect when his services can be spared.—*S. O. 244, A. G. O.*, October 20, 1886.

Ives, Francis J., *First Lieutenant and Assistant Surgeon.*—In obedience to instructions received from the Division Commander, ordered to report in person at headquarters, Department of the Platte, for duty.—*S. O. 146, Department of Texas*, October 16, 1886.

Banister, W. B., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Wingate, New Mexico.—*S. O. 97, Department of Arizona*, September 29, 1886.

Mason, Chas. T., *First Lieutenant and Assistant Surgeon.*—Relieved from temporary duty at Fort Verde, Arizona Territory, and ordered for duty at Fort Huachuca, Arizona Territory.—*S. O. 99, Department of Arizona*, October 12, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING OCTOBER 23, 1886.

Urquhart, F. M., *Passed Assistant Surgeon.*—Relieved from duty at Cape Charles Quarantine, to proceed to Washington, D. C., with Steamer "Woodworth," October 20, 1886.

Wasdin, Eugene, *Passed Assistant Surgeon.*—Promoted, and appointed Passed Assistant Surgeon from October 1, 1886, October 20, 1886.

Williams, L. L., *Assistant Surgeon.*—Granted leave of absence for three days, October 16, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIX. SATURDAY, NOVEMBER 6, 1886. No. 19.

ORIGINAL LECTURES.

ON ALIMENTARY RATIONS.[1]

A Lecture on Hygienic Therapeutics.

BY PROF. DUJARDIN-BEAUMETZ,
OF PARIS, FRANCE.

GENTLEMEN: We have now passed in review in successive lectures the primordial alimentary principles, complete aliments, complex aliments, and beverages. It now remains for us to coördinate these elements, and establish the basis of dietetics.

Man, as I have told you, loses by the operations of nutrition, nitrogen, carbon, salts, and water. In the course of the twenty-four hours, these expenditures amount to 20 grammes of nitrogen, of which 14.5 grammes pass off in the urine under the form of urea and uric acid, and 5.5 grammes represent the nitrogen contained in the excrements, sweat, and mucus.

As for carbon, the daily waste is 310 grammes; of which, 250 are excreted by the lungs, 45 are eliminated by the kidneys, and 15 by the other excretions.

The salts are represented by a daily loss of 30 grammes. Lastly, we lose every day by the perspiration, by the pulmonary exhalations, by the urine and fecal matters, three litres of water.

Man must find in his food the elements needed to repair these incessant wastes. When these elements are furnished in insufficient quantity, nutrition suffers, there is commencing inanition; when the diet is too abundant, other troubles appear in the economy, of manifold nature, as we shall see. But there may be many variations in the amounts of these daily losses; age and sex, for instance, modify the quantity of carbon and nitrogen excreted, and this is due largely to the fact that the diet of infancy, mature life, and old age, cannot be precisely the same. This subject of alimentary regimen, and the data on which it is established, is one of exceeding interest, and in order satisfactorily to study it, we need to inform ourselves about what has been accomplished by zoötechnics.

Regarded from the limited standpoint of his alimentation, man is an animal, and all the laws which regulate the daily diet, the work, and the fattening of animals are in part applicable to man. I am, for my part, astonished that medical writers who have occupied themselves with this subject of alimentary hygiene have not drawn more largely from the numerous works which this important topic of the alimentation of domestic animals has produced.

Having been myself a pupil of the Zoötechnic Institute at Versailles, I am glad to be able to-day to turn to account the instructions which I have received from this school.

As has been shown by the masters of modern zoötechnics, one may at will develop in our domestic animals muscle, fat, and bone; one may even so modify the external constitution of animals as to create new varieties and even new species, which are to-day types of the domestic animals, varying according to the usage to which they are put. We ought then to have recourse to these same methods when we desire to establish a rational system of dietetics for man, and you will see me continually fortifying my position by facts drawn from zoötechnics.

The adult man, as I have said, when subjected to moderate labor, loses daily 20 grammes of nitrogen and 300 grammes of carbon; these 20 grammes of nitrogen represent 124 grammes of dried proteid matters. As these proteinaceous or azotized substances contain 64 grammes of carbon, deducting these 64 grammes from the 300 grammes necessary for nutrition, there remain 236 grammes of carbon, which must be furnished by amylaceous matters and by fats.

Moleschott, who has bestowed much study on the subject of alimentation, thinks that there is always a constant relation between the azotized matters, carbohydrates, and fatty matters, and he thinks that the relation between the proteid principles and the carbohydrates is as 1 to 3.47; and to the fatty matters, as 1 to 0.45. These different relations between the nitrogenous principles and carbohydrates on the one hand, and fats on the other, constitute what is called in zoötechnics *the nutritive relation of aliments*. These relations are represented by the following formulæ:

$$\frac{ma}{mna}, \text{ or } ma : mna.$$

$$\frac{ma}{mg}, \text{ or } ma : mg.$$

In these formulæ ma stands for the azotized matters, mna for the carbohydrates, and mg for the fats.

A diet based on these relations ought to consist daily of 124 grammes of proteid matters, 430 grammes of starch or other carbohydrates, and 54 grammes of fat for an adult man; this corresponds to the following *mixed ration* of bread and meat.

	Weight.	Azotized matters	Starch.	Fat.
	grms.	grms.	grms.	grms.
White bread	819	61.83	435	48.20
Meat	259	62.17	.....	5.80
	1078	124.00	435	54.00

If from the domain of theory we pass to that of practice—*i. e.*, to the dietary of the adult man, as carried out on a large scale—we may take as type the daily fare of the soldier.

In a recent study of the highest interest made by Kirn,[1] this question has been studied in all its aspects. We there see that to-day, according to the latest official regu-

[1] Translated, from advance sheets, by E. P. Hurd, M.D., of Newburyport, Mass.

[1] Kirn: On the Diet of the Soldier. (Journal des Sciences Militaires, October, 1884.)

lations which went into effect July 1, 1873, the daily ration of the French soldier in times of peace is established on the following basis:

	Quantity. grms.	Nitrogen. grms.	Carbon. grms.	Fat. grms.
Bread	1000	12.00	300.0	15.0
Meat (with bones)	300	5.41	19.8	3.6
Fresh vegetables	100	0.24	5.6	0.1
Dry legumes (beans, peas, etc.)	30	1.02	12.6	0.6
Total	1430	18.67	338.0	19.3

This ration is superior to that of the soldiers of other countries, as may be seen by the following table:

Daily Ration of Different Armies.

	Nitrogen. grms.	Carbon. grms.	Fat. grms.
French Army	18.607	338.0	19.30
Austro-Hungarian	17.00	363.9	38.80
English	17.39	382.1	39.10
Italian	17.47	363.3	17.42
German	18.02	283.9	16.42

But there is a point which should particularly interest hospital physicians, namely, hospital diet. In the full dietary regimen of hospitals the quantity of meat should never be less than 300 grammes (10 ounces) a day. Here I agree fully with Regnard, Inspector of Hospitals, who shows that a great many of these eleemosynary institutions of the departments furnish an alimentary regimen which is quite insufficient, in some instances not attaining the figure of 120 grammes of meat a day for each individual in average health. In these cases the high mortality of these hospitals must be attributed in great part to the bad aëration and meagre alimentation. We have seen in fact this mortality vary from 3 to 31 per cent., according to the statistics of Regnard,[1] and this enormous difference is sufficiently explained by the bad hygienic and alimentary conditions observed in certain of our hospitals and infirmaries.

Therefore, when you are called upon to direct or superintend these charitable institutions, you should insist not only that this quantity of 300 grammes of meat per day shall be supplied to each inmate, but also that the relation between the amylaceous and fatty aliments shall correspond as nearly as possible to the proportions which I have given above.

But we have been thus far occupied only with the daily fare of a man at rest, and such as is necessary to prevent bodily wasting. Multiple conditions present themselves which augment the phenomena of combustion, and hence necessitate an increase in the daily rations. One of the most active factors in bringing about this augmentation of the combustions is work.

In order to judge of this increased activity of the combustions of the economy, we may make use of three modes of investigation: the analysis of the gases of respiration (*i.e.*, the determination of the quantity of oxygen consumed, and of carbonic acid exhaled), the study of the temperature of the body by finding the rise or fall of the animal heat; lastly, by examination of the urine, and ascertaining the quantity of nitrogen daily excreted. The last two methods are the ones which we find the most available in clinical practice, and it is on them that I shall rely in endeavoring to show you the influence of work in augmenting the combustion of the economy.

Lavoisier was one of the first to show that muscular labor increases the quantity of oxygen consumed, and while a man at rest utilizes 36.6 litres of oxygen per hour, he requires in that time 91.25 litres in order to raise in fifteen minutes a weight 7.54 kilogrammes to 211 metres of height.

As for the quantity of urea, it also follows an ascending progression, and there is nothing more interesting in this regard than the figures furnished by Ritter, which are summed up in the following table:

Influence of Work on the Excretion of Urea.

	Quantity of urine. grms.	Total of nitrogen. grms.	Ammonia. grms.	Urea. grms.	Uric acid. grms.
Rest	1340	17.89	0.48	32 90	0 90
A walk of 4 hours	1940	20.00	0.62	39.25	0.88
A march of 4 days	2120	20.30	0.59	40.30	0.62

I call your attention especially to the last two columns; you will there see that the proportions of urea and uric acid maintain an inverse relation, and that while during rest you observe a urea production of 32.90 grammes, and a uric acid production of 0.90 gramme, after four days' marching the proportion had risen to 40.30 of urea, while the uric acid had fallen to 0.62. The physical exercise had here produced a double effect: increased elimination of nitrogen, and increased oxidation of albuminoid matters; because, as you know, the uric acid represents an incomplete combustion of proteid elements. You should always have these facts before your eyes when you have to combat the symptoms which result from the accumulation of uric acid in the economy.

It is not muscular work alone which augments the activity of combustions. Brain work has the same effect, and Byasson, in a very remarkable monograph,[1] has shown us very clearly the increase of the excretion of urea under the influence of mental labor, as you may judge by the following figures:

	Average of 24 hours. Urea.
1. A period of 3 days of rest	20.46 grammes.
2. " " muscular work	21.90 "
3. " " cerebral labor	23.88 "

Moreover, Moritz-Schiff has proved that cerebral labor raises the temperature, and Burdach, by his experiments, has demonstrated an increased consumption of oxygen under the influence of mental toil. If both muscular and mental work augment the combustions of the economy, it may be inferred that during sleep, when body and brain are at rest, there is diminished oxidation. This is what really takes place, and Boussingault, in his experiments on turtles, has shown that the quantity of carbon lost per hour which is 0.258 gramme during the waking state, is only 0.162 gramme during sleep.

Vasal, in his turn, has remarked that the mean for the urea excretion is 42.48 grammes for the twelve hours of day, and 36.24 grammes for the twelve hours of night.

There exists then a ration of labor as well as one of sustenance, and there is practically a sense in which the quantity of work done is proportional to the quantity of food ingested.

[1] Regnard: On the Mortality in the Provincial Hospitals, and on the Necessity of a Reform in the Administration of the Public Charities. (Progrès Méd., June 12, 1886, p. 489.)

[1] Byasson: The Relations which exist between Cerebral Activity and the Composition of the Urine. (Thése de Paris, 1868.)

Professor Germain Sée, who has recently delivered an interesting course of lectures on diet in health and disease, has in these lectures dwelt at length on the increase of food necessitated by labor. He would thus fix the daily fare of the workingman and the soldier:

	Azotized matters. grms.	Fats. grms.	Starchy matters. grms.
The workingman should consume	130–160	68	580
The soldier should consume	140–160	40–60	500

But it is to Hervé-Mangon that we owe the most precise and scientific indications as to the alimentary ration of sustenance and that of work. By an admirable series of investigations, which I cannot here even summarize, and for the details of which I must refer you to his writings,[1] he has arrived at the conclusion that the mean ration *per diem* of an adult living in France, *and by living kilogramme*, is 5.119 grammes of carbon, and 0.280 of nitrogen. In this total estimate it is important to distinguish the population of the large cities, like Paris, from that of the country. In Paris the consumption by day and by kilogramme is 5.673 grammes of carbon, and 0.332 gramme of nitrogen; in the country 5.808 grammes of carbon, and 0.275 gramme of nitrogen. The following table clearly shows these differences, from which it is seen that in the country more hydrocarbon is consumed and less nitrogen.

Average Ration by Day and by Kilogramme.

	Carbon. grammes.	Nitrogen. grammes.
For entire France	5.179	0.280
For Paris	5.575	0.320
For the country	5.808	0.275

Edward Smith has, in his turn, studied the minimum ration by day and by living kilogramme according to ages, and with the following results:

Minimum Ration of Sustenance according to Ages, by Day and by Living Kilogramme.

	Carbon. grammes.	Nitrogen. grammes.
Infancy	9.84	0.96
Age of ten years	6.84	0.40
Age of sixteen years	4.27	0.38
Adult age	3.60	0.20

In taking these last figures, 360 grammes of carbon, and 0.20 gramme of nitrogen, as the basis, the ration of sustenance for a man weighing 65 kilogrammes would be 234 grammes of carbon, and 13 grammes of nitrogen.

But these figures are modified in the following way when the individual works:

	Carbon. grammes.	Nitrogen. grammes.
Rest	234	13.00
Moderate labor	337.92	19.56
Hard labor	442.00	25.00

As you see by these careful statistics, there is a great difference between the ration of sustenance and that of labor, the ration of labor being nearly double that of sustenance.

In the great industrial enterprises, as, for example, the building of railroads, or the development of mines, the amount of work performed will vary according to the food supplied to the laborer, increasing or diminishing as the daily rations are abundant or insufficient; it is the same in zoötechnics, the horse doing an amount of work proportioned to the quantity of food which he consumes. In this production of labor do the azotized or non-azotized aliments play the principal part?

When, in 1842, Liebig showed that the special function of the muscles was the production of work, and that the necessary force was obtained only by the destruction of the albuminoid matters which the muscular tissue contained, all the physiologists of the period were agreed in accepting the division which he established of foods into non-azotized—which he considered as respiratory or calorifacient aliments—and azotized or plastic, which he thought were destined to repair the incessant wastes of the muscular system, and to which Liebig gave the names of "histogenetic" and "force producing."

But it was soon found that the augmentation in the production of urea had not *work* for its sole factor, and that the kind of food used had most to do with this increase; a sort of mixed theory now came into vogue, to which was given the name of *luxus-consumption theory*. In this *luxus-consumption*, it was supposed that only a feeble part of the azotized materials absorbed served for the reparation of the muscular tissue, and that the other part, the excess or *luxus* portion, being incapable of appropriation, was burned for production of animal heat, and eliminated under the form of urea and uric acid. Lehmann, Frerichs, and Schmidt have been the most conspicuous advocates of this *luxus-consumption* theory of Liebig.

But it was not long before new experiments, and especially the discovery of glycogen in the muscles, showed that during muscular effort the muscle consumes chiefly carbohydrates. Zoötechnic experiments confirm in a measure this view, in proving that in the herbivora the production of force is in relation with an alimentation which is non-azotized, and the experiments of Grandeau and Leclerc with the draught horses of the omnibus companies of Paris are in this regard completely conclusive, showing that non-azotized bodies, and especially carbohydrates, are, if not the exclusive, at least the preponderant source of the force which is manifested in muscular contraction.[1]

This conclusion, which I believe is applicable to herbivora, is it also applicable to omnivorous animals, and in particular to man? I do not think so; and while recognizing the fact that individuals living on a purely vegetable diet, like our peasants, may accomplish a considerable amount of hard work, it is nevertheless a fact that they can do a great deal more work when you augment the fat, and especially the azotized matters in their rations. This is, moreover, the conclusion to

[1] Hervé-Mangon: Traité de Genie Rural, Paris, 1875. On the Average Ration of the Inhabitant of the Country in France. (Acad. des Sciences, t. lxxix. 1874.)

[1] According to this view, plants accumulate force, and animals expend it. A plant while growing absorbs the solar rays, and thereby decomposes carbon dioxide, and stores carbon in its tissues. Thus the solar rays are transformed into static force, which accumulates in the plant. The animal consumes the plant, and converts this static force (latent in the plant) into *vis viva*, or work. So the circle of life completes itself on our earth. "The solar ray sleeps in the tissues of the plant to waken in the animal in the form of heat and work."—Hervé-Mangon.

which Lambing has arrived in his interesting treatise on the *Sources of Work and of Force in Living Beings*.[1]

Therefore, in the ration of work you ought always to augment in notable proportions the quantity of azotized materials, of starchy matters and of fat, the sum of which constitutes the daily fare of the workingman; and in the experiments made by the Western Railroad Company, the alimentary regimen which enabled the laborers to perform the maximum of work was as follows:

Meat	600 grammes.
White bread	550 "
Potatoes	1000 "
Beer	1000 "

In this study experimenters have gone even further, and have calculated the quantity of heat units and of kilogrammetres[2] produced by foods, and the data furnished by Frankland on this point are most interesting. By referring to the "mixed ration" table before given, you will find that, in accordance with Frankland's careful estimates, the number of heat units amounts to 2792, and it may be roughly stated that a man subjected to an average diet in our climate loses per day 3000 heat units, as the following table shows:

	Heat units.
For 124 grammes of dried proteid matter	541.6
" 430 " " " starchy matters	4806.0
" 49 " of fat	444.4
Total	2792.4

Or you may express it in this way, that an adult man produces by day and by kilogramme of weight, 1.5 heat units.

A man may transform into work, at the most, 540 heat units, which correspond to 229,500 kilogrammetres. Ordinarily, a man in working seven hours, does not exceed 100,000 to 150,000 kilogrammetres, and if we wished to establish on this basis, as Armand Gautier has done, the coefficient of the human machine, we might say that of 100 heat units produced, 25 serve to maintain our temperature; of the 75 which remain, 20 may be transformed into effective work, and the remaining 55 are lost in the friction of the machine. Our bodily machine then, from the point of view of the production of force, is not absolutely a pattern machine, since a great part of the force is lost.

We have just seen the importance of this estimate of heat-units, hence it is of interest to know what quantity of heat-units one kilogramme of different kinds of food may produce. Without reproducing here all the figures furnished by Frankland, I can give you the following calculation:

	Heat units
One kilogramme of dried albumen, in undergoing transformation into urea, gives	4.368
One kilogramme of starch, in undergoing oxidation, gives	4.200
" " " fat " " " "	9.069

Moreover, experimental physiologists have gone still further in this study of nutrition, and have inquired into the foods proper for each organ; and while muscle consumes chiefly albumen, the nervous tissue appropriates albuminoid matters, and especially *lecithin*, a phosphorized fat, which, in conjunction with neurine, forms protogon; lastly, bones utilize calcareous salts, and, in particular, phosphates.

Such are the facts which I designed to present relative to daily rations; to complete them, you have but to cast your eyes over the following table, which shows the quantity of nitrogen and carbon furnished by the greater part of aliments which serve for the nutrition of man.

Name of food.	Nitrogen.	C — H. Combustibles calculated in carbon.
Beef steak	3.00 per ct.	11.00 per ct.
Roast beef	3.53 "	17.76 "
Veal	3.09 "	15.68 "
Fois gras (of goose)	2.12 "	65.58 "
Mutton chop	2.66 "	12.13 "
Salt herrings	3.11 "	23.00 "
Fresh "	1.83 "	21.00 "
Mackerel	3.74 "	19.26 "
Salmon	2.09 "	16.00 "
Eel	2.00 "	30.00 "
Mussel	1.80 "	9.00 "
Oyster	2.13 "	7 18 "
Lobster	2 93 "	10.96 "
Eggs	1.90 "	13.50 "
Cow's milk	0.66 "	8 00 "
Goat's "	0.69 "	8.60 "
Gruyere cheese	5.00 "	38.00 "
Roquefort cheese	4.21 "	44.44 "
Brie cheese	2.93 "	35 00 "
Chocolate	1.52 "	58.00 "
Wheat	3.00 "	41.00 "
Wheaten flour (superfine)	1.64 "	38 56 "
Rye flour	1.75 "	41.00 "
Winter barley	1.90 "	40.00 "
Indian corn	1.70 "	44.00 "
Buckwheat	2.20 "	42 50 "
Rice	1.80 "	41.00 "
Oatmeal gruel	1 95 "	44.00 "
White bread of Paris (44 per cent. of water)	1.08 "	29 50 "
Army bread of France	1.20 "	30.00 "
Fresh chestnuts	0.64 "	35 00 "
Dried chestnuts	1.04 "	48 00 "
Potatoes	0.33 "	11.00 "
Beans	4.50 "	42.00 "
Dried peas	3.66 "	44.00 "
Carrots	0.31 "	5.50 "
Mushrooms	0.60 "	4.52 "
Fresh figs	0.41 "	15.50 "
Dried figs	0.92 "	34 00 "
Prunes	0.75 "	28.00 "
Infusion of 100 grms. coffee	1.10 "	9 00 "
" " " tea	1.00 "	10.50 "
Fat pork	1.28 "	71.14 "
Fresh butter	0.64 "	83.00 "
Olive oil	traces.	98.00 "
Strong beer	0.05 "	4.50 "
Wine	0.15 "	4.00 "

In my *Diseases of the Stomach and Intestines* I have given a similar table, but this time I have simplified it, by referring all the figures to the quantity of nitrogen and carbon utilized by the economy. You can, by the help of this table, establish on scientific data the alimentary regimen of different patients. It will suffice to multiply the figure of nitrogen by 6.5 to obtain the weight of dry proteid matters contained in 100 grammes

[1] Lambing: Des origines du travail et de la force chez les êtres humains. (Thèse d'Agrégation, 1886.)

[2] Under the Continental system, the mechanical equivalent of heat is expressed in *kilogrammetres*, a kilogrammetre constituting one kilogramme (2.2046 pounds avoirdupois) raised to the height of a metre (3.2808 feet). Kilogrammetres are convertible into foot pounds by multiplying by 7.232; one kilogramme raised one metre high, equalling one pound raised 7.232 feet high.

of fresh aliments. You have only to know the weight of the individual, and to remember that in the adult the average alimentary ration should oscillate—by day and by living kilogramme—between the following figures: 6 to 9 grammes of carbon, and 0.360 to 0.250 gramme of nitrogen.

When once these data are mastered you will be prepared to go on with me to the consideration of insufficient and superabundant dietary regimens, and their application to therapeutics. In the next lecture we will take up the subject of insufficient regimen, and the treatment of obesity.

ORIGINAL ARTICLES.

A NOTE ON THE PRODUCTION OF CATHARSIS BY MEANS OF HYPODERMATIC MEDICATION.[1]

By WM. L. DUDLEY, M.D.,
PROF. OF CHEMISTRY, VANDERBILT UNIVERSITY, NASHVILLE, TENN.,
AND
CHAS. H. CASTLE, M.D.,
DEMONSTRATOR OF CHEMISTRY, MIAMI MEDICAL COLLEGE, CINCINNATI, OHIO.

It is often necessary to produce catharsis with the least possible loss of time. It is also frequently the case that cathartics cannot be administered *per orem*, and that injections per rectum will not accomplish our purpose. In such emergencies, it has been our habit to rely upon croton oil, dropped upon and absorbed by the tongue; but experience will bear us out when we say that croton oil is not always reliable. How, then, are we to attain our object certainly, expeditiously, and safely? We must seek our reply in an appeal to the hypodermatic syringe, and that class of drugs which produce catharsis by their absorption into the circulation, and subsequent action through the nervous system. The list of the latter is of goodly length. We have already employed not a few of them upon the lower animals, and with the most gratifying results. We are not prepared to assert positively that we have found an agent which, when used hypodermetically, will invariably produce catharsis expeditiously and safely, but we believe that further observation—leading to a better knowledge of solubility and dosage—will establish this claim for two or more of the substances with which we have lately been working.

We present herewith the results of some observations upon cathartic acid, podophyllotoxin, and elaterin.

Cathartic Acid was first isolated from senna by Dragendorff and Kubly, in 1866, and described by them to be a glucoside, of weak, acid character, having the formula $C_{150}H_{192}N_4O_{82}S$. Cathartin was isolated and described by Lassaigne and Feneulle, who considered it the active, purgative principle of senna; but it was afterward found to be a mixture having little, if any, purgative properties, and it is now generally admitted that cathartic acid is the active principle of the plant. Cathartic acid has a brown color while moist, and is nearly black when dry. It is an amorphous substance, nearly insoluble in water, and insoluble in ether and alcohol, but readily combines with the alkalies and earths, forming salts soluble in water, which are decomposed by acids with precipitation of the cathartic acid. It may be purified by dialysis, as it has strong colloidal properties.

The cathartic acid used in these experiments was that found in the market, prepared by H. Trommsdorff. It was of a dark brown color, having an odor and taste resembling licorice. It was completely soluble in water, forming a wine-red colored solution. From its chemical and physical properties, we were convinced that the preparation was by no means pure, and the results here given are only of value so far as the commercial acid is concerned. We are now preparing the pure cathartic acid, and will soon be able to present data obtained by its use. The difficulty in obtaining, in a pure state, drugs which are little used, is recognized by every experimenter.

We have used cathartic acid four times upon young kittens. In the first two experiments we injected one-third of a grain and one-half of a grain, respectively. These kittens were in a poor physical condition when they came to us. The injections made into the subcutaneous tissue of the belly caused no discoverable local irritation. The kittens died in about two days, no catharsis having been produced; but, upon post-mortem examination, the small intestines were found empty and slightly injected, and the colon enormously distended with impacted feces. In the third experiment we employed one grain of the acid without local irritation or the production of catharsis. In the fourth observation two grains of the acid were used, and in ten hours free catharsis came on. The stools were at first hard; later, soft and clay colored. This effect continued for several days.

In two instances we used the cathartate of ammonium—giving one grain of the salt. One of the kittens experimented upon died in about thirteen hours, and, as in the case of the other two, the stomach and intestines were found empty and somewhat injected, and the large intestine distended with impacted feces. Free catharsis was induced in the other kitten in about four hours.

We propose now, from a chemically pure cathartic acid, to make a cathartate of ammonium of purity and known composition, and on the basis of our former observations, soon to determine the cathartic dose for man.

Podophyllotoxin.—D. V. Podowissotsky (*Pharm. Zeitschrift für Russland*, 1882, vol. xx. p. 777) found, after careful examination, the root and resin of podophyllum to contain podophyllotoxin as the active purgative principle. This body he described as being composed of a resin acid, picropodophyllic acid, and a neutral crystalline principle which he called picropodophyllin. Podophyllotoxin, when pure, is described as a bitter, white, resinous powder, soluble in weak alcohol and hot water, while that of commerce is a light yellow powder. It is precipitated from its alcoholic solution by water in large quantity. The slight color of the commercial article

[1] Read before the Cincinnati Medical Society.

is probably due to the coloring matter which has been imperfectly separated.

Brunton states that the resin of podophyllum "acts on the bowels when injected subcutaneously, as well as when introduced into the intestinal canal." In 1880, Dr. D. O. Brau reported that he had used podophyllotoxin as a purgative for children and found it completely to represent podophyllin. To a child 13 years old he gave from $\frac{6}{100}$ths to $\frac{9}{100}$ths of a grain.

We have used podophyllotoxin upon kittens three times, producing free catharsis in each case within an hour. In two of the experiments catharsis was carried to the extent of bloody, mucous passages, the bowels remaining loose for several days. In these cases there was no depression of any kind manifest until after many watery stools had been voided, when the cats betrayed the weakening effect of this drain of albuminous fluid. In one case the catharsis was promptly checked by the hypodermatic administration of a sixteenth of a grain of morphia. We have also used podophyllotoxin upon man four times —two of the cases being in the Cincinnati Hospital.

I will quote the notes of the resident physicians making the observations.

Dr. Nicehelser reports:

April 26. A. P., aet. fifty-eight. Chronic rheumatism. Bowels were usually irregular. Has now had a constipation of five days' standing. In the morning complained of pain in abdomen. Ordered tinct. opium gtt. x. Pain relieved. At 3.45 P. M., was given gr. $\frac{1}{10}$th podophyllotoxin in a fifty per cent. alcoholic solution hypodermatically. Hourly observations were made of pulse and temperature. Neither of these was in any way affected. Nine hours after the injection, at 12.45 A.M., he had one hard moulded stool, and at 5 A. M. another stool, soft in character. Thereafter his bowels continued regular until May 4, when he was discharged from the house. There was some local irritation at the point of injection, but it was inconsiderable in amount.

Mr. Mussey reports:

April 30. O. M., colored, æt. twenty-one. Syphilis of nine months' duration. Now has several abscesses on neck, and an antero-posterior curvature of the spine. Patient's bowels have been constipated and it has always been necessary to give a cathartic to bring about a movement, the one usually employed being epsom salts ℥ss. States to-day that he has had no stool for two weeks.

8.40 A. M. Gave ♏xx podophyllotoxin in solution fifty per cent. alcohol, equalling gr. $\frac{1}{10}$th of the drug, hypodermatically. Pulse 84, temperature normal.

9.40. No stool, pulse 84, strong and full. Temperature not taken.

1.40 P. M. No stool, nor has patient had any inclination in that direction. Pulse 72, good and full. Some swelling, redness, and tenderness at point of injection.

At some time during the early morning of May 1, patient had a large stool and during the day had another. No pain accompanied either movement. Questioning brought to light the fact that the night before the podophyllotoxin was given, the nurse had, without orders, given a dose of salts, which had produced a small stool that very morning. For some days after administration of drug, bowels moved without any trouble. Patient had at the time the podophyllotoxin was given, complete paralysis of motion and sensation in lower limbs.

The doses used in these cases were those recommended by Dr. Brau for children of thirteen years of age.

In view of the smallness of the dose, therefore, the results may be held to be satisfactory, especially when we consider that we were working with a preparation which was probably not at all equal in strength to chemically pure podophyllotoxin.

It will be observed that the absence of any effect upon the circulation and temperature is a matter of importance, especially in a class of drugs the influence of which, in the main, is depressing.

A few days ago, two healthy adults took respectively $\frac{1}{10}$th gr. and $\frac{1}{7}$th gr., hypodermatically, from this same solution that had been used in the Hospital, and was now some two months old. There was no cathartic effect produced, the glucoside having probably undergone decomposition. There was not a little local irritation at the seats of injection.

Elaterin—$C_{20}H_{28}O_5$—is the principal constituent of elaterium, and when pure is obtained in colorless, shining, hexagonal scales or prisms, with an acrid and extremely bitter taste. It is soluble in 125 parts of alcohol at 15° C., in 2 parts of boiling alcohol, in 290 parts of ether, in amylic alcohol, carbon disulphide, and chloroform. It is insoluble in petroleum benzine. According to various authorities, it is present in elaterium in from 15 to 50 per cent. Brunton states that elaterin used in subcutaneous injections "acts on the nervous system, causing salivation, insensibility, tetanus, and dyspnœa, and also that it only acts as a purgative when taken internally, and appears to require bile in order to act." It is a powerful and valuable remedy, and is especially indicated in dropsies and in those cerebral affections in which a reduction of the general blood pressure is necessary.

The results of our experiments, if verified, will be much more satisfactory to the therapist. In two experiments we have used $\frac{1}{10}$th gr. and $\frac{1}{20}$th gr. of elaterin instantaneously. In neither instance was there any untoward effect—the kittens remaining playful and evidencing no discomfort during the time of operation of the drug, and in both cases large watery stools were produced within an hour. We have not, as yet, used it upon man.

Elaterium.—The striking difference in the results attained by us and those arrived at by other observers in the use of elaterin, urged us to extend our observations and make comparative experiments with elaterium.

Elaterium is a substance deposited from the juice of the squirting cucumber. It contains, besides elaterin, pectin, prophetin, ecbatin, or elateric acid, hydroelaterin, etc. We could not but think that a mistake had been made in setting down the physiological action of elaterium and its active purgative principle as identical, and we were inclined to believe that the distressing fatal symptoms observed after the hypodermatic use of elaterium were due to some other one of the ingredients of the juice than elaterin. It is certain that in no instance in our hands did the hypodermatic employment of elaterin lead to the results to be found set down in our standard text-books; while the employment of the elaterium did give rise to the apathy, somnolence,

coma, dyspnœa, convulsions, and death, as described by former observers. Our confirmatory observations were as follows:

An extract of elaterium was prepared by treating four grains of the pulverized elaterium with 120 minims of commercial alcohol, and boiling for a few minutes. After cooling, the clear extract was decanted from the insoluble residue.

In one case five minims of the solution (representing $\frac{1}{6}$th of a grain of elaterium) were diluted with an equal quantity of distilled water, and injected into a cat. In a second case ten minims of the solution (representing one-third grain of elaterium) were diluted with an equal quantity of water, and also injected into a cat.

The details of the cases are as follows:

Experiment No. 1.—Elaterium, gr. $\frac{1}{6}$th, 1.40 P. M. 2.21 hard stools. 2.25 disturbed respiration, salivation, muscular weakness, attempted vomiting, symptoms rapidly increasing in severity. Coma, convulsions, profuse salivation, apnœa, and death at 2.38. Autopsy: lungs intensely congested; heart ceased action in diastole, and was full of blood; stomach and upper part of small intestine empty, injected, and succulent; large intestine impacted.

Experiment No. 2.—Elaterium, gr. $\frac{1}{3}$d, 1.35 P. M. 2.45 some uneasiness. 3.45 somnolent. 4.30 still somnolent, apathetic, and has some salivation. No stool. No alarming symptoms. This kitten was given to the physiological laboratory the next day, that its organs might be used as injected specimens. When killed and opened, its alimentary canal was found to contain vast numbers of large lumbricoid worms. The small intestine was so distended that the injection was a failure.

We again used elaterin with the following results:

Experiment No. 3.—Elaterin, gr. $\frac{1}{25}$th, 11.12 A. M. 2.45 has been sleeping most of the time since the injection was given. 3.35 same as above. 5 no stool—no bad symptoms.

Experiment No. 4.—Elaterin, gr. $\frac{1}{12}$th, 11.16 A. M. 1.40 large watery stool. 1.47 copious watery, yellowish stool. 4.30 cat quiet—no bad symptoms.

Note.—The approaching departure of one of us for new fields of labor, interrupts the further prosecution of our joint observations. We, therefore, offer the results of our studies to our professional brethren without a promise of further extension, as a suggestion of what may be accomplished in the future, and as a guide, however insufficient, to the production of catharsis by means of hypodermatic medication.

Cincinnati, August, 1886.

ON THE MICROÖRGANISMS OF LACTIC ACID FERMENTATION.[1]

By H. G. BEYER, M.D., M.R.C.S.,

PASSED ASSISTANT SURGEON U. S. N.; HONORARY CURATOR, SECTION MATERIA MEDICA, UNITED STATES NATIONAL MUSEUM.

The presence of microörganisms in liquids undergoing fermentation has hitherto been interpreted and explained in various ways. While some looked at these low forms of life as the mere associates of these processes, attributing the real cause of the resulting decomposition to chemical ferments, others, though believing in the causation of fermentation by microörganisms, looked at these processes as physiological ones or else attributed them to a certain power of adaptability possessed by certain microbes to different conditions of life.

Lister was, perhaps, the first clearly to point out the fact that the peculiar and characteristic fermentative process by which milk becomes sour, is initiated or directly caused by a certain species of microbe. While, however, Lister had proved this fact, it did not necessarily follow from his experiments alone, that the same process might not also be called into existence by a chemical ferment produced by the lacteal glands and which was already contained in the milk when it left these glands.

The matter, therefore, even after Lister's famous experiments, remained as undecided as ever, and the contention which had grown up between chemists and biologists for ages past, had not been diminished in any way.

In the mean time, our methods of bacteriological research having been greatly improved by the patient and admirable researches of Professor Robert Koch, it had become necessary to reinvestigate this whole question. This task has, indeed, been most ably performed by Dr. Hueppe, whose researches will be found embodied in a recent contribution to our knowledge of lactic acid fermentation and fermentation in general, published in the *Mittheilungen d. kaiserlichen Gesundheitsamtes*, Berlin, 1884.

In this paper Hueppe has, we think, successfully demonstrated the fact that lactic acid fermentation, or the process of the souring of milk, by which the sugar contained in milk is converted into lactic and carbonic acids, is directly dependent on or caused by a certain definite variety of microorganism, the morphological and physiological characters of which render it sufficiently distinct from any other known microbe.

Hueppe has demonstrated his point in the following manner: First, by showing that this particular organism is constantly associated with lactic acid fermentation; second, by separating it from other microörganisms; third, by cultivating it outside the original media in which it occurs, so as to separate chemical by-products; fourth, by the inoculation of pure cultures into the proper media, producing the characteristic decomposition; fifth, by ascertaining the biological conditions under which this process of fermentation is brought about in the best manner.

Although Hueppe himself is exceedingly guarded in his conclusions, the results obtained by him from the very accurate series of experiments made according to the most modern and advanced methods, will, no doubt, be fully realized by even those who are but slightly familiar with the history of fermentation and the long struggle which has existed for ages, and still exists between chemists and biologists with regard to the nature and causes of fermentation. This alone would, no doubt, form sufficient pretext for a critical examination and repetition of at least a portion of Hueppe's experiments. But aside from

[1] Read at the meeting of the United States Naval Medical Society, held Sept. 7 at the Museum of Hygiene, Washington, D. C.

this, and in spite of the fact that the importation of Hueppe's lactic acid germ is most likely to be an almost daily occurrence on this side of the Atlantic, the identity between it and the germs which cause the same decomposition in American milk, must be proven by the same methods and experiments, in order to make this mere supposition a certainty.

With this object in view, I gladly took advantage of an opportunity kindly offered to me this summer by Drs. E. D. Salmon and Theobald Smith, of the Bureau of Animal Industry, of working out this problem in their well-equipped laboratory.

In repeating Hueppe's experiments, so far as this was done by me, it was, of course, thought best to follow out the same course of experimenting and use the same methods as were used by him, and the first question, therefore, which naturally arose was, What microörganisms, if any, do we find in sour milk as it occurs in our market?

In order to determine this point, four sterilized test tubes were each charged with ten cubic centimetres of ordinary milk and set aside at the temperature of the room which, during our summer, is about 80° F. On the following morning, an examination showed that the contents of these tubes had undergone a change which seemed the same in all. A solid precipitate was found at the bottom of the tubes, showing only here and there a few superficial cracks or fissures and a slightly turbid, watery supernatant liquid; the precipitate was of the consistency of soft butter, and the liquid reacted very decidedly acid to litmus paper.

From each one of the test tubes several cover-glass preparations were now made and examined under the microscope, partly stained with methyl-violet, partly unstained. After a careful examination of these preparations, three different kinds of microorganisms were found to be present, namely: 1. A rather long and narrow, much curved bacillus. 2. A micrococcus. 3. A form of bacterium. The bacillus was found to be present in but one of the test tubes, the micrococcus in another, but the bacterium could be demonstrated as present in all four of the tubes, and in two of them it existed almost in the form of a pure culture.

It now became, of course, necessary to produce pure cultures of the various organisms which had been found, and to this end Koch's method of plate cultures was resorted to as follows: Three sterilized glass plates were thinly coated on one side with a layer of sterilized beef infusion-peptone-gelatine, previously liquefied at a gentle heat; the plates were supported by a glass vessel containing ice, and the whole protected by a bell-jar from dust and other atmospheric impurities, and set aside to cool until the gelatine had almost solidified. That time having arrived, a small trace of the contents of the tubes was taken out by means of a previously sterilized platinum wire, and each plate separately inoculated by drawing several lines lightly across it with the end of the wire which had been lightly dipped into the contents of the tubes.

All the plates were transferred under the bell-jar to a chamber in which the temperature remained constant at 70° F., which is sufficiently low to prevent the gelatine from melting, and still high enough to allow of the development of most bacterial organisms.

At the expiration of the first twenty-four hours after inoculation, all the lines which had been drawn over the surface of the plates seemed crowded with colonies of bacteria, the first lines on each plate having received more of the inoculated material than the rest, were continuous lines, the colonies having fused into one another. The margins of the lines were jagged, looking not unlike the plate of a fine saw with blunt teeth. The lower lines, however, showed distinct and isolated colonies having, apparently, originated from a single germ. Both lines and isolated colonies were of a porcelain-like whiteness, the latter looking like little drops of white paint sprinkled over the surface. Examined under a very low power of the microscope, most of the isolated colonies were seen to form round little knobs, projecting slightly from the surrounding surface and possessing very finely granular contents. There were also a few other colonies differing slightly from those described, but, owing to the fact that development in them had not as yet proceeded far enough, their characters were not very distinctly shown. On two of the plates quite a number of fungi had also developed.

From several of the isolated bacterial colonies, resembling in appearance the great majority of the colonies on the plates, two culture tubes containing sterilized beef-infusion-peptone were inoculated by means of a previously heated platinum wire. The colonies from which the material for inoculation was taken were identical in appearance with those described by Hueppe as "porcellanartige Knöpfe," being round or nearly so, with a well-defined contour, elevated and much thicker in the centre, uniformly slanting and growing thinner toward their margins.

Two other culture tubes containing beef-infusion-peptone were inoculated in the same manner from colonies showing slight differences from the majority of them, and all were set aside in a warm chamber, the temperature of which varied between 95° and 98° F.

On the following morning every one of the inoculated tubes showed slight but unmistakable turbidity, a very thin bluish-white membrane was seen floating on the surface and adhering to the sides of the tubes near the surface of the culture liquid.

Forty-eight hours from the time of inoculation a rather thick membrane was found on the surface of all four of the inoculated tubes, and the turbidity had considerably increased in extent. In two of them an abundant pulverulent deposit of a dirty yellow color was found to occupy the entire concavity of the bottom of the culture tube. These were the ones which had been inoculated from those colonies which showed slight differences from the majority. In the remaining two culture tubes this deposit was entirely absent, the membrane on the surface of the liquid, and the turbidity marking the only change which had taken place in them.

From the latter, several cover-glass preparations

were now made and examined under a one-eighteenth homogeneous immersion lens. The examination showed them to consist of a pure culture of the bacterium already mentioned, and to be described more in detail presently. Cover-glass preparations made from the other tubes proved their contents to be mixtures of all three of the original microörganisms observed in the sour milk.

Examined in the glass cell, the bacillus exhibited active movements, the micrococcus and the bacterium were both motionless.

From each of the two culture tubes containing the bacterium in the pure state, so far as that can be ascertained by cover-glass preparations, two plate-cultures were now prepared in the following manner: About ten cubic centimetres of sterilized beef-infusion-peptone-gelatine were liquefied in a test tube by gentle heat over a Bunsen burner, a very small quantity from the pure culture was transferred into the liquefied gelatine by means of a heated platinum wire, and the contents, after slight agitation, poured on a sterilized glass plate and set aside to cool, well protected by a bell-jar. The temperature of the chamber remained constant at 70° F.

On the next morning an examination showed that the whole surface of the gelatine-covered plate was thickly studded with a rich growth of colonies which, to the naked eye, were small, round, of a dirty white color and a peculiar lustre; they were slightly elevated from the surrounding surface of the gelatine, pretty uniform in size, and very evenly distributed and not liquefying gelatine. No differences whatever could be made out as existing between the colonies either by the naked eye or by means of the microscope.

Cover-glass preparations, made from a number of these colonies, which were afterward examined by means of the one-eighteenth homogeneous immersion lens of Zeiss, partly stained in methyl-violet, partly unstained, showed that on all pure cultures of the bacterium were present which was identical with that described by Hueppe as bacillus lactis.[1]

Four culture tubes, containing beef-infusion-peptone, were next inoculated each with a small trace of material coming from a different colony on the plates, and placed in a chamber where the temperature remained at 98° F. At the end of the first twenty-four hours from the time of inoculation, an examination showed slight turbidity in the contents of the tubes; in all, a very thin and delicate bluish-white membrane could be seen floating on the surface of the liquid and adhering to the sides of the tubes. After forty-eight hours from the time of inoculation, the membrane had grown slightly thicker and fell to the bottom on slight manipulation. Cover-glass preparations made from each of these cultures showed bacterium lactis in a state of purity.

In the same manner as described for bacterium lactis, pure cultures were obtained from the coccus and also the bacillus mentioned above. For, although it was to be supposed that the bacterium was the organism in question and that both bacillus and coccus were mere accidental impurities, it had still to be proven by actual experiment that this was no mere supposition, but the fact, and for this reason pure cultures were made from them also.

Four culture tubes, containing about ten cubic centimetres each of milk, sterilized by discontinuous heating, were now inoculated from one of the pure cultures of bacterium lactis and set aside in the culture-oven. An examination of these tubes, twenty-four hours from the time of inoculation, showed very plainly that the change characteristic of the souring of milk had already taken place. A precipitate or deposit had formed which was both voluminous and solid, showing a few superficial cracks and fissures which deepened somewhat during the succeeding days. The supernatant liquid was clear and watery, possessing a very decidedly acid reaction. Further examination showed the characteristic microörganism in the pure state.

Several culture tubes, containing sterilized milk, had also been inoculated with pure cultures of the bacillus and the coccus respectively, but no such change was found to have taken place in them. In fact, with the exception of a slight yellowish discoloration, no change whatever was noticed in them, the milk having remained fluid even up to the end of the fourth day when observation on them was discontinued.

The milk used in these experiments had been sterilized by discontinuous boiling. According to Hueppe, milk may be sterilized by a temperature of 75° C., but 100° C. is perfectly admissible, though higher ones are not.

So far, then, a peculiar bacterium, identical in all respects with that described by Hueppe as bacillus lactis, had been found constantly associated with the process of lactic acid fermentation; the bacterium had been isolated and pure cultures produced from it, the inoculation of which into sterilized milk produced the characteristic decomposition, while pure cultures from the other microörganisms inoculated in the same way did not produce this change.

It still remained to be proven that the peculiar and very characteristic change brought about by the inoculation into sterilized milk of a pure culture of this germ, was due to the decomposition of the sugar contained in milk into lactic and carbonic acids.

To this end a large quantity of a solution of certain salts in distilled water was made, recommended by Hueppe as best supporting the growth of this bacterium. The solution contained dipotassium phosphate 0.3 per cent., magnesium sulphate 0.1 per cent., and chloride of calcium 0.025 per cent. A fine flocculent precipitate was formed when the salts were mixed together; this precipitate was not filtered off, but was allowed to remain in the solution. Using this as a menstruum, three culture flasks were charged with 100 centimetres each of the solution. To

[1] The term *bacillus*, which has been applied to this form of bacterium, by Hueppe and also by Dr. James Eisenberg (*Bacteriologische Diagnostik*), is by no means incorrect. A bacterium which, according to the medium in which it happens to be cultivated, is found to vary in length all the way from 1-2.5 μ, may, perhaps, well deserve the name of *bacillus*; when, however, it is cultivated in milk and examined before the process of fermentation has ceased—in other words, when this process is at its height—its length, according to Hueppe's own measurements, remains within that of a bacterium; and we have, for this reason, preferred the latter term to that of bacillus.

one of the flasks one gramme of peptone was added, to another, three grammes of milk sugar, and to the third, three grammes of glucose were added. Three exhaustion bulbs were likewise charged with about ten cubic centimetres each of the same fluid. All the flasks and bulbs being well protected with cotton plugs, were now sterilized in the steam sterilizer, where they remained for two consecutive hours; the thermometer showing that the maximum temperature during that time had reached 108° C.

On the following day the three flasks were inoculated with a pure culture of bacterium lactis and placed in the culture oven. The bulbs were likewise inoculated, and immediately afterward the air was exhausted by means of an air-pump which was kept working steadily for fifteen minutes, the bulbs being immersed in a water bath, the temperature of which was kept at 103° F. At the end of that time, the necks of the bulbs, having been previously drawn out to a fine capillary tube, were sealed up by means of an alcohol flame, and thus hermetically sealed they were placed in the culture oven and kept at a temperature varying between 95° and 98° F.

Those of the flasks and bulbs which contained the sugar solutions had changed color slightly during sterilization. The solutions, from being colorless or almost so, had assumed an amber tint, due, of course, to the fact that some of the sugar had been caramelized by the heat applied to it during the process of sterilization. The precipitate which formed on mixing the various salt solutions together, had become somewhat granular and settled to the bottom, leaving a perfectly clear supernatant fluid.

On the following morning, or about twenty hours from the time of inoculation, the contents of all the culture flasks had become turbid, the exhaustion bulbs, on the contrary, remaining perfectly clear. Forty-eight hours after inoculation, those of the culture flasks containing the sugars in solution, exhibited signs of active fermentation. An abundance of large air bubbles had collected on the surface and small ones could be seen constantly rising in the fluid. Nothing like this was noticed about the bulbs. This process of fermentation seemed to be ended on the fourth day, when all the flasks became turbid, and membranes had formed on the surface of the fluids, especially on the surface of the peptone solution.

On the eighth day after inoculation the contents of the flasks were examined. Pure cultures of bacterium lactis were found to be present in every one, as was easily ascertained by cover-glass preparations. The reaction of the fluids containing the sugars in solution was very decidedly acid. The quantity of the acid as determined volumetrically, was 0.125 or exactly one-eighth of a per cent., and was the same in both the flasks.

The bulbs from which the air had been exhausted, by means of an air-pump, showed no traces of either turbidity or fermentation after an exposure in the culture oven to a temperature of 98° F. for the period of two weeks. At this time, the sealed points of the necks of the bulbs were broken off under a sterilized cotton plug, and both turbidity and fermentation appeared promptly on the following day, bacterium lactis developing quickly and abundantly in the pure state as was afterward ascertained by cover-glass preparations.

All these experiments were repeated several times with results practically identical with those which have been here described. In some of the experiments the sugar solutions had been exposed to too high a temperature (112° C.) during sterilization, and, consequently, most all the sugar had been caramelized; the quantity of lactic acid produced, therefore, was not equally large in all cases, but enough had remained to give an acid reaction to litmus paper.

In salt solutions, made with the acid phosphate of potassium instead of with the dipotassium phosphate, bacterium lactis remained undeveloped and no sign of either turbidity or fermentation was noticed, even one month after inoculation.

While thus engaged in the study of the physiological properties of bacterium lactis, Dr. Theobald Smith was investigating the character of a bacterium obtained from the spleen of a pig supposed to have died of swine-plague. Examining one day some of his cover-glass preparations, I was impressed with the remarkable morphological similarity existing between the two germs. Discussing the subject, I was informed by Dr. Smith that this germ turned sterilized milk sour, and this led me to investigate further the germ in its relation to lactic acid fermentation.

A fresh lot of salt solutions was accordingly made and four culture flasks were charged with 100 centimetres each. Two of them received three grammes of milk sugar, and the remaining two three grammes each of cane sugar. These solutions were sterilized by discontinuous boiling. The boiling was kept up for five minutes, and done once a day for five days; the solutions remained colorless and came out perfectly clear and transparent. After sterilization one of the sugar- and one of the lactose-containing flasks received a small portion of a pure culture of the supposed swine-plague germ,[1] and the other two were inoculated with bacterium lactis.

Forty-eight hours after inoculation fermentation was found to be active in the flasks inoculated with bacterium lactis, as was evidenced by the number of air-bubbles rising to the surface. No change whatever, with the exception of some turbidity, was noticed in the flasks which had been inoculated with the supposed swine-plague germ.

At the expiration of two weeks of exposure to a temperature in the culture oven of 98° F., the contents of the flasks were examined. Those inoculated with bacterium lactis were very decidedly acid to litmus paper, those containing the bacterium of swine-plague reacted slightly, but distinctly alkaline, thus, leaving bacterium lactis alone in the field as possessing the power of converting sugar into lactic and carbonic acids.

The quantity of lactic acid, as determined by volumetric analysis, for the sugar flasks, was 0.178 or nearly one-fifth of one per cent.

[1] Presumed to be a modification of the germ which gives rise to swine-plagues in the East; was brought from the State of Illinois.

Bacterium lactis may be described as a short, thick, plump, little rod, distinctly ovoidal in shape, about half as broad as long, and varying in length from 1 to 2 μ, its breadth remaining tolerably uniform. The best specimens may be found in milk cultures, the smallest in beef-infusion-peptone-gelatine cultures. As the bacterium lengthens, a slight constriction about its middle portion becomes noticeable which soon broadens and deepens, giving rise just before complete division takes place, to the figure-8 form. This form becomes more especially noticeable in preparations stained with methyl-violet, which leaves a very minute central portion of the protoplasm unstained. The germ does not liquefy gelatine, and when examined on the hollow slide, it is found to be motionless. With regard to spore-formation, our experiments have not been attended by very positive results, although everything else seems to indicate that they do form spores. The settlement of this question will form one of the subjects of future investigations.

The results of the foregoing experiments have led me to agree fully with those obtained by Hueppe, namely: lactic acid fermentation, or the process of the souring of milk during which the sugar contained in the latter is converted into lactic and carbonic acids, is directly dependent on or caused by the life and growth of a certain definite variety of micro-organism, the physiological characters of which are sufficiently distinct to differentiate it from any other known organism, and which, therefore, may be properly designated as bacterium lactis.

A MODIFICATION OF WEIGERT'S METHOD OF STAINING THE TISSUES OF THE CENTRAL NERVOUS SYSTEM.

By W. M. GRAY, M.D.,
MICROSCOPIST, ARMY MEDICAL MUSEUM, WASHINGTON, D. C.

The specimens, hardened in Müller's or Erlicki's fluid, are transferred directly (without coming in contact with water) to alcohol 70 per cent. The pieces to be embedded are now gradually dehydrated, advancing from 70 per cent. to 95 per cent. alcohol, and finally to absolute. After soaking in absolute alcohol for several days, they are transferred to a mixture of equal parts of ether and absolute alcohol, and allowed to soak for one or two days; they are then transferred to a solution of celloidin, and are embedded in celloidin on cork.

The pieces, fastened to a cork with celloidin, are immersed in a solution of neutral acetate of copper (a saturated filtered solution of this salt, diluted with an equal volume of water), and allowed to remain in an incubator at 30° or 40° C. for one or two days.

The specimens become pea-green after the copper treatment, the celloidin mantle more of a blue-green; they may now be preserved in 80 per cent. alcohol indefinitely.

After having made the sections, which must still be kept clear of water, they are immersed in the hæmatoxylin solution, the formula for which is as follows: hæmatoxylon (Merck's, in crystals), one part; absolute alcohol, ten parts; water, ninety parts; boil twenty minutes, cool and filter, and to each one hundred parts add one part of a cold saturated solution of lithium carbonate.

The time required for staining varies with different specimens; in general, the rule prevails that the longer one colors, the surer the result; for cord sections, two or three hours are usually sufficient; in brain sections, twenty-four hours are required in order to color the very fine fibres of the cortex.

After staining, the sections, now black in color, are differentiated by immersion in the following solution: borax, two parts; ferricyanide of potassium (red prussiate), two and one-half parts; water, one hundred parts. It will be found that the time required for perfect differentiation varies in different specimens: in cord sections, it usually takes from one-half hour to several hours before the desired contrast between white and gray matter is obtained, and in brain sections it is longer. No fear of spoiling the sections need be felt. I have frequently allowed sections to remain in this solution for twelve hours without ill result.

From this solution the sections are transferred to water and well washed; then to 80 per cent. or 90 per cent. alcohol; they are then spread on slides and dehydrated thoroughly with absolute alcohol, and then clarified. I prefer xylol or creasote for clarifying, and xylol or benzole balsam for mounting.

If the steps in this method are carefully followed, success is certain; and it is without exception the method for tracing nerve fibres or demonstrating nerve lesions.

HOSPITAL NOTES.

DISPENSARY FOR NERVOUS DISEASES, BALTIMORE.

Service of John Van Bibber, M.D.

SOME ANOMALOUS AND COMPLICATED EXAMPLES OF CHOREA.

While there is no definite pathology for chorea, and it is possible that different types of the disease may be due to entirely distinct causes, it is very interesting to study the following cases, which I select from the notes of my assistant, Dr. H. C. Ohle.

Case I. *Chorea Nutans seu Vibratoria.*—M. K., ten years of age, was presented for treatment March 16, 1886. Both arms were affected with a constant and *regular* twitching, which also involved the head to a less degree. The twitching of the arms was as constant and rhythmical as in a severe case of palsy, and was not choreic in type. Patient gave a history of having been subject to severe attacks of malarial fever for several years. The child was well nourished, strong, and finely developed. On the morning of March 13, 1886, she was seized with a slight chill, followed by diarrhœa and fever; on the evening of the same day she developed slight tremor of the right arm, which gradually involved the left arm, and finally the head. There was no history of punishment or fright. From the day when the first symptoms appeared until she was presented for treatment, the twitchings became so exaggerated in force and frequency that the child could not obtain sleep or rest. No other portion of the body was affected.

On examination, all the organs were apparently in

a healthy condition, functions properly performed, and her appetite fairly good. Treatment: friction with sedative lotions, quiet and rest in bed, hot douches to her spine; at night, potass. bromide to induce sleep, succ. conium, Fowler's solution, and bitter tonics. By March 25th, under this treatment the twitchings of head had entirely disappeared, and the tremor in the arms was much less pronounced and exhausting. April 5th, the tremor had entirely disappeared, leaving the general health in as good condition as could be expected after three weeks' close confinement to bed. She was discharged cured, with instructions to continue for several weeks the treatment prescribed.

Remarks. This little girl showed, in a highly exaggerated form, the movements of a marked case of paralysis agitans. The motions of the head and arms were rhythmical and violent. The lower extremities were not disturbed. It was considered necessary to treat the case in bed, yet it was impossible for her to lie down with any comfort, for the movements were continuous, except during the time when she was actually asleep. Toward the end of the attack the movements became more choreic in character. The hot spinal douche was more productive of sedative effect than any other remedy. There was no history of rheumatism, and in chorea complicated by this disease I have learned to look for general choreic symptoms. The pathological condition was evidently confined to the upper portion of the spinal cord, for we could hardly suppose the motor centres in each hemisphere to have been similarly affected.

Case II. *Post-hemiplegic Chorea.*—C. H., six years of age, was presented for treatment March 15, 1886. She was affected with apparent paralysis on the right side of the body, involving both the right arm and leg; in addition, she was completely aphasic. On inquiry, it was learned that she was quite healthy and robust until last fall, when she suffered with a protracted attack of malarial fever, which debilitated her very much. She was considered well, however, when, on Feb. 19th, of this year, she was badly frightened by a pet monkey, which attacked her, and attempted to bite her. The mother claims that she was thrown into a spasm; when she recovered from this attack it was found that she had lost her speech, and was paralyzed on the right side. After a time, choreic movements began to develop, which were, however, slight in degree. This condition gradually grew worse. She lost interest in her play, and became stupid. On examination, I found a right hemiplegia, with inability to pronounce even the simplest words; she could not protrude her tongue and hold it still, and the affected side showed decided choreic twitchings. The child was very anæmic, restless at night, and had loss of appetite. The case was diagnosticated as a post-hemiplegic chorea, and treated with mercurial inunction, and ammonium carbonate in solution. Potassium bromide was given at night, to induce sleep. She was ordered to rest quietly in bed, and a hot spinal douche at night. Under this regimen the child recovered with remarkable rapidity; her appetite improved, and with it her general condition. The functions of her limbs have again been restored; she can pronounce words sufficiently well and clearly to be readily understood, and a speedy and complete recovery is anticipated.

On referring to the Dispensary Case Book, I find that the child was discharged well in the latter part of April.

Remarks. In this case of hemi-chorea, resulting from a unilateral brain lesion, we have the reverse of the usual order of symptoms. In severe cases of hemi-chorea we find, after some weeks, a resulting paresis in the muscles of the diseased side, which almost amounts to a hemiplegia, and in this case we find a right hemiplegia and aphasia, followed by a decided chorea in the paralyzed side. The improvement in the case, however, proves that the brain lesion was functional, rather than organic, and gives an interesting lesson in prognosis. The minute embolism theory would seem to give the most reasonable pathology for the chorea, and the transitory stage of hemiplegia was most likely due to some gross circulatory lesion of the brain.

Case III. *Chorea with Histrionic Spasm.*—F. K., fifteen years of age, presented himself for treatment at this Dispensary February 26, 1886. He was well developed for his age, but anæmic and apparently poorly nourished. He gave the following history: About six weeks previous to the date mentioned, his appetite began to fail, and he noticed a twitching of his left eyelid, which he could not control. Then he found that he would drop articles which he held in his hand; this occurred so often that he was compelled to stop work. The twitchings of his left eyelid became aggravated, becoming more frequent in number and longer in duration, the right eyelids not being affected at all; the irregular movements of both arms increased in violence, and finally extended to the legs. On examination, I found that the muscles of the left side of the face, particularly of the left eyelid, in less degree, and the muscles of left side of the mouth, were affected by clonic spasms, the attacks following each other in rapid succession, with intervals of rest, during which the movements of the left side of the face were normal. At the same time both arms were found affected with choreic movements of a mild type; also both legs, though in a less degree. The right side of his face was perfectly normal; his speech was not at all affected, nor did we find any choreic movements of the muscles of either side of his face. This is the first attack of the kind, and he had otherwise been healthy. He was ordered to remain as quiet as possible, and to rest, retiring early, and remaining in bed late in the morning. Sponge baths daily, to be followed by rubbing with a coarse towel. He was ordered nutritious and easily digestible food, and bitter tonics and iron preparations, in connection with conium, were prescribed in full doses. This treatment was followed by marked improvement at the end of one week. This was kept up, with slight modifications, for one month, the patient being discharged March 25th, apparently entirely well.

Remarks. The convulsive tic or histrionic spasm in this case was so marked and so entirely different from the movement of the muscles of the extremities, that it looked as if two distinct diseases were present. If both these morbid movements were brought on by the same cause, certainly the local irritation of the left motor nerve of the face was much greater than the impression which produced the choreic movements of the arms and legs. The spasms of the muscles of the left side of the face were symmetrical and paroxysmal, the movements of the other muscles were irregular and choreic in character. The symptoms of central origin, as demonstrated by the disturbance in the function of a motor cranial nerve, differed entirely in nature and intensity from the symp-

toms of spinal origin, as manifested by the exaggerated movements of the extremities. And yet the prompt and satisfactory improvement of all symptoms under a general treatment, seems to prove that the cranial spasm and the spinal incoördination were due to the same cause.

MEDICAL PROGRESS.

Cold Baths in Scarlatina.—Molière presents two cases in which cold baths were successfully employed in the treatment of the hyperthermic stage of scarlatina. The baths were of short duration (five to eight minutes) and of a temperature of approximately 72° F. One of the patients manifested a very grave angina with considerable hypertrophy of the ganglia of the neck, and the other suffered from gangrenous angina. Neither pneumonia nor pericarditis was developed, and an albuminuria which had existed in one of the patients, disappeared quite rapidly.—*Gazette Hebdomadaire*, September 17, 1886.

A Case of Rapid Pleural Effusion Treated by Antiseptic Incision.—Dr. Albert Wilson narrates in the *Lancet* of October 9, 1886, the following case, which is of interest, as it shows the advantage of an incision made during the early stage of pleural effusion before it had become a case of empyema. In fact, the effusion was so large and so rapid, and the dyspnœa and cardiac depression were so great, that the case would never have reached the stage of empyema if prompt operative treatment had been delayed.

The patient, Mrs. B., aged thirty-five, was first seen by me on March 3, 1886. She complained of breathlessness and increased cough, and she had been ill nearly a week. There had been no rigors; the pulse was 140, small and weak; the expectoration was mucous, slightly rusty; respiration 40; temperature under the tongue 102°. On examining the chest, the left base was dull on percussion. The front of the chest was normal in all respects. Auscultation: At the right base there were moist râles and crepitations; at the left base there were no respiratory sounds audible; vocal resonance was increased over the right base, whilst it was ægophonic over the left base; vocal fremitus was increased over the right base, but absent over the left. The absence of vocal fremitus decided the diagnosis as pleurisy and pneumonia.

March 4. The dulness is higher posteriorly, and in the axillary line there is also dulness in front from the left side when she sits up. The first sound, which is weak, is loudest behind the sternum. Temperature 101°; pulse 140; respiration 46.

5th. General condition worse, and increased effusion. Absolute dulness at and below the third rib in front, and from a line parallel with the fourth dorsal vertebra behind. The right chest is normal, except for cardiac dulness over the fourth right costal cartilage. The apex of the heart is now almost under the right mamma. There is a total absence of respiratory sounds all over the left chest, both back and front, except above and just below the clavicle. Ægophony is well marked at the angle of the left scapula, the vocal resonance is altered in front, vocal fremitus is absent on the left side, and there are moist sounds over the right base. Temperature 101°; respiration 48; pulse 140. The pulse tracing shows a very small wave, due to the feeble cardiac impulse and the contracted arteries. Operative treatment was now imperative. Being a disciple of Lister, I did not feel justified in opening this large cavity without the spray, as it was a small foul room, and the impure air entering the pleural cavity would be very dangerous and certain to cause suppuration. Further, to wash out the cavity, which I had allowed to become septic, would be an unnecessary labor for me, and a needless and a rather dangerous entertainment for the patient. I preferred prevention to cure. I made an incision between the seventh and eighth ribs posteriorly to the axillary line. Clear serum poured forth in abundance; more than five pints were collected and about a pint was wasted. Air entered the chest freely. When I introduced my finger through the ribs, I could not reach the lung for at least half an hour after the incision was made. When the lung did expand the surface of the pleura was found to be quite rough. A tube four inches long was inserted downward and backward, and I applied a small dressing of boracic lint soaked in mercurial solution. Within an hour the heart sounds were to be heard under the left breast. Friction was heard posteriorly as soon as the pleural surfaces were apposed. The friction gradually appeared from above downward, as the expansion of the lung was very gradual, and when I left it had not fully expanded at the base, which I proved with my finger. The pulse tracings, taken every few minutes, were very interesting. Before the operation it was a slight deviation from a straight line, being so feeble. Soon after the operation the pulse wave expanded, getting larger and fuller, until there was a full, sharp, apex systolic wave with a marked dicrotic wave, showing low arterial tension, due to the relaxation of the arteries and the removal of the pressure on the heart and main vessels.

6th. Temperature 101°; pulse 120; respiration 32. The wound was dressed under the spray. There was a free serous discharge through the tube, and the air entered with inspiration. The physical signs of pleurisy are well marked.

7th. Temperature 101°; pulse 120; respiration 26. Wound dressed and tube removed. I inserted my finger to feel the pleura. It felt rough and spongy, like placenta. I passed my finger round, separating the adhesions of the two surfaces, and it reminded me of a case of placenta prævia. It was the adhesion of the surfaces that determined me to remove the tube.

8th. Temperature 101°; pulse 108; respiration 26.

10th. Temperature 100°; pulse 98; respiration 24. Wound dressed. Very little thin serous discharges. Physical signs normal over both lungs. I could not trace the cause of the slow fall in temperature. The patient, though very weak, is doing well considering that she was at death's door before I operated.

15th. Temperature 99°; pulse 90; respiration 20. Wound dressed, and healing satisfactorily. Before the operation I measured each side of the chest from the anterior to the posterior mesial line just below the mammæ. The right half was 16 inches, the left 17½ inches. To-day, five days after the operation, each side measures 16 inches alike. The spine is perfectly straight, and the left chest is not shrunken. These results could not be attained by aspiration, however

skilfully done. The patient was soon restored to perfect health.

The Treatment of Thread-worms in Children.—Dr. Sidney Martin writes as follows to *The Practitioner* of October, 1886:

The complete cure of thread-worms in children is often very difficult. While the ordinary methods used, such as rectal injections of salt and water, infusions of quassia, and other remedies, do good for a time, yet they often fail to relieve the attendant symptoms of "worms," symptoms usually very irregular, and in some cases severe, in character. In many cases, though the irritation about the anus is relieved by injections, the irregularity of the bowels and the disturbance of sleep remain the same. This is probably due to the fact that the habitat of the worms is higher up in the large intestine, where no remedy introduced by the rectum can reach them.

In many cases I have found that rhubarb in small doses brings away large numbers of worms, and at the same time regulates the bowels: so that the use of injections may in most cases be dispensed with. The formula which I have found most useful is as follows, varying slightly with the age of the child:

R.—Tincturæ rhei	♏iij.
Magnesii carbonatis . . .	gr. iij.
Tincturæ zingiberis	♏j.
Aquam	ad ℥j.

This is to be taken twice or three times daily, according to the effect on the bowels. Whether the rhubarb acts as a vermicide or simply by "moving the worms on," I am unable to say.

Pharyngeal and Laryngeal "Nystagmus."—Dr. Herbert R. Spencer writes as follows to the *Lancet* of October 9, 1886:

I am indebted to Dr. Gowers for permission to publish the following observations I have made on a patient under his care at University College Hospital. The patient, a girl aged twelve, has a cerebral tumor, and presents the symptoms of reeling gait (with a tendency to fall backward and to one side, usually the right), vertigo, intense occipital headache, constipation, vomiting, ocular nystagmus, but no optic neuritis. The pulse is usually 100. These symptoms have been present for the last fifteen months. The ocular nystagmus is vertical and horizontal, occurs at the rate of 180 to the minute, is slightly increased in frequency during accommodation for very near, or in looking at far distant objects. On examining the throat, I noticed the superior constrictor of the pharynx to be in a state of constant rhythmical movement in a horizontal direction, as if the posterior pharyngeal curtain were being rapidly drawn together, the twitchings occurring at the same rate as the movement of the eyes, 180 to the minute. The movement does not affect the soft palate or pillars of the fauces, the faintest possible tremor only being transmitted to them from the action of the adjacent constrictor. By pressing the point of a quill pen againt the pharynx and pivoting the quill on a pin held fixed against the upper teeth, I have been able to write with the feather end a tracing of the movement on sphygmograph paper. The laryngeal muscles are similarly affected. The arytenoid cartilages are seen rapidly ghding to and from each other synchronously with the movement of the pharynx. When the patient is breathing quietly the main movement of widening the glottis during inspiration is interrupted by slight twitches, and similarly the movement of respiration. When the patient stops breathing the cords gradually close with five or six contractions, till they finally lie parallel and close to each other; here they remain, undergoing only a slight tremor till the patient recommences to breathe. I have had this patient under observation for over two months, and the movement has always been present. There is now a slight alteration in the state of the larynx, in that the left cord twitches more than the right, and the cords do not so nearly close when the patient stops breathing. I am not aware that a movement of this kind has been previously described, and I am anxious that it should be looked for in cases of intracranial tumor, so that its localizing value may be determined. It is possible it may throw some light on the etiology of ocular nystagmus, and it may be of value to the surgeon, perhaps, in showing pressure on the medulla, and so assist in the diagnosis of the position of a cerebellar tumor. As regards the term "nystagmus" applied to the pharynx and larynx, its association and synchronism with the ocular nystagmus, and the fact that movement of the eyes in a horizontal direction is called "nodding," would seem to warrant a slight departure from strict etymological accuracy.

Cocaine in Gonorrhœal Ophthalmia.—A. Leahy, I.M.S., recommends a trial of cocaine in gonorrhœal ophthalmia. In his hands he has found that the ocular and circumorbital pain is much diminished, the chemosis reduced, and the congestion of the conjunctival vessels much diminished. He used the following preparation: Cocain. sulph. 4 gr., atrop. sulph. ½ gr., vaseline 100 gr. To be applied with a camel's hair brush.—*Indian Med. Gazette*, July, 1886.

Suprapubic Lithotomy.—Thomas Annandale, F.R.S.E., writes as follows in the *British Medical Journal* of October 9, 1886:

In the *Journal* of January 2d of this year, I published an account of a new method of performing suprapubic lithotomy in male children, and I reported a case in illustration. Since then, further experience has convinced me that this method is an improvement in the case of adults, as well as in the case of children; and I therefore trust that some of my surgical friends will try it and report their experience.

Briefly stated, the steps of the operation are:

1. The gradual and thorough dilatation of the bladder by the injection of some antiseptic fluid.

2. The introduction of a lithotrite, and the seizing and fixing of the stone in its blades.

3. The depression of the handle of the lithotrite, so as to press the stone against the abdominal wall immediately above the pubes in the middle line.

4. Cutting down through the abdominal wall, in the middle line, upon the pubes, and immediately above it, in the usual way, until the bladder is reached.

5. Depressing the handle of the lithotrite still more, so as to stretch the wall of the bladder over the stone, and make it prominent at the wound.

6. Incising the stretched bladder wall upon the stone, to a sufficient extent, in a direction downward, and then protruding, through the opening, the stone and blades of the lithotrite.

7. Gently opening the blades of the lithotrite and removing the stone, and in withdrawing the lithotrite, catching one end of an India-rubber catheter in its blades, and bringing it out through the urethral orifice, the other end of the catheter being left in the bladder.

8. Stitching the wound in the abdominal wall, and introducing a drainage tube at its lower end.

If the wound in the bladder wall be small, I think it is better not to stitch it; but if it be large, two or more catgut sutures should be inserted.

The dilatation of the rectum is not, in my opinion, required, and if employed, only complicates the operation.

Failure of the Bacterial Treatment of Consumption.—At a recent meeting of the Odessa Medical Society (*Proceedings of the Odessa Medical Society*, 1886, No. 6, pp. 1–12), Dr. Filipovitch, of the Odessa Town Hospital, made a very instructive communication on six cases of advanced pulmonary phthisis, which had been treated by him after the bacterio-therapeutic method recommended by Professor Arnaldo Cantani (see the *British Medical Journal*, 1885, August 29th and Nov. 18th; and 1886, March 6th and 13th). Having obtained by fractional cultivation, pure cultures of the bacterium termo in meat broth, the author took five cubic centimetres of the bacterial fluid, diluted them with ten cubic centimetres of boiled water (37° C.), aromatized the mixture with one or two drops of tincture of peppermint (to disguise an offensive odor), and made the patient inhale the whole by means of Richardson's spray-producer. The inhalations were repeated twice daily. In one of the patients, the experiment was given up at the end of a week, since the man's state commenced to grow worse from the very beginning, and fever, steadily increasing bronchitis, and hæmoptysis had developed. Three other patients died under the treatment, one after fifteen days' inhalations, another after seventeen days, and the third after twenty-five days. The remaining two patients left the hospital after treatment for seventeen and fifty-two days respectively. In none of them was anything like a diminution of the expectoration observed. In one of the fatal cases, shortly before death, the sputum became more profuse, more liquid, and assumed a characteristic bad odor, resembling that of a pure culture of the bacterium termo. At the necropsy, numerous excavations "represented, as it were, a culture of the bacterium;" the spleen was enlarged, flabby, partly of a dark red, partly of a pale red color; the liver was also enlarged and anæmic. In the non-fatal cases, nothing like a diminution or disappearance of the tubercle bacilli from the sputum was detected. In the patient who was treated by the inhalation for more than seven successive weeks, the number of bacilli was distinctly increased during the seventh week. In none of the cases was any influence exerted by this treatment on the temperature, or perspiration, or the body-weight discovered. Finally, Dr. Filipovitch came to the general conclusion that "no good whatever may be expected from the treatment of tuberculosis by the inoculation of the bacterium termo;" while some of his cases seemed to point out that the infection of the human system with the putrefactive bacteria might prove not nearly so harmless as had been alleged.

Cure of Rheumatic Tetanus by Pilocarpine.—Brünner describes the case of a peasant woman aged forty, suffering from rheumatic tetanus, whom he treated for five days without result, despite the administration of morphia, chloral, quinine, etc. Pilocarpine was then used in the single daily dose of one-third of one grain. The induced perspiration was moderate, but the increased salivary secretion was very great. Chloral hydrate was given at night. On the ninth day of treatment the convulsions disappeared completely.—*Centralb. f. klin. Med.*, September 18, 1886.

Clinical Examination of Urine in Children's Diseases.—In the preliminary note in the *Vratch*, Nos. 44 and 45, 1885, p. 730, Dr. Alexandra J. Eckert, house-physician to the Elizavetinskaia Infirmary for Children, in St. Petersburg, states that she had made 1500 analyses of urine in 104 children, in order to study its changes under the influence of various affections attacking the child's organism, and to determine quantitatively the albuminoid losses sustained by the system in febrile albuminuria. The albumen in the urine was estimated after a method based on Heller's test, and introduced simultaneously by Professor Roberts, of Manchester, and Dr. J. J. Stolnikoff, of St. Petersburg (see Professor V. A. Manasseïn's *Sbornik Rabot*, Part II., 1877). The author divides her cases into four groups.

The first group consists of the following cases—*a. Typhus fever* (seven cases in children, aged from 6 to 15). During the febrile period the urine was scanty, highly colored, and of a high specific gravity; in five of seven cases albuminuria, lasting from four to twenty-one days was present, the quantity of albumen varying from 0.024 to 0.502 per cent. It rapidly disappeared with the advent of pyrexia. *b. Enteric fever* (nineteen cases in patients aged from 3 to 14). In fourteen of them albumen was found during the febrile period for four to fourteen days, its quantity varying from mere traces to 0.7 per cent. *c. Relapsing fever* (two cases, aged 8 and 11). No albuminuria was observed. *d. Intermittent fever* (three cases, aged 9 to 12). No albuminuria was found.

A second group included—*a. Croupous pneumonia* in twelve patients, aged from 8 months to 12 years, with scanty, highly colored, and very dense urine during the febrile stage. In ten of them from a mere trace to 0.104 per cent. of albumen was found at the time of high temperature, for four to seven days. *b. Catarrhal pneumonia*, in two patients, aged 7 and 8. In the former, who had fever of an intermittent type and ultimately recovered, no albumen was found in his scanty urine of a high specific gravity. In the other, 0.064 per cent. of albumen appeared shortly before his death. *c. Pulmonary tuberculosis.* In all four fatal cases (in children aged 2½ to 10) albuminuria was present, varying from traces to 0.84 per cent. *d. Chronic pneumonia* (one case) and *exudative pleurisy* (one) without albuminuria.

A third group is composed of—*a. Measles*, two cases, aged 3 and 10, with albuminuria of one to three days' duration; the amount of albumen varied from 0.012 to 0.067 per cent. *b. Diphtheria*, faucial; two cases, aged 6 and 10, with albuminuria of one to five days' duration,

varying from 0.024 to 0.144 per cent. *c. Scarlet fever*, six cases, aged 3½ to 8. In five, albuminuria was observed, and that in two forms—as a *febrile* one, during breaking out of the rash, of one to seven days' duration, and with 0.012 to 0.044 per cent. of albuminuria; and as a *nephritic* one in the third week of the disease, of a monthly or longer duration, with 0.012 to 0.244 per cent. of albumen. *d. Parenchymatous nephritis*, eight cases. In seven, albuminuria of one to six weeks' duration was found, with 0.024 to 0.164 per cent. of albumen.

The fourth group consists of—*a*, a case of *catarrhal angina with erysipelas*, no albumen; three cases of *tonsillitis*, 0.052 per cent. of albumen in one; and four cases of *intestinal catarrh*, 0.052 to 0.184 per cent. in one. *b. Non febrile internal diseases*—scurvy, aortic stenosis, anæmia, cerebral tumor, dyspepsia, chorea, icterus, etc., seven patients, aged 5 to 14. Only in a case of syphilitic interstitial hepatitis were some traces of albumen noted. *c. External affections*, in twenty cases, aged from 9 months to 16 years. No albumen was detected in femoral phlegmon, in eczema with nettle-rash, in a case of femoral osteotomy, in fracture of the femur, and in rheumatic synovitis of the knee. Albumen was present in a fatal case of extensive burn, 0.184 per cent.; of multiple lymphoma, 0.064 per cent.; rachitis with bedsores, 0.008 to 0.124 per cent. It was observed also in three of eight cases of caries, in quantity varying from traces to 0.024 per cent. Finally, albumen (from 0.024 to 0.244 per cent.) was detected also in three cases of vesical stone and cystitis, its source being of course not in the kidneys.

The general conclusions reached by the diligent author are given as follows: 1. All affections considerably disturbing nutrition of the child's system, and running their course in association with a high febrile state, give rise to albuminuria in an overwhelming majority of cases. 2. The characteristics of albuminuria are usually dependent upon the intensity of the morbid process, and the duration of the febrile period. 3. As a rule, albumen rapidly disappears after abatement or cessation of fever. 4. Non-febrile affections, as well as those accompanied only by slight fleeting febrile movements, seldom give rise to albuminuria of any considerable degree; and when they cause albuminuria, it occurs only as a phenomenon of very short duration.—*The London Medical Record*, Oct. 15, 1886.

STRYCHNIA IN DIPSOMANIA.—The treatment of various forms of the alcoholic habit by means of strychnine, which has been recommended from theoretical and clinical researches by Luton, Giacomini, Magnus Huss, Morey, Lecuyé, Jaillet, Minoz, Dujardin-Beaumetz, and Amagat, has recently been tried by some Russian practitioners, and found to give gratifying results. DR. POPOFF, writing in the *Vratch* (No. 10, 1886), after giving a *résumé* of the results obtained by the French and Italian observers above named, mentions some cases of dipsomania which he had successfully treated in the same way, and in the last number of the *Vratch* (No. 38), DR. K. K. TOLVINSKI describes the case of a man, aged thirty-four, belonging to a neurotic family, very anæmic, but with no organic disease, who had drunk hard for many years, and with whom of late the outbreaks had been as frequent as two or three every month. He was treated with chloral, bromide of potassium, and opium, with but little success, his extreme distress, desire for drink, nausea, vomiting, and unusual weakness being unaffected. On the last occasion, when he had been drinking for some days, Dr. Tolvinski decided to make trial of strychnine, and began with the sixtieth of a grain of the nitrate in pilules three times a day, and did not prohibit spirits. The next day the man felt better, and asked for wine; but the sleeplessness, the want of appetite, and nausea and vomiting still continued, though in a somewhat less severe degree. Four days after the commencement of the strychnine treatment the patient had greatly improved in every way, and was soon afterward able to resume his work. He continued to take the sixtieth of a grain twice a day for six weeks, and during the four months which have elapsed since the attack he has had no inclination for drink. Upon this case the editor of the *Vratch*, PROF. MANASSEIN, who holds the chair of Special Pathology and Therapeutics in the Imperial Military Academy at St. Petersburg, remarks: "There is no doubt that, with abundant materials at hand, observations on the effect of strychnine on different forms of alcoholism will in the immediate future be accumulated in considerable numbers. It may be desirable as a preliminary to distinguish the different classes of the affection: (1) Anæmic cases (literally 'white fever'); (2) actual drunkenness; (3) constant drinking without symptoms of chronic alcoholism; (4) chronic alcoholism. It is very possible that the effect of strychnine on these very dissimilar conditions may be different, and if all these forms are confounded together, as is done by many writers, it can only lead to confusion when the strychnine treatment is mentioned." Prof. Manassein goes on to relate the case of a cook, an honest, respectable woman of forty-five, who was subject to attacks of insuperable craving for drink, which attacks were preceded by a depressed and highly irritable condition. They gradually increased in frequency, so that latterly they came on about every fortnight. Sulphate of strychnine was ordered in pills from the sixtieth to the thirtieth of a grain after breakfast and dinner. During four months of the strychnine treatment the patient continued in excellent health, not only having no outbursts, but not even experiencing any inclination for drink.

In another Russian medical journal, the *Meditsinskoe Obozrenie*, DR. PARTSEVSKI gives an account of nine cases of acute and chronic alcoholism treated by means of hypodermatic injections of strychnine. Seven of the cases gave excellent results, but in the remaining two cases the strychnine had to be discontinued and chloral substituted. In the majority of cases the treatment began to take effect very quickly on the appetite, sleeplessness, and hallucinations. The trembling of the hands, too, entirely disappeared, and the general irritability subsided. The author says that under no other kind of treatment has he found patients recover so quickly from an attack. Even the blueness of the skin and the puffiness of the face and hands quickly disappeared, and the quantity of urine became notably increased. The dose given is not very clearly stated, but the number of injections required in the different cases was usually from four to eight. In only one case were fifteen necessary. They were given twice a day.—*The Lancet*, October 16, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

PHILADELPHIA.

SATURDAY, NOVEMBER 6, 1886.

CEREBRAL SURGERY.

ON November 25, 1884, MR. RICKMAN J. GODLEE removed a glioma, the size of a walnut, from the ascending parietal convolution, where its presence had been localized by Dr. A. Hughes Bennett. The abundant hemorrhage was arrested by the galvanic cautery, and the edges of the superficial wound were approximated by sutures. The patient progressed well for thirty-one days, despite the formation of a hernia cerebri, when he was suddenly seized with a rigor and symptoms of cerebral inflammation, and died precisely four weeks after the operation, the fatal issue being due to a local meningitis, which, as admitted by Mr. Godlee, was the result of putrefaction from want of proper attention to antiseptic precautions.

About a year prior to the operation of Godlee, DR. WILLIAM MACEWEN, of Glasgow, cut into the ascending frontal convolution toward the paracentral lobule, and evacuated a broken-down gumma. The patient made a rapid recovery, and was able to attend to her household duties at the end of two months. Both cases demonstrated, first, that small, as well as large, lesions can be accurately located, and, secondly, that incisions into the motor area not far removed from the cortex can be made, with as much prospect of success as incisions into other organs or tissues, provided a vital spot is not injured.

As the natural outcome of the reports of these cases, and of still further recent advances in cerebral localization—a study with which the names of Hughlings Jackson and Ferrier are conspicuous—the profession was led to anticipate a great future for brain surgery. That these hopes have been fully realized will become apparent after a perusal of a paper read at the late meeting of the British Medical Association, at Brighton, by MR. VICTOR HORSLEY, and published in the *British Medical Journal* for October 9th. In this communication that surgeon gives the details of three successful operations upon the motor area of the brain. In one of these a small tubercular tumor, along with more than half an inch of the surrounding cerebral tissue, was removed, and five-sixths of the external wound healed by the first intention in a week. In a second case, one of epilepsy, a mass of cicatricial tissue and the adjacent brain substance were excised, and the wound was firmly united in seven days; while in the third case, also one of epilepsy, fragments of bone and a wedge-shaped cavity were removed, and the wound was completely healed in four days.

In addition to these cases, Mr. Horsley, on September 23d, successfully extirpated from the motor region of the right hemisphere a tumor which weighed four and one half ounces, was three inches long, two and one-half inches broad, and two inches deep. The wound had closed in four days.

These brilliant operations demonstrate the comparative harmlessness of trephining the skull and incising or cutting out the brain tissue under antiseptic precautions, as well as the great value of the scientific application of facts derived from experimental researches on the cortex of monkeys to operations on man. Indeed, Mr. Horsley states that the repair of wounds in the lower animals does not differ from that in the human subject, and that the stereotyped views on this subject, namely, that safe deductions cannot be made from one to the other, are utterly groundless, and have done much to hinder the progress of brain surgery.

It is impossible, in the limits of this article, to discuss the various symptoms which led Mr. Horsley to locate the lesions which he so successfully attacked, so that we shall limit ourselves to describing his method of operating, as a future guide to practical surgeons, particularly as it differs in some important points from the practice ordinarily pursued.

On the day before the operation the head is shaved and washed with soft soap, and then with ether, after which the position of the lesion is ascertained by measurement, and marked on the scalp. The head is then covered for twelve hours with lint soaked in a five per cent. carbolic solution, oiled silk, and cotton-wool. On the previous evening a purgative is administered, and followed by an enema on the morning of the operation.

Ether is rejected, unless there is a heart-complication, on account of its tendency to cause cerebral excitement. Before administering chloroform, a quarter of a grain of morphia is thrown under the skin, with the double object of diminishing the

quantity of the anæsthetic used in the operation, and of inducing contraction of the arterioles of the brain, through which important action of the drug the incisions into the cortex are accompanied by very little oozing.

Strict antiseptic precautions are, of course, observed throughout, and Lister's original plan as to the agents employed and their manner of application is preferred, although sublimate wool, the skin being protected by carbolic gauze, may be used.

The incision through the superficial coverings of the skull is semilunar, and so planned as not to divide the main arterial trunks supplying that portion of the scalp. The periosteum, on the other hand, is reflected by a crucial cut from an area corresponding to the first trephine-hole, and subsequently as more bone is removed.

In cutting away the bone a hole is made with a trephine, two inches in diameter, at each extremity of the area to be excised; the sides of the area are then divided through one-half the thickness of the bone with a Hey's saw; and the section is completed with a strong cutting forceps. If it be possible to preserve the dura mater intact, the buttons of bone should be preserved in warm aseptic sponges, and be placed, after having been divided into small fragments, between the dura mater and the skin, as originally practised by Macewen, to insure osseous repair of the loss of substance.

In connection with the removal of the bone, we may call attention to an important fact pointed out by Dr. W. Hale White, in *Guy's Hospital Reports*, vol. xliii., 1885. In the post-mortem examinations which he made of subjects dead of tumors of the brain, he found almost invariably that the bones of the vertex were very light and thin, although quite hard, the thinness in extreme cases being the same as that of cardboard. Hence, in using so large a trephine as that recommended by Horsley upon so uneven a surface as the calvaria, the atrophied condition of the bones should be borne in mind, lest the cranial contents be injured.

The dura mater is incised around four-fifths of the circumference of the area exposed at one-eighth of an inch distant from the edge of the wound of the bone, in order that its edges may afterward be sutured. The incision is begun with a scalpel and finished by blunt-pointed scissors, great care being taken not to wound the subjacent membranes. The main branches of the middle meningeal artery are secured by ligatures passed through the dura mater just outside its cut edge.

After the incision of the dura mater the brain bulges into the wound. The existence of a slight yellowish tinge, or of lividity, will indicate the presence of a tumor beneath the cortex in the corona radiata. In removing the morbid growth the incision is made exactly vertical to the surface, or parallel with the course of the arterioles, and directed, when necessary, into the corona radiata in such a way as to prevent damage to the fibres coming from the cortex, and surrounding the seat of the operation. All bleeding vessels are ligatured.

After the removal of a portion of the brain, there is not left, as one would suppose, a gap with vertical sides, since the floor of the gap bulges almost to a level with the surrounding cortex. In addition, the cut edges become slightly everted, and they are extruded into the opening in the skull if less brain than bone is removed. In other words, there is a tendency to hernia cerebri, and it is for this reason that the semilunar flap of the scalp, when united, offers sufficient resistance to the upward pushing brain, while the point of meeting of the four angles of a crucial incision never does. All oozing having been arrested by gentle pressure with a soft sponge, a drainage tube is inserted into the most dependent portion of the wound, and the latter closed with silk sutures inserted at distances of two-fifths of an inch, and, between these, horsehairs. During the first twenty-four hours there is a steady oozing of blood and serous fluid, but at the end of this time the tube is removed, and the wound carefully dressed, firm but gentle pressure being made over the centre of the flap. At the expiration of five or six days, the wound may be covered with a little powdered boracic acid, cotton-wool, and collodion; and the stitches may be removed at any time after the first week.

With the single exception of the antiseptic agent used by Mr. Horsley, we consider that his plan of operating in all its details is most judicious. The exhibition of morphia and the employment of ligatures for the prevention and arrest of hemorrhage, instead of the galvanic cautery resorted to by Godlee; the semilunar superficial flap, which can be laid down like the lid of a box; the suturing of the dura mater; and the early withdrawal of the drainage tube are rules which are in perfect accord with the guiding principles of the management of wounds elsewhere. The short period of drainage is the one point regarding which he will probably be unfavorably criticised. His reasons, however, for this action are, to us, conclusive. He states that he wishes to obtain a certain amount of tension of wound-exudation within the cavity. First, because it reduces the tendency to hernia cerebri; secondly, because it compels the lymphatics to remove the fluid, thereby facilitating primary union of the skin wound; and, thirdly, because it acts as a kind of scaffold for the building up of a non-inflammatory connective tissue by which the brain is separated from the flap of skin. Whether or not these reasons be generally deemed sufficient for the course he pursues, it must be re-

membered that all of his cases have terminated favorably, and that it will be best to follow him in this particular until increasing experience leads us to modify the practice.

THE EXTRACTION OF THE AFTER-COMING HEAD.

From time to time, during the past few years, an animated discussion has arisen in the German medical press, as to the comparative merits of manual and instrumental extraction of the after-coming head in breech presentations, and after turning, especially in cases of contracted pelvis. Credé has been the foremost advocate for the use of the forceps, while Schröder and his followers condemn this practice, and recommend manual extraction alone.

In a recent number of the *Berliner klinische Wochenschrift*, A. Martin declares himself also in favor of manual extraction; but, appreciating the danger to the child which undoubtedly attends the present manner of applying this method, he proposes a modification which he has practised in thirty-eight cases with very good results. Instead of the usual method of placing the finger of one hand in the child's mouth, and hooking the fingers of the other over its shoulders and then pulling vigorously, throwing all the strain on the lower jaw and cervical vertebra, Martin's plan is to introduce the middle finger of the hand, the palmar surface of which corresponds to the abdomen of the child, into the mouth, and make moderate traction upon the lower jaw, while the other hand is used to make powerful pressure upon the child's head externally and from above. Of thirty-eight children extracted, or rather expressed in this manner, seven, or eighteen per cent., were stillborn, a result better than that obtained by the forceps in the hands of Credé himself, who reports in the *Archiv für Gynäkologie*, Band xxv., sixteen cases, of which number four, or twenty-five per cent., were stillborn. In view, therefore, of the comparatively good results achieved, the wish expressed by Martin that the profession may at least deem this method worthy of trial will probably be gratified.

FRAUDULENT OPIUM CURES.

Among the many calls for sympathy occurring in a doctor's practice, few have a more valid claim than those of the unfortunate victims of the opium vice. The dose taken at first to alleviate pain gives relief so perfect, that if the suffering be due to chronic disease, the dosing, too, is almost sure to become chronic. The narcotic habit, with its attendant perversion of physical function and moral control, is accepted as the lesser evil. With the sense of moral obligation blunted, and the power of self-control impaired, the slave to opium drifts at the mercy of circumstances. But at some conjuncture the will is prompted to a decided effort to regain control, and he who can reinforce this resolution and tide the drifting man to solid ground is a benefactor indeed. Such recoveries have been made, but only through abstinence maintained by personal restraint, and supplemented by a supporting regimen of food, sleep, tonics, and, when necessary, stimulants. The man who would take advantage of the struggling opium victim at such a time, and, under the pretence of helping, only hold him longer in the stream, is deserving of most severe punishment.

This is the very offence of which nineteen persons are guilty, according to the recent report of the analyst to the Massachusetts State Board of Health, and some of the names given are not unfrequently found in the advertising columns of medical journals. Twenty samples of widely advertised opium "cures," including Baker's, Beck's, Collin's, H. H. Kane's, and others less known, were examined and all but one were found to contain morphine. The exception was "Keeley's Double Chloride of Gold Cure," which is exorbitantly expensive on account of the alleged presence of the precious metal, but which contained neither morphine nor gold.

The dupe of these so-called antidotes simply pays a higher price for his opium than he has hitherto done, the difference being the profit of the fraud. To crown the infamy of this business, the advertising circulars give endorsements which are in many cases published without the least shadow of authority.

The Journal of Comparative Medicine and Surgery, now in the seventh year of its existence, has just transferred its publication office to Philadelphia, and its last number appears in an enlarged form, and with marked evidence of improvement in every department. Dr. Huidekoper, of the Veterinary Department of the University of Pennsylvania, has joined Dr. Conklin on the editorial staff, and a number of our leading teachers of comparative medicine have consented to act as collaborators. The *Journal* is one in which the general practitioner will also find very much of interest. A glance through the present number shows a series of valuable original communications. The beautifully illustrated article by Mr. Bland Sutton, on "Tuberculosis in Birds," is of special value, and illustrates the wide zoölogical distribution of this fatal disease, which appears to be identical in birds and mammals.

During the past twelve years the veterinary profession of this country has developed rapidly, and the public is beginning to recognize its power and usefulness. Such an organ as the *Journal of Comparative Medicine* will represent its best interests, and deserves the support of all who would see this branch of the profession take its rightful position in the community.

OUR readers will remember the Dwight life insurance case, which was some time ago the subject of discussion in THE NEWS, and in which the decisions of the jury and the lower court were in favor of the family of the insured. Within a few days, the final court of appeal in the State of New York has given its decision, in which it affirms that the lower court was in error in not granting to the defendants—that is, the Germania Life Insurance Company—a nonsuit. The trial is, therefore, set aside. Whether there will be any further proceedings in the case is, of course, uncertain; but, so far as the Germania Life Insurance policies are concerned—*i. e.*, those which were especially in question at the trial—the affair is definitely settled against the family.

THE Louisiana State Board of Health on Sunday revoked the quarantine against all of Harrison County, Mississippi, except the town of Biloxi, which still remains under the ban.

THE German physicians of Philadelphia propose to organize "Der Deutsche Medicinische Verein von Philadelphia."

REVIEWS.

THE MEDICAL NEWS VISITING LIST FOR 1887. Philadelphia: Lea Brothers & Co., 1886.

THE MEDICAL NEWS VISITING LIST for 1887 has just been issued. In addition to the visiting list proper, it contains upward of fifty pages of memoranda, which are most useful to the practitioner in emergencies, such as a list of poisons and antidotes, rules for disinfection, for artificial respiration, a table of doses, a therapeutic table, lines for the ligature of arteries, a list of incompatibles, etc. A new and useful feature is the celluloid memoranda leaf, which is as flexible as paper, and pencil marks can be erased from it with rubber or moisture. The whole is handsomely bound in red seal leather with patent thumb-letter index for quick reference, and is of convenient size and weight for pocket use. The aim has been to make it an indispensable volume to the busy practitioner.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, October 11, 1886.

DR. L. A. STIMSON IN THE CHAIR.

DR. WM. T. BULL reported

TWO CASES OF ABDOMINAL SECTION FOR PENETRATING GUNSHOT WOUND OF THE ABDOMEN,

giving the history of the cases, and presenting his last patient before the Society. The first case proved fatal, and the operation was only performed to prevent a serious hemorrhage of the liver which was the result of the injury. The histories of these cases were as follows:

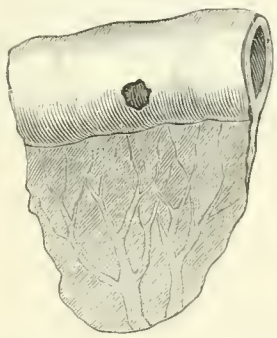
CASE I. *Wound of Liver; Laparotomy; Death after Operation.*—A clerk, fifty-seven years of age, of intemperate habits, shot himself in the abdomen, with a pistol of 32 calibre, about 9 A. M. on Jan. 10, 1885, and was brought to Chambers Street Hospital by ambulance two hours later. On admission he was suffering from shock and loss of blood, the surface of the body and extremities was cold and very pale, the pulse 100 and feeble, resp. 24, and temp. 94° (axillary). He was rational but dull; had vomited once the contents of the stomach, and had little or no pain. In the epigastric region was the entrance wound of the bullet, three inches above the umbilicus, and one and three-quarter inches to the left of the median line. The wound of exit was in the right side in the axillary line midway between the ribs and crest of ilium. There was no bleeding from either wound. Urine drawn was normal in appearance. Four hours later, notwithstanding every effort, his condition was worse: pulse (temporal) 134, resp. 28, temp. 97°. Seven hundred and fifty cubic centimetres of saline solution were infused into the cephalic vein in the course of twelve minutes. This was followed by improvement, and at the expiration of three hours the radial pulse was 112, of fair volume, resp. 24, temp. 96¼°. At 9.30 P. M., after consultation with Dr. Weir, I performed abdominal section. It was just seven and three-quarter hours after admission, and the general condition had undergone no decided change from that noted three hours after the infusion. From the situation of the two wounds, and the evident signs of hemorrhage, I inferred that the liver had been wounded, and undertook the operation in the hope of arresting the bleeding. The incision was made from an inch below the ensiform cartilage to three inches above the pubis, and showed at once that the bullet had entered the left lobe of the liver, cutting it nearly in two (transversely). The intestines were floating in bloody serum and clots. A few loops of uninjured intestine were drawn out in order to expose the right lobe of the liver, and the blood rapidly sponged out, but it welled up from beneath the liver as fast as it was removed. The pulse began to fail after the abdomen was opened, and before the cavity had been cleared so as to allow a satisfactory inspection, the patient expired, just half an hour from the time the administration of ether was begun. There were no other visceral wounds. The bullet had traversed the left lobe, as described, then passed through the round ligament, the lower edge of the right lobe and the abdominal wall. The vessels in the transverse fissure escaped injury.

CASE II. *Gunshot Wound of Intestine and Mesentery, with Hemorrhage; Laparotomy, with Suture of Intestine; Recovery.*—Daniel Mahoney, aged twenty-five years, sailor, was brought to the Chambers Street Hospital in a cab, August 12, 1886, at 7.40 P. M. He came into the reception-room without assistance, complaining only of pain in the abdomen while walking. Twenty minutes before, he had been shot during a friendly scuffle, with a pistol of 38 calibre. He was slightly pale, and was perspiring freely, and since the injury had felt some nausea, but had not vomited. The axillary temperature was 97°, pulse 96, full, resp. 26. The abdomen was normal to sight and touch, but for the presence of a bullet wound two inches below and two inches to the left of the umbilicus, in the vicinity of which it was tender on pressure. The skin about the wound was normal, the edges were blackened, and the lumen occupied by a clot of dried blood. The trowsers,

just below the waistband, and two shirts, were found to be pierced by the bullet, no trace of which could be found under the skin of the trunk. The urine was drawn: it was free from blood. Rectal examination was negative. After washing the skin thoroughly, the wound was covered with a compress of iodoform gauze and absorbent cotton, and gr. ⅓ morphine administered hypodermatically. The man had always been in good health, drank only occasionally, and was of excellent physique. The dangerous character of his wound was explained to him; and he consented at once to an operation.

Two hours later his condition was as follows: pulse 104, resp. 24, temp. 98°; no pain; slight rectal tenesmus; abdomen unchanged. A probe could not be introduced beyond the muscular layer. Hepatic dulness normal. No emphysema about the wound. He had made an ante-mortem statement to the coroner, and been visited by several friends. At 9.40 P. M. ether was administered by Dr. Tiernan; the operation begun fifteen minutes later. The wound was explored by an incision three inches long, and found to pass directly backward through the rectus muscle. The incision was then made in the median line from the umbilicus to the pubes. Coils of small intestine came at once into view. They were bathed in odorless, bloody serum, several ounces of which escaped from the cavity. As the general condition did not indicate any serious hemorrhage, I proceeded to examine the intestine without waiting to sponge out the cavity. About half the length of the small intestine was drawn out, rapidly sponged, inspected, and placed under warm towels, before a wound was discovered. Then a loop was met *through* which the ball had evidently passed. The wound on one side was evidently that of entrance (Fig. 1). It was as large

FIG. 1.

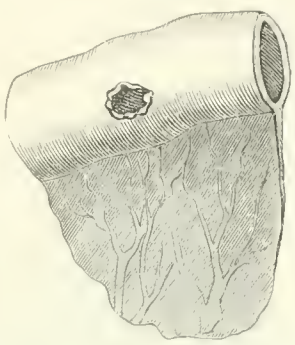


First perforating wound of small intestine.

as the top of a lead-pencil, its edges adhering, without prolapse of the mucous membrane. The other, directly opposite, and midway between the free and attached border of the gut, was twice as large, with a little fold of mucous membrane occupying its lumen (Fig. 2). There was no escape of feces. The gut was held up by an assistant, a sponge placed beneath each wound, and the abdominal incision protected by a large flat sponge, while the sutures were inserted after Lembert's method. The finest iron-dyed silk was employed. Three sutures sufficed for the first, and six for the second wound. Iodoform was rubbed along the line of suture.

Several more feet of small intestine were examined without finding any other signs of injury than half a dozen subperitoneal extravasations of blood, no greater

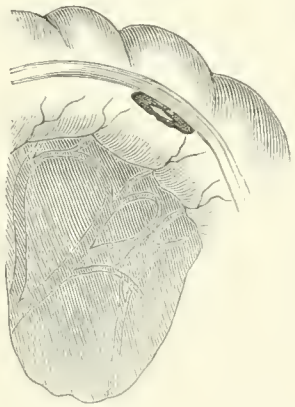
FIG. 2.



Second wound (of exit) opposite the preceding one.

in area than a pea. The mesentery was *dotted* with smaller extravasations. There was no decided congestion of the gut, nor any lymph exudation on its surface. The pelvis was then occupied by one or two coils of small intestine and the sigmoid flexure, while the cæcum projected from the right side, partly obscured by the small intestine. To examine the rest of the gut, I removed with the hand and sponges at least two tumblerfuls of clotted blood. It was then evident that there was hemorrhage from some vessel deep in the pelvis. It was not very active, for the pressure of a large sponge controlled it. All the small intestine that could be drawn out was then held under towels outside the wound, and the sigmoid flexure also exposed to view. A longitudinal wound, half an inch in length, was met with close to its attached border. The muscular coat was bared, but no mucous membrane was seen. (Fig. 3.) This wound

FIG. 3.

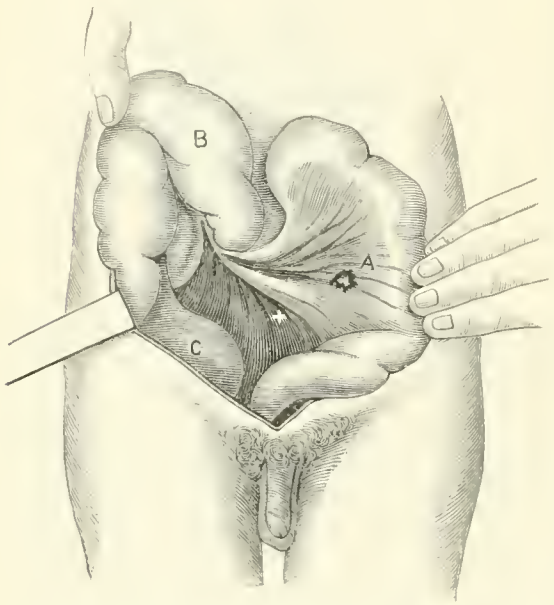


Third wound of sigmoid flexure. Perforation uncertain.

was closed with four sutures. The cæcum was now pushed out of the way, and a view obtained of the sigmoid mesocolon, and the source of the bleeding discovered to be a circular wound near to its attachment to the middle line, and fully three inches from the top of the gut. (Fig. 4.) When the mesocolon was made tense by traction on the flexure, the bleeding ceased; when relaxed, a stream of venous blood issued from the wound so copiously as to fill the cavity of the pelvis one-

third full several times before it was controlled. Pressure below the wound stopped it, but the vessel from which the blood issued could not be seen even after the wound was enlarged with scissors. The tissues on the

Fig. 4.



The sigmoid flexure drawn out, showing the situation of the two wounds of the mesocolon, *A* the superficial one involving the peritoneum only, † the deeper one, which was the source of hemorrhage.

lower edge, when pressure was effective, was finally grasped in a large "bite" with long artery clamps, a silk ligature passed by means of a curved needle under the blade of the forceps, and tied as the forceps were withdrawn. This controlled the bleeding. Above, and to the inner side of the wound, there was an extravasation of blood, which, as it was firmly clotted, was not interfered with. Another wound of the mesocolon stripping off its peritoneal coat over an area as large as a quarter-dollar was found close by. (Fig. 4.) This, and the preceding one, were not sutured, but rubbed thoroughly with iodoform. One of the appendiculæ epiploicæ, of good size, was found torn and bleeding at its extremity. It was tied at its base with catgut and cut off.

Considerable blood had been observed to come into the pelvis from the region of the cæcum, during the efforts to stop the hemorrhage already referred to, but on careful sponging there was found no fresh source of bleeding. A sponge in the grasp of a long forceps was passed into both lumbar and epigastric regions, and brought out perfectly clean. The omentum had not been seen up to this time, but the sponge drew it out from the left lumbar region, and its extremity being found lacerated (but not bleeding), was tied to the extent of three inches with silk and cut off. The rectum was again examined with the finger, and the bullet not being found there, I concluded that it was lodged in the extravasated blood in the mesocolon, and decided not to search for it further. Several pints of warm carbolic acid solution (about 1 to 100) were poured from a pitcher into the pelvis and sponged out, and the intestines, as they were replaced, freely washed with the same solution. The abdominal wound was sutured with silver wire, and silk sutures passing through all the layers with superficial catgut sutures; and a continuous catgut suture was applied to the peritoneum. Iodoform gauze covered the line of suture, and over this a compress of carbolized gauze, with a metallic coil (Leiter's) held in place by a binder. The incision into the bullet wound was stuffed lightly with iodoform gauze.

The duration of the operation was one hour and fifty minutes. The intestines were held outside the cavity just one hour, and thirty minutes were spent in applying the sutures. Ether was given for two hours and ten minutes. The pulse at the end of the first hour was 116, at the close of the operation 128, and of fair volume. The extremities were cold, but respiration was satisfactory. Four subcutaneous injections, each of whiskey ℥j, and tinct. digitalis ♏x, were given in the last hour.

Dr. Bull considered himself fortunate in having the advice of Professor J. D. Bryant, who agreed with him as the propriety of the operation, and the assistance of Drs. C. H. Wilkins, B. Farquhar Curtis, Garrison, Parke, Treniard, and Bryant, of the house staff. Drs. J. Robert Eustice and John P. Adams also rendered valuable help. The room was not specially prepared for the operation. It is used for out-patients during the day. But in other respects the utmost attention was given to antiseptic details. The sponges were taken from a five per cent. solution of carbolic acid, in which they had been lying for two months, and rinsed in warm two and a half per cent. solution. During the operation they were washed in a much weaker—about 1 to 100. All the silk employed I boiled myself in a five per cent. solution for half an hour previous to the operation. The towels employed were old ones, which had been washed in a two and a half per cent. solution, and were kept warm with a weaker one.

August 14. 10 A.M.; pulse 108, resp. 34, temp. 100°. Thirty-six hours after operation, reaction was prompt, and ice water was run through the coil twelve hours later, and is now continued. Magendie's solution ♏ xxxij, has been given subcutaneously in five injections; ice by the mouth, and by rectum five enemata of beef peptonoids ℥iijss, and whiskey ℥ss. During the last twelve hours he has been allowed champagne ℥ij, or milk and lime-water ℥ij, every two hours. He has dozed most of the time; complained of a little pain. There is slight tympanites. He is troubled with occasional cough with slight mucous expectoration. Urine drawn by catheter has amounted to ℥xx; it is high-colored and contains urates but no albumen; specific gravity 1.020. 10 P.M.: pulse 98, resp. 26, temp. 100°. Tongue is moist and there has been no nausea.

17th. Fifth day. 9 A.M.: pulse 80, resp. 24, temp. 101°. Up to this time the progress of the patient has been uneventful. There has been slight pain and tympanites; no nausea or vomiting. Liquid diet has been given and occasional doses of morphine hypodermatically. The cold water coil has been continued, though the temperature has not been over 100½°, or the pulse over 100. A copious normal but soft fecal evacuation took place after an enema. A purulent collection in the wound made itself evident by discharge about the sutures. The line of union which was firm,

was broken down and a thin layer of pus found at the bottom in the extra-peritoneal tissue. But in the upper half of the wound the peritoneum along the line of suture was sloughy, and on parting its edges a portion of intestine was visible, firmly adherent to the parietes. I mopped out with a two and a half per cent. carbolic acid; stuffed lightly with iodoform gauze. The pulse, respiration, and temperature were normal after this.

18th. Sixth day. While coughing in the night a piece of gut protruded from the upper third of the wound, but did not overlap the skin. Its surface was coated with grayish lymph, with granulations in places. The wound was five inches long and two inches wide. The

Fig. 5.

C. Silver-wire suture secured with pieces of wood.

edges were held together with two "relaxation-sutures" of silver wire, and compression made on the intestine with a small pad of iodoform gauze and wool. (Fig. 5.) By means of this the gut was pushed back from day to day, while the edges being were drawn together and the lower part of the wound was filling with granulations. On the ninth day solid food was allowed. On the eighteenth day the intestine was on a level with the rest of the wound. The whole surface (3¾ inches long by ⅝ inch wide) was granulating finely. Skin grafts were put on several times. Balsam of Peru replaced the iodoform, and at the end of eight weeks cicatrization was complete. It is now only a week that he has been out of bed.

Dr. Bull thought his cases demonstrated the utility of the operation in preventing shock, which means loss of blood. He thought we had no satisfactory means of dealing with serious internal hemorrhage without resorting to laparotomy. He mentioned those cases published by Dr. Dennis as also showing the necessity of an early operation in this class of injuries.

The patient was then brought before the Society and his abdomen exposed, showing the cicatrices and line of incision, with entrance point of the bullet. The illustrations exhibited were made from the cadaver, which was placed in a position to represent that of the patient when he was shot.

He thought we should devise some satisfactory method of recording the unsuccessful cases as well as the successful ones; he had added one to the list of the former to-day, and he did not know of more than five or six such cases which had been published. He also believed it best, in gunshot wounds of the abdomen, to explore the wound to see if it be penetrating or not, and, if it be penetrating, to perform abdominal section and repair the injury if possible. He believed, however, that at present there are only three successful similar cases on record.

Dr. Markoe asked if he understood there were only three successful cases published.

Dr. Bull replied that that was all he had been able to verify.

Dr. Lange stated that there had been a case reported to him, lately, by a country practitioner in Germany, but he was not certain whether it had been published in the medical journals, as the case was sent to him in pamphlet form. He then asked what was the calibre of the bullet in Mahoney's case.

Dr. Bull replied that it was thirty-eight calibre, and in the fatal case thirty-two.

Dr. Stimson asked whether the wound of the mesentery was simply an abrasion.

Dr. Bull replied that the peritoneum was stripped off and lost.

Dr. Abbe thought that the absence of fecal contamination was of some importance in this case, and that it was a favorable point in preserving the patient from shock.

Dr. Markoe asked whether there was any fecal extravasation in the first case, and if he incised the wound to start with.

Dr. Bull replied no, to both questions.

Dr. Briddon asked whether he would advise exploration in all wounds of the abdominal cavity.

Dr. Bull thought it would be generally admitted that no such rules can be applied to every case; each one must be treated on its being examined by the surgeon; but he thought that if the operator waits until serious peritoneal symptoms set in, he stands less chance of success than if he had operated earlier. He therefore thought it desirable to make an early exploration, and if it be properly made it will not be injurious. If there be blood in the cavity an exploration should be made at once, and if the intestine is found to be injured laparotomy should be performed.

Dr. Wyeth asked Dr. Bull whether he attached much importance to emphysema of the intestines.

Dr. Bull replied that he had never seen it and never thought of it until Dr. Dennis read his paper; but since then he had seen it in two cases.

Dr. Wyeth remarked that he had had two cases of extra-peritoneal abscess in which there was emphyse-

matous crackling, and he had found that about nine inches above that point a fecal fistula had been established in the alimentary canal; this condition was very distinct.

Dr. Stimson asked if he had understood correctly that it was an extra-peritoneal abscess which communicated with the intestines.

Dr. Wyeth replied that it occurred in a case of Pott's disease.

Dr. Briddon thought it a very uncommon thing, but said that he had seen several cases of emphysematous crackling somewhat similar to the case referred to.

Dr. Wyeth remarked that he did not see how there could be fecal gas there unless the intestine was perforated.

Dr. Abbe then gave the history in brief, of a case of gunshot wound coming under his care in St. Luke's Hospital, which he thought might be of interest to the Society.

Case I. *Gunshot Wound of the Abdomen with Four Intestinal Perforations, and also One of the Bladder; Laparotomy and Suturing Six Hours Later; Death Nine Hours after Laparotomy.*—G. H., aged fifty-three years, of large physique and very fat, accidentally shot himself on the morning of July 8, 1886, while drawing some article from a low cupboard; he was bending over at the time and drew a small revolver toward him, which discharged its contents into his belly. He walked to another room and from there a distance of two blocks. He was taken to St. Luke's Hospital, reaching there at 11.30 A.M., and was seen by Dr. Abbe at 12 o'clock. There was then slight shock, dulled intellect with depression; pulse was 82; he had vomited once. He complained of rapidly increasing abdominal pain. Tympanites was not marked, but there was a full feeling about the belly. A small bullet wound was discovered in the median line three inches above the pubes; the probe passed at right angles with the surface. Eight ounces of clear bloodless urine were withdrawn by a soft catheter.

Laparotomy was performed at 2.30 P. M. of the same day, the incision extending from two inches below the umbilicus to just above the pubes; cutting through the inflamed peritoneum lined with lymph; this opened up an encysted collection, of about a pint of greenish, watery fluid, somewhat muddy with lymph flakes and feces. It was confined against the abdominal wall anteriorly by the matted intestines, which were already coated with a thick layer of lymph. The fluid came from a coil of small intestine centrally placed, showing two perforations, one near its attached border, the other opposite the mesenteric side; the latter discharged freely the same greenish watery fluid as was in the sac; each inspiration pumped it out in copious jets. The perforation close to the mesentery had its mucous coat everted and seemed plugged up; the fluid was perfectly confined by the lymph barrier on all sides.

On sponging this cavity the wounds of the gut were readily and thoroughly closed by Lembert's suture. No other coils were injured in this space. The intestines were now gently parted, and it was readily demonstrated that there was no general peritonitis, for the portion of each coil facing the inflamed sac was red and heavily coated with lymph, while the free sides were uninflamed and retained their lustre. Another piece of small intestine, wounded by a double perforation from side to side, was found somewhat below the large collection of fluid just described. It also was isolated by excellent plastic adhesions between neighboring coils, and contained a small amount of feculent inflammatory fluid. The involved parts were cleaned, and these two perforations sutured. No other wounds being seen, a rapid and careful survey of the intestine from duodenum to colon was made.

The bowel was passed from the fingers of one hand to those of the other, mostly within the abdominal cavity; warm sponges, dipped in sublimate solution, at once enveloped any coils that escaped. There was no further injury of the bowel. A final inspection of the pelvis showed a perforation of the peritoneum between the bladder and rectum, which in this subject was underlaid by fat an inch thick.

The wound was small and not inflamed. It was evident that no urine or feces had escaped to set up irritation. A probe was passed downward and backward an inch or so, but gave no clew to the direction of the bullet. It seemed probable that the missile had overshot the bladder, and, traversing the rectum, embedded itself in the sacrum. There had been no bleeding into the peritoneal cavity, and the loop of intestine drawn from the pelvis was free from all signs of inflammation. The fifth wound was sutured, and the peritoneal cavity sponged out with care, Dr. McBurney assisting. Sponges were thrust down into the pelvis and about the kidneys, but returned quite as dry as when introduced; showing that no fluid had leaked in during the operation. The pelvis was drained by a Thomas glass tube, emerging at the lower end of the wound, which was otherwise treated as usual. Before leaving the table a soft catheter was introduced into the bladder, and two or three ounces of clear urine drawn. The wounds suggested a small bullet, No. 22.

The patient did not come out from ether well, but remained in a somnolent condition, his breathing being characteristic of pulmonary œdema. He was restless, and had to be tied in bed. Pulse intermittent and not strong. A catheter being passed at 7 o'clock, no urine was found in bladder. He was freely stimulated with whiskey and digitalis, and heart's action greatly improved. A cold water coil was placed over abdomen. At 11 P. M. his pulse could scarcely be felt at the wrist, though it had been fairly good a few moments before. Prompt stimulation brought it up, yet soon afterward he was taken with a short convulsive attack, tossing about the bed, and throwing arms about. He suddenly ceased breathing. Artificial respiration was immediately begun, and an enema of brandy given, which was not retained. He died at 11.15 P. M.

To the above hospital record, Dr. Abbe added that from the time of operation, as he watched him from hour to hour, he seemed to be laboring under the strain of pulmonary œdema; breathing was oppressed, with more and more coarse râles and labored shallow inspiration. This, with semi-coma and suppression (which latter was complete after operation), and finally a fatal convulsion which he saw, led him to assign uræmia as the real cause of death.

Autopsy, July 9, 11.30 A.M.—The body is well nourished; rigor mortis well marked, no œdema. Veins of legs very varicose. There is an incision in the median

line of abdomen extending from a point one inch below the umbilicus to over the symphysis pubis; extending from the lower end of the incision is a large drainage tube. The wound is united by numerous sutures about one-quarter of an inch apart, and by four metal sutures one and a quarter inches apart. Peritoneum is intensely hyperæmic, and contains recently exuded lymph. The peritoneal cavity contains twelve ounces of purulent fluid.

Intestines. There are two wounds in the lower portion of the jejunum, opposite to each other, and carefully sutured; about seven feet above these two wounds are two other wounds opposite to each other and carefully sutured. The intestines are not elsewhere wounded. The mucous membrane is intensely congested. The mucous membrane of the large intestine is deeply pigmented. *Kidneys* are normal in size; they seem to contain fat in the cortices, and are moderately hyperæmic. *Stomach* is normal. *Spleen* is a trifle large, and soft in consistency. *Bladder:* There is a penetrating wound in the roof of the bladder, which is carefully sutured. An incision two inches in length was made in the roof of the organ, to the left of the wound, and showed the bladder to contain about an ounce of mud-colored urine. The organ was then carefully removed, and slit up through the anterior wall, through the prostatic urethra, and an area of half an inch in diameter of intense hyperæmia was seen at the outlet of the right ureter. *Liver* contains very considerable fat and a slight increase of fibrous tissue. *Heart:* Cavities are dilated; the valves are competent. The aortic and mitral valves are moderately thickened.

Microscopic Examination.—Heart: The muscular fibre of the heart is granular; the transverse striæ are very generally obliterated. There are free globules seen in the cell fibre. The interstitial fat is also increased. *Kidneys:* Hyperæmic; some atrophied glomeruli; very slight increase in the fibrous tissue and epithelium in convoluted tubes; granular, and in places fatty. *Liver:* There is considerable fat in the liver, and moderate increase in its fibrous tissue.

Regarding the note by Dr. Ferguson that twelve ounces of fluid were found in the cavity of the abdomen, Dr. Abbe noted two important points: First, it was like peritoneal secretion in severe acute peritonitis, but had a shade of greenish color about it that suggested to him the possibility that he had left some fluid as a cause for part of this, and that it had lurked in the loins, or between the folds of intestine not reached by sponging. Second, the fluid was found in the lumbar region of the abdomen at the autopsy, and his sponging certainly swept into this section before closing the abdomen.

The bullet was lodged in the bladder, and was not discovered by using soft catheters. The point of impact on the posterior bladder wall was bruised but not lacerated.

Dr. Abbe then exhibited some specimens of the parts, to elucidate more fully the nature of the wounds.

Dr. Joseph C. Hutchison remarked that some years ago, while attending a meeting in New Orleans, a case was reported in which the number of intestinal wounds was astonishing, but complete recovery occurred; he could not remember the exact number of the wounds, they were gunshot wounds; he presumed Dr. Bull had not heard of the case from his report.

Dr. Bull replied that he had not. From Dr. Abbe's statements, he inferred that the urine will generally be bloody if the bladder has been wounded, and yet, in one case quoted, although clear urine was drawn from the bladder, at the post-mortem an ounce of bloody urine was found in the bladder.

Dr. Abbe said that after the operation the patient suffered from suppression, and congestion of the kidneys would account for the two tablespoonfuls of muddy urine found post-mortem.

Dr. Bull asked whether it would not be advisable to leave a catheter in the bladder, in order to drain it thoroughly.

Dr. Abbe replied that Dr. McBurney and himself were perfectly satisfied that the wound did not penetrate the bladder, and thought there was no necessity.

Dr. Lange then exhibited specimens from a case of

FIBROMYOMATA OF THE UTERUS; SUPRAVAGINAL AMPUTATION; RECOVERY.

The specimen was removed, about four months ago, from a lady thirty-five years of age, who, for a number of years, without success, had tried the usual remedies. The tumor consisted of two main portions. The larger one, about the size of a man's head, had a pedunculated insertion on the upper part of the uterus. It had first to be cut away above, and an elastic ligature applied in order to allow of access to the smaller portion, which was about the size of the two fists and presented a broad insertion in front and to the right of the uterus, having developed below the peritoneum.

For his way of operating he had this time adopted the method of Martin and Schröder of treating the pedicle. The elastic ligature was definitely removed after sewing up the stump by catgut and silk sutures. The operation lasted more than three hours, and the patient finally made a good recovery after some disagreeable and critical disturbances.

Almost immediately after the operation she suffered from an acute nephritis, for which Dr. Lange could assign no cause. An enormous number of casts appeared in the urine, but in about a week it was normal; it had been examined before the operation repeatedly, and had never shown any abnormality. Iodoform had been left in very small quantities in the abdominal cavity. Dr. Lange thought it probable that the protracted ether-narcosis had some relation with this renal affection.

The stump of the uterus did not heal by first intention, though there was not any evidence of secondary hemorrhage. Suppuration and partial peritonitis set in, and an abscess opened itself through the os externus of the uterus. Several silk sutures were discharged or extracted, also some catgut sutures, which had not been absorbed, together with some sloughy tissue. The patient is now in good health and perfectly well. She also had an umbilical hernia before the laparotomy, which was at the same time cured by peritoneal suture. Dr. Lange called special attention to the condition of the right Fallopian tube. It was so much dilated that it almost looked like a filled gut, and when he cut across it after double ligation, and saw its greenish mucous contents, for a moment he thought that he had cut across the gut, the field of operation being so inaccessible in consequence of numerous adhesions.

Dr. Lange also reported two cases of

SUBSEROUS PAPILLARY CYSTOMATA OF THE OVARY, WITH OVARIOTOMY, FOLLOWED BY RECOVERY.

Both of these cases had this in common, that the tumors were of moderate size, situated on the right side, and rested with broad base between the layer of the broad ligament covered by peritoneum, without in any way showing the formation of a pedicle.

In both, the internal surface of the sac showed papillary formations; which in one case were very numerous and well developed, so that in some parts they gave to a large extent to the inner surface a papillary aspect. Both cases were operated on in such a way that the tumor was gradually shelled out of its peritoneal covering under due consideration of preventing hemorrhage by mass ligatures. In one case the peritoneum was thin and could be only incompletely preserved. In the other it was fastened to the lower part of the abdominal wound and the parietal peritoneum in such a way that the peritoneal cavity was entirely shut off. In the other this peritoneal partition was incomplete. In both cases the wound surface in the depth of the peritoneum was filled loosely with iodoform gauze, which was removed on the second or third day, to be replaced by less gauze, and finally by a drainage tube. In this way gradual diminution of the cavity took place, but in one of the cases where the closure had been imperfect, a fistula has remained, through which, so far, some coarse silk sutures have been discharged and more are expected to come out. The patients move about without much discomfort. The specimen of this latter case presents the rare variety of tubo-ovarian cyst, the Fallopian tube being in free communication with the inside of the cystic sac. Its canal was found dilated, the mucous membrane hypertrophied, and the contents a bloody mucus. The contents of the cyst itself at a puncture several months previous to the radical operation were clear, yellowish, thin, containing a great deal of cholesterine crystals.

The other case had the following interesting history: The patient, after having recovered from the operation sufficiently, went to the Catskill Mountains, suffering from unmistakable tuberculosis of the lungs. About four months after the operation I was called to see her, in consultation with Dr. Chubb, of Palenville. Three days previous the symptoms of obstruction of the intestine had suddenly developed, apparently after an indigestion. When I saw her the obstruction was complete, and stercoraceous vomiting had occurred repeatedly. Without much delay I brought the patient to New York, and after having tried, without success, the stomach pump and carbonic acid enemata, I performed laparotomy on the evening of September 17th. The obstruction was due to constriction of a loop of intestine about the size of a duck's egg, by a sharp peritoneal band, which spread between two points near the attachment of the mesentery to the small intestine. Under this band a coil of intestine had apparently slipped, and was so tightly strangulated that it looked almost gangrenous; around it there was a small gathering of brownish, bloody fluid, just as we find it in cases of strangulated hernia. There was no connection with the original field of operation. The peritoneal sac remaining after the ovariotomy, had shrunk to a small, hard lump; some adhesions of the omentum to it were removed. Numerous tubercles were found to be spread over the peritoneum, also one large, cheesy nodule within the omentum.

No disturbance followed the operation from the side of the abdominal cavity. The function of the gut returned in four or five days after the operation, and has, since then, remained normal.

During the second week, however, the lung trouble became more serious, and the formation of a cavity in the right upper lobe of the lung could be clearly made out. The present condition of the patient now, four weeks after the operation, is tolerably good, though there is no doubt that finally she will die from tuberculosis.

Dr. Bull asked whether he understood aright, that the iodoform tampon was used in the three cases; and to what extent the abdominal wound was left open.

Dr. Lange replied that the application of the iodoform gauze was different in each case; in one, the wound was left open at the upper portion; in another, the wound was left open below for about two inches; in still another, the peritoneum was sutured, and formed a sort of pouch of the wound, and the gauze simply laid in; removing it on the third day, and replacing new dressing as long as secretions remain, using the long forceps for this purpose. Contraction of the cavity gradually occurs until the wound is entirely healed. In one of these cases there yet remains a fistulous opening, which he thought would soon close.

Dr. Briddon asked whether it is not common in those cases in which high temperature ensues, to meet with nephritis.

Dr. Lange replied that he thought, perhaps, it was.

Dr. Briddon remarked that he had frequently found it so, but it all passed off in a few days.

Dr. Lange, in conclusion, stated that there was no septic condition in any of the cases.

CORRESPONDENCE.

NOTE ON PRIORITY AS TO REMOVAL OF THE UTERINE APPENDAGES FOR BLEEDING MYOMA.

To the Editor of The Medical News,

Sir: In your issue of the 24th of April last I have noted a communication from Mr. Lawson Tait, of Birmingham, England, upon the "Removal of the Uterine Appendages," in which he criticises a paper by his esteemed friend Dr. G. Taber Johnson, of Washington. With this controversy I have nothing to do, but would here state that removal of the appendages does not invariably induce the menopause. I reported a case, last year, where the menses have continued with the utmost regularity and in normal amount for the past eighteen months. In this case, a careful search was made for any supernumerary ovaries, and the tubes and ovaries were exhibited before the Medico-Chirurgical Society at the time.

There is, however, under the second head of his summary, a statement which needs attention, and should not have found its place there without a full and explicit explanation. I allude to his, Mr. Lawson Tait's, there claiming that the "Removal of the uterine appendages for uterine myoma . . . was first performed by me [Mr. Tait] on August 1, 1872, with a successful result. I

am, therefore, entitled to have the operation described by my name."

Now, there are several facts which lead to the conclusion that the priority for this operation heretofore accorded to me seems to be just, which have been overlooked by Mr. Lawson Tait.

1st. In the second volume of the *Gynecological Transactions* for 1876, page 297, I there stated that "I would add to Dr. Battey's four concluding propositions a *fifth*, to the effect that the operation is indicated when severe and exhausting hemorrhages occurred at the menstrual period, which have resisted all forms of treatment. I have published two cases in which I removed the ovaries under these conditions for the purpose of arresting the excessive hemorrhages."

This claim of priority is conceded to me by Drs. Emmet, Goodell, Englemann, and all other writers upon the subject.

In 1884 the meeting of the Canada Medical Association was held in Montreal. Mr. Tait was at the meetings, and *present* when the ablation of the uterine appendages was discussed, and *my claim to priority was asserted without question upon his part.* Now, however, after fourteen years' silence, this gentleman makes known an unsupported and unauthenticated case, claims priority for the operation, and that his name should be connected with it.

These facts are offered to the profession for their judgment, and one can rest assured that their verdict will be in accordance with truth and justice.

NEWS ITEMS.

Mrs. Woerishoffer's Gift to the New York Academy of Medicine.—The following correspondence in relation to the munificent gift of Mrs. Woerishoffer, will be read with interest:

New York, October 13, 1886.

Dr. A. Jacobi,

Dear Sir: Please find enclosed a check for the "Academy of Medicine," which I send you in memory of my husband, the late C. F. Woerishoffer. In selecting the Academy of Medicine as one of the institutions to which I intend to distribute a certain sum in accordance with the wishes of my husband, I am led by the high appreciation Mr. Woerishoffer always entertained for the medical profession.

Yours very sincerely,
Anna Woerishoffer.

New York, October 15, 1886.

Dr. Everett Herrick,
Chairman Board of Trustees New York Academy of Medicine.

Sir: In presenting a munificent donation to the New York Academy of Medicine, Mrs. Anna Woerishoffer was guided, firstly, by the great respect her late husband, Mr. Charles F. Woerishoffer, always felt and expressed for medical science and the medical profession, and secondly, by her conviction that it is better to aid and sustain such institutions of either science or charity as have already proved their faculty and right to exist by duration, results, and accumulated property, than to create new institutions.

After mature deliberation she came to the conclusion that the New York Academy of Medicine has, by its publications in the journals of the country, and in numerous volumes of transactions and bulletins, and by its regular, stated, and section meetings, largely contributed to the progress of medical science, and deserves eminently the name of a scientific body; that after having existed forty years, collected an ever increasing library, and accumulated considerable property, the New York Academy of Medicine holds out the promise of perpetuity; that, by excluding politics and ethical strifes from its constitution and gatherings, it deserves the name of a purely and exclusively scientific body, and thereby the confidence of the public; and that it must necessarily become and be the centre of the scientific interests and labors of the medical profession of New York.

Mrs. Woerishoffer was also struck with the fact that the present building of the New York Academy is too small for its present and future purposes; that not only its sections require more accommodations, but that every medical and scientific society of the city ought to find ample room within its walls, and look upon the Academy as its proper centre; and finally, that the increasing library is in urgent need of a fire-proof building.

From these points of view, Mrs. Woerishoffer desires to contribute to the means required for enabling the New York Academy of Medicine to accomplish its great ends, and reach its high aims, which she takes to be both truly scientific and truly humane.

I have the honor, Mr. Chairman, of enclosing Mrs. Woerishoffer's letter and her check for twenty-five thousand dollars.

Very respectfully yours,
A. Jacobi, M.D.,
President.

New York, October 16, 1886.

Mrs. Anna Woerishoffer,

Dear Madame: The Trustees of the New York Academy of Medicine gratefully acknowledge the receipt of your check, through Dr. Jacobi, for twenty-five thousand dollars, sent in memory of your husband, the late Mr. C. F. Woerishoffer, and in accordance with his wishes.

In accepting the gift, the Trustees desire to thank you as the almoner of your husband's estate, and hope so to use it that no one bearing his name shall have cause to regret "the high appreciation which Mr. Woerishoffer always entertained for the medical profession."

Yours very truly,
Everett Herrick, M.D.,
President.

George A. Peters, M.D.,
Secretary.

New York, October 22, 1886.

Mrs. Anna Woerishoffer,

Dear Madame: At a meeting of the Academy held Thursday evening, October 21, 1886, the following resolutions, moved by Fordyce Barker, M.D., and seconded by C. R. Agnew, M.D., were unanimously adopted:

Resolved, That the New York Academy of Medicine accept with the warmest thanks and gratitude, the noble gift of twenty-five thousand dollars from Mrs. Anna Woerishoffer, as an expression of the appreciation by her late husband, Mr. Charles F. Woerishoffer, and her-

self, of the importance of the medical profession to the health and welfare of the public, as well as to individuals, and the necessity for the development of its highest culture.

Resolved, That the names of Mr. and Mrs. Charles F. Woerishoffer be inscribed in the Academy for permanent record as Benefactors.

Resolved, That a copy of these resolutions, duly engrossed, and signed by the President, Recording Secretary, and Treasurer, be transmitted to Mrs. Woerishoffer.

A. Jacobi, M.D.,
President.
A. M. Jacobus, M.D.,
Recording Secretary.
F. A. Castle, M.D.,
Treasurer.

Low Water in Wells and Typhoid Fever.—Dr. Henry B. Baker, of Lansing, Michigan, supposes a close relation to exist between typhoid fever and low water in wells. The diagrams which he presents in his paper of the prevalence of sickness from typhoid fever in Michigan, and the depth of the earth above the ground-water in the wells during six successive years, seem to show that, beginning with June in each year, the sickness-curve follows more or less closely the well water-curve. The author believes that one of the causes, probably the principal cause, of sickness, is the contamination of the water by the drainage from stableyards, privy-vaults, and cesspools, which reaches the wells more directly when the water in them is low, and forms in them stronger solutions than when it is high. On the other hand, the curves in several years, from January to June, show no such correspondence. The difference in results is explained by the frozen condition of the ground in the winters when typhoid did not prevail; a condition which, while it tended to reduce the quantity of water in the wells, at the same time prevented percolation from the surface sources of contamination. The fever was more prevalent in the open winters when percolation was not thus impeded. Corroboration is given to these views by a remark made by Dr. Foster Pratt, of Kalamazoo, at the meeting of the American Medical Association in June, 1874, that typhoid fever was unusually prevalent in Kalamazoo in a certain year in the autumn, at about the time the water in the wells was very low, and some wells became dry.

Changes in Tooth-form.—Professor Windle has announced to the British Association, as conclusions from his researches on the subject, that man's original dentition included six incisors in either jaw; that two from each jaw have gradually disappeared; that this loss is due to the contraction of the anterior part of the palate; that this process of contraction will probably go on and result in the loss of two further incisors; and that the conical shape of many of the supernumerary teeth indicates a reversion to the primitive type of tooth.

A New Manifestation of Argyria.—M. Lewin has reported to the Berlin Medical Society his observation of an affection that seems to be peculiar to workers in silver. It appears in the form of round or oval bluish spots on the skin, which in extreme cases may be as large as a nickel five-cent piece, generally on the back of the left hand. Workmen in metals who do not use silver are free from it. The manner in which the spots are produced is not clear, for experiments with the direct application of silver in various forms have failed to generate them. The silver probably falls upon some scratch—for the spots are usually developed where there has been a lesion—in a solution, and afterward undergoes some chemical change by the action of the bodily fluids which induces this peculiar color.

Absence of Alkaloids in Hot-house Plants.—According to Prof. A. Vogel, plants do not always contain their characteristic alkaloids when grown under other than natural conditions. Hemlock does not yield coniine in Scotland, and cinchona plants are nearly free from quinine when grown in hot-houses. Tannin is found in the greatest quantity in trees which have had a full supply of direct sunlight.

NOTES AND QUERIES.

COCAINE ADDICTION.

To the Editor of The Medical News.

If any reader of your journal has met with a case of cocaine addiction, and will send me the fullest details at his command, I'll thank him for the courtesy, reimburse him for any expense incurred, and give him full credit in a forthcoming paper.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 30, 1886.

Diehl, Oliver, *Passed Assistant Surgeon U. S. N.*—Granted three months leave of absence from October 26, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM OCTOBER 26 TO NOVEMBER 1, 1886.

Middleton, J. V. D., *Major and Surgeon.*—Ordered from the Department of Missouri to David's Island, N. Y. H.—*S. O. 252, A. G. O.*, October 29, 1886.

Woodhull, A. A., *Major and Surgeon.*—Ordered from David's Island, N. Y. H. to the Department, of Missouri.—*S. O. 252, A. G. O.*, October 29, 1886.

Williams, J. W., *Major and Surgeon.*—Ordered fom the Department of Colorado to the Department of the East—*S. O. 252, A. G. O.*, October 29, 1886.

Carson, J. K., *Captain and Assistant Surgeon.*—Ordered from Jefferson Barracks, Missouri, to the Department of Colorado, upon expiration of present leave of absence.—*S. O. 252, A. G. O.*, October 29, 1886.

Turrill, H. S., *Captain and Assistant Surgeon.*—Ordered from the Department of the Platte to the Department of Colorado.—*S. O. 252, A. G. O.*, October 29, 1886.

Munday, Benj., *First Lieutenant and Assistant Surgeon.*—Ordered from the Department of Colorado to Jefferson Barracks, Missouri—*S. O. 252, A. G. O.*, October 29, 1886.

Lauderdale, John V., *Captain and Assistant Surgeon.*—Leave of absence extended one month—*S. O. 249, A. G. O.*, October 29, 1886.

Owen, Wm. O., Jr., *First Lieutenant and Assistant Surgeon.*—Relieved from duty at Fort Schuyler, N. Y. H., and ordered for duty as post-surgeon at Plattsburg Barracks, N. Y.—*S. O. 170, Division of the Atlantic*, October 29, 1886.

Edie, Guy L., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort McIntosh, Texas, to Post of San Antonio, Texas.—*S. O. 152, Department of Texas*, October 27, 1886.

Harris, H. S. T., *First Lieutenant and Assistant Surgeon.*—Ordered from Post of San Antonio, Texas, to Fort Clark, Texas.—*S. O. 152, Department of Texas*, October 27, 1886.

ORIGINAL ARTICLES.

SOME POINTS OF SPECIAL INTEREST IN THE TREATMENT OF COMPOUND FRACTURES,

INCLUDING A REPORT OF FIVE HUNDRED AND SIXTEEN CASES.[1]

BY FREDERIC S. DENNIS, M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, ATTENDING SURGEON TO THE ST. VINCENT, NINETY-NINTH STREET, AND BELLEVUE HOSPITALS, NEW YORK CITY.

AT a meeting of the American Medical Association which convened in Washington, in June, 1884, I presented a paper on the treatment of compound fractures, in which were reported one hundred and forty-four cases treated consecutively, without a death from blood-poisoning. In the present contribution I shall present five hundred and sixteen cases of compound fractures, all of which, excluding those which were at that time reported, have occurred within the past two years in my hospital practice at St. Vincent, Ninety-ninth Street, and Bellevue hospitals. As many of these cases are of special interest from several points of view, I have undertaken the task of reporting them for the purpose of eliciting a discussion from members of this Association upon some important questions which naturally arise in connection with the general treatment of compound fractures. There are some recommendations discussed in my last paper which a larger experience has taught me the wisdom of modifying to accord with more recent views in surgical pathology.

The procrustean rules of absolute cleanliness, of immediate fixation, and of provision for free drainage in every compound fracture, need no modification. The technique involved in carrying out the details of these rules may vary, but the general principles remain the same. A more extended experience in the treatment of compound fractures has taught me that, while absolute cleanliness is essential, and immediate fixation is necessary, that no splint should be left on a limb longer than eight days without either its entire removal, or at least an examination of the seat of fracture. Formerly I inclined rather to the view that a splint had better remain undisturbed throughout the entire period of repair; but within the past year I have seen several bad results arising from a too rigid adherence to this rule. In one case, I saw a compound fracture which was skilfully dressed with plaster of Paris examined at the expiration of six weeks, during which time the patient's condition was in every way satisfactory. Upon removal of the splint, the bone was protruding, the displacement was great, and considerable union had taken place. A complete osteotomy corrected the deformity, and six additional weeks were occupied in obtaining a result which was perfectly satisfactory. If this fracture had been examined at the end of eight days, the protrusion of the bone would have been detected at once, and the faulty position rectified. While this result is exceptional, such unfortunate complications can always be obviated by a simple inspection of the fracture after eight days, and then again in ten days, after which time no serious deviation can occur. The time involved in the careful examination of every compound fracture is not to be considered in comparison with the risk which an omission to do so may involve.

Every compound fracture needs careful study and attention. I am more and more convinced of the importance of the first dressing. The patient who suffers from a severe compound fracture of any bone should be placed upon the operating table and the fracture examined and dressed with the same care with which a resected joint or a laparotomy should be dressed. The parts should be made aseptic at once, the deformity immediately overcome, the bones brought in exact apposition while the patient is under ether and the muscles are relaxed. Loose pieces of bone not adherent to periosteum are removed and the fragments are now adjusted, the antiseptic dressings applied with great care, a plaster-of-Paris bandage neatly placed upon the limb, and the fracture is certain to do well.

The manner in which the first dressing is applied has much to do with the prognosis. Esmarch has said that the fate of a patient often hangs upon the surgeon who first touches the wounded man. Wherever the circumstances are within the control of the surgeon, I would go even still further and recommend that ambulance surgeons should exercise great care in the transfer of a compound fracture to the hospital. I have made it a rule of practice at the Ninety-ninth Street Hospital that antiseptic irrigation should be employed at the station-house or upon the sidewalk before the patient is moved, and that at once after the irrigation a clean antiseptic dressing be applied before the patient is lifted into the ambulance. I feel sure that the success of treatment in the large number of compound fractures which have been admitted to this hospital is in great part due to the strict adherence of this important rule, which I have found willingly and cheerfully obeyed by the ambulance surgeons, who have begun to realize how important is their position in the matter of antiseptics.

There are some new questions which have arisen that are of interest when discussed in the light of the recent revelations in modern surgical pathology. Among these many subjects for special study and observation I have selected a few which seem to me

[1] Read before the New York County Medical Association, in the Carnegie Laboratory, October 18, 1886.

as possessing unusual interest in connection with the report of these compound fractures.

1st. Meningeal hemorrhage.
2d. Fat embolism.
3d. Insanity following fracture of skull.
4th. Malignant disease.
5th. Tenotomy.
6th. Healing by Schede's method.
7th. Amputation.

Meningeal Hemorrhage.—This variety of hemorrhage occurring in compound fractures of the skull has been a subject about which there existed much diversity of opinion among surgeons. It has been the routine treatment for many years to ligate the common or the external carotid artery in case of severe hemorrhage from the middle meningeal artery or one of its large branches. I have ligated the carotid in a case of severe meningeal hemorrhage and the bleeding was at once arrested. Among the cases in my list of compound fractures of the skull is one which is of great practical interest as bearing upon a new method of arresting hemorrhage without resorting to a ligation of the carotid.

In the case referred to, a man received a severe compound fracture of the skull upon the right side. The accident was caused by a stone weighing 700 pounds falling upon his skull. I trephined the seat of fracture and removed over forty pieces of bone, loose in the wound, of which two fragments were larger than a twenty-five cent piece.. I found a large epidural blood-clot nearly the size of the palm of my hand between the dura and the internal surface of the skull. I removed the blood-clot, which I have preserved as far as possible in this glass jar, and upon the removal of the blood-clots I found the middle meningeal artery bleeding to an alarming extent. I controlled the hemorrhage as best I could temporarily with sponges and tampon until I was enabled to remove more bone in order to secure the open vessel. Having removed bone to the extent of six inches I attempted with artery forceps to seize the bleeding point. Every attempt failed and I was unable to grasp the artery on account of the dura mater receding when the artery forceps caught hold of the depressed dura mater through the opening in the skull. Whenever the ends of the forceps were applied to the dura mater this membrane was pushed down and the forceps could not be made to catch hold of the bleeding point.

The idea suggested itself to me in this crisis to introduce the point of a tenaculum through the membrane and out again in such a way as to include the bleeding vessel in the cuvre of the tenaculum. With this instrument I now raised up the dura mater from the brain on a level with the skull, and then applied the artery forceps. The dura mater, which before receded from the grasp of the forceps, and formed a tense, concave surface, was now held firmly, and that part of the membrane held between the curve of the tenaculum was lax, and permitted the forceps to seize tissue and artery. The vessel was tied with catgut, and the hemorrhage was arrested. The paralysis upon the left side of the body disappeared. The wound healed in an aseptic manner, and the patient recovered so far as the operation was concerned. He died some four or five weeks after the injury, and I was enabled to secure an autopsy, which was made by Dr. Grauer. There was nothing in the brain, or in its coverings, which could have caused death; the patient had died from exhaustion and inanition, with no local brain lesion. The use of the tenaculum in the manner described, to seize a torn middle meningeal artery through an opening made in the skull, seems to me a better operation than ligation of the external or common carotid artery in the continuity.

Besides the question of the arrest of hemorrhage by ligation of the meningeal artery by means of a tenaculum introduced through an opening in the skull, another question has arisen in connection with these cases of meningeal hemorrhage. The possibility of a surface clot by contre-coup has been denied by many surgeons. I have here two specimens which I believe will settle this long-disputed question.

In the first of these cases, a patient was found by a policeman on the street, at eight o'clock in the evening, in a condition of what was supposed intoxication. He walked to the station-house, and was locked up for the night, and at ten o'clock the following morning he was brought before the police justice in court, and was sentenced to ten days for intoxication. At eleven o'clock he was returned to the station-house, awaiting the time to be sent to the Island. While in the cell, a few minutes after his arrival, he became unconscious, an ambulance was summoned, and he was taken by Dr. Rau to the Ninety-ninth Street Hospital. I saw the patient that day, and from the history of the injury and the paralysis, I diagnosticated meningeal hemorrhage. The patient was anæsthetized and the uninjured scalp was incised, exposing to view a linear fracture. The trephine was applied, and a large epidural clot was discovered. The dura mater was torn, and the brain substance lacerated. The wound was dressed antiseptically. In fourteen hours the patient died. The autopsy revealed the presence of a second epidural clot which was almost opposite, and was the result of contre-coup. The scalp over the skull corresponding to this clot was normal as upon the opposite side.

The second case was also seen by Dr. Rau, the house surgeon of Ninety-ninth Street Hospital. The patient was brought to the hospital in an unconscious condition with general paralysis. The case was supposed to be a fracture at the base of the skull. The patient died the next day, and the autopsy showed a linear fracture of the parietal bone upon one side, and extending to the middle fossa, under which fracture was a large epidural clot, and upon removing the calvarium another surface clot was found at a point directly opposite to the fracture. This fracture did not extend upon the other side of the skull, and the clot here was also the result of an injury by contre-coup.

These two specimens settle the important question whether a meningeal hemorrhage may be produced by contre-coup. The diagnostic points of epidural meningeal hemorrhage by contre-coup, or by trau-

matism without fracture, suggest operative interference in these cases.

The presence of symptoms of cerebral irritation, followed by unilateral paralysis, with a slow tense pulse, the Cheyne-Stokes respiration, accompanied by a sudden rise of the temperature due to disturbance of the heat centre, form a group of symptoms, which, if they were preceded by a short interval after the injury in which no serious manifestations of brain lesion were present, make it extremely probable that an intracranial meningeal hemorrhage had occurred.

This group of symptoms appearing at the time, and in the order mentioned, with or without any fracture, would indicate the application of the trephine over the seat of pressure, the removal of the clot, and the ligation of the middle meningeal artery through the opening made in the skull by means of a tenaculum applied in the manner already described. To some this may seem too bold; but when the fact is considered that it has been demonstrated that formerly nine-tenths of these cases perished under the expectant plan of treatment, and when further it is considered how safe the operation of trephining is in the hands of antiseptic surgeons, it would seem that a surgeon might be derelict in his duty if he did not resect a portion of the skull and remove the clot and arrest the bleeding. I have applied this principle in several cases with success where I trephined in head injuries, suspecting, but having no knowledge of a fracture of the internal table, and have removed many pieces from the inner surface of the skull.

Fat Embolism.—This interesting complication in the treatment of fractures in general was first described fully by Wagner and Zenker. Fat embolism means the entrance of fluid fat probably derived from the medulla of the bone into the veins in the immediate vicinity of the fracture, and through these channels into the capillaries of the brain, spinal cord, lungs, kidneys, and other essential organs.

The presence of fluid fat in the blood had been described as early as 1836 by Dr. R. W. Smith; but the clinical importance of this symptom was not investigated until recently by Bergman, Czerny, and Scriba. Déjérine has experimentally produced in the lower animals fat embolism by inserting laminaria-tents into the medullary cavity of the long bones. The occurrence of fat embolism in fractures is undoubtedly much more frequent than has been formerly supposed, and without doubt, also, the dangers of this condition have been over-estimated. Fat embolism has been fatal in laceration of the liver where the patient had a fatty liver, as in alcoholic or in tuberculous patients; but these cases are altogether different from the fat embolism which is found in connection with a fracture. Flournoy pointed out three essential conditions necessary to the development of this complication. He demonstrated that there must exist large openings in the veins, free fluid fat, and a *vis a tergo*, which is found in copious extravasations of blood.

The symptoms of fat embolism appear within the first three days as a rule, and consist of those of secondary shock. They occur before the time at which venous thrombosis or pulmonary embolism would be expected to arise. Great dyspnœa associated with the Cheyne-Stokes respiration, and great irregularity of the heart with a sudden rise of temperature, together with twitchings of the muscles, as well as paralysis of certain muscles, have been observed in these cases. There have been no metastatic abscesses found in the cases of fat embolism where a report of the autopsy has been published. In several cases I have been able to find an abundance of fat globules in the urine following a train of symptoms such as has been mentioned.

I have seen these symptoms appear after osteotomy where the condition of the wound itself was perfect. Fat embolism is said to be found more frequently in fractures in the aged, because the medulla contains much fat, and not often in children, owing to absence of fat in the medulla.

The treatment which has been recommended in this condition, with a view of dissolving the fat, is the administration of ether, and also a free use of the diffusible stimulants. In cases of cyanosis with great dyspnœa, artificial respiration has been suggested. I have never seen a case of fat embolism where it became necessary to resort to these severe measures, but the attacks have been of short duration, and have been followed by the presence of fat in the urine. In pathological specimens, osmic acid stains the tissues so that the fat appears in black globules of irregular shape, but in the urine the fat globules are detected by the microscope.

I have at present under treatment, in Bellevue Hospital, a case of simple fracture of the fibula, in which the complication of fat embolism has arisen. On the 5th of October the patient sustained a fracture of the fibula, and upon admittance to the ward was in good condition. Two days later she suddenly developed a temperature of 104½° F., associated with vomiting and diarrhœa. Her pulse was rapid and feeble. The urine, which upon admittance was normal, now became bloody, contained casts, and was loaded with fat globules. The examination of the urine was made by Dr. Houghton, who exercised great care in the investigation. The patient grew better under treatment with Hoffmann's anodyne and ammonium carbonate, and her condition now is in every way satisfactory.

This group of symptoms must not be mistaken for shock following a fracture, nor for pulmonary embolism. The former condition may be said to be present three hours after the fracture, fat embolism three days after the fracture, and pulmonary embolism three weeks after the fracture. For convenience, I have arranged these complications in the order in which they are most likely to occur, and by associating these conditions which simulate each other by the time in which they appear, no mistake in diagnosis is likely to arise.

Insanity following Fracture.—There have been a good many cases of insanity following traumatism of the head, and this is a generally accepted view among specialists in nervous diseases. To trace the etiology of insanity to a fracture of the skull is more difficult. I have now a patient in an asylum as a re-

sult of a fracture of the skull, and I understand that he is hopelessly insane. I have under observation, also, a case of imbecility and idiocy which resulted from a pistol-shot wound of the skull. In another case of severe and persistent headache extending over a period of six years, I trephined over the site of a previous fracture, and found the dura thickened and the seat of a pachymeningitis. The removal of the depressed bone relieved the intracranial pressure, and the patient—whom I now see from time to time—has never had any return of the agonizing pain in her head, and her mental condition seems much improved. This patient is now at work, and expresses herself as perfectly well.

In three cases of traumatic epilepsy attended with more or less mental disturbance I have used the trephine with most excellent results. I am aware that, as a rule, trephining is not uniformly successful in epilepsy, and my own experience has led me to expect little from the operation in those cases where there is not a well-marked depression produced by a fracture.

There is a case reported recently by Dr. McDonald, in which insanity followed a compound fracture of the skull, and where the patient recovered completely after an operation. The depression in this case was situated over the first frontal gyrus marked 12 by Ferrier. There is also a case reported by Dr. McEwen, of Glasgow, where insanity was produced by a fracture of the skull with depression, and where the patient recovered after trephining. Schroeter mentions a case where a patient became insane on account of a fracture of the skull. Dr. Spitzka was kind enough to show me in his collection several interesting specimens bearing upon this point. One specimen was part of a brain belonging to a patient who was struck by a fragment of a shell at Chancellorville. He became insane and died after some time. The injury was in the median line, the dura was thickened and adherent, and there was milky opacity. The lepto-meninges were thickened, the sulci beneath gaped, and the perivascular spaces were enlarged. Dr. Spitzka also gave me the notes of another patient who became insane after a depressed fracture of the skull produced by the explosion of a shell at the battle of Bull Run. At the autopsy there was found periencephalitis corresponding to the indentation upon the inner surface of the skull. The dura was universally adherent on both hemispheres, and there were hæmatomatous efflorescences in both dural sacs. In another case where a patient had been kicked by a horse on the left frontal region over the superciliary ridge, the depression internally was an exaggeration of the mamillary eminences, and they stood forth like spiculæ of bone. The hemispheres were unsymmetrical, and a well-marked depression was seen upon the frontal lobe beneath the seat of fracture.

Many other cases might be found where the cause of insanity is due to an old and unrelieved depressed fracture. In all these cases depression existed, hence the important point of elevating at the time of accident, even though no symptoms exist. A study of these cases shows clearly that insanity may result if a depression is left in the skull in a recent injury, and when it is demonstrated how free from danger is trephining in careful hands, and what serious conditions may follow neglect to perform this operation, it seems clearly evident that in every case of marked depressed fracture, with or without symptoms, the surgeon should elevate the bone for fear that some form of mental disturbance may follow.

The kind of insanity which follows in these traumatic cases is that form which is attended with great irritability and mental excitement, and which is also accompanied with fits of violent temper and passion. These phenomena are suggestive in depressed fracture, and call for surgical interference in a class of cases where, until recently, no relief could be extended to the sufferers.

Malignant Disease.—The question of development of malignant tumors at the seat of fracture is an exceedingly important one in surgical pathology. Gross, of Philadelphia, has pointed out the important fact that almost half of the cases of malignant bone disease can be traced to traumatism. His valuable contribution upon this point is worthy of careful study. I have been able to verify in my own experience the conclusions which Gross draws from a study of a large number of his own cases.

During the last month I operated upon a child with an immense sarcoma developed upon the occiput. The child sustained a heavy fall upon the back of the head six months previous and a large hæmatoma was at once developed. The hæmatoma was not incised and in all probability a linear fracture existed beneath it. For some weeks after the injury there was nothing special except the presence of the hæmatoma; but the tumor then began to grow very rapidly and in less than six months from the receipt of the injury the sarcoma was much larger than the child's head. The patient died some weeks after an incomplete operation for its removal. No autopsy was permitted; but at the time of the operation I found the skull perforated and the brain exposed. The tumor was examined by Dr. McNamara, who pronounced it to be a sarcoma. The history of the case and the nature of the fall, make it extremely probable that a linear fracture existed and from this point the malignant disease took its origin.

I have here a beautiful specimen illustrating the clinical fact that a fracture may be the starting-point of sarcoma. The patient from whom this thigh was removed was treated by Dr. Robb for a fracture of the femur just above the condyles. Some six months after the accident a rapidly growing sarcoma developed at the seat of fracture. Dr. Robb sent the patient to me for an amputation at the hip-joint. The patient would not, for a long time, consent to the operation, and when he finally acceded the tumor had made great progress and had seriously affected his general health. He did not survive the operation, but died within twenty-four hours.

I have had a large number of cases of malignant disease which could be traced to traumatism; but to trace the traumatism directly to a fracture of the bone is not a common occurrence.

The variety of tumor which develops is sarcoma, as carcinoma is, as a rule, a metastatic disease in bone. True sarcomata may be central—that is, growing from the cancellous tissue of the medullary canal of the bone; or else periosteal, in which case the starting-point is from the covering of the bone. These tumors grow very rapidly, and soon infect the patient.

The prognosis, while grave, is not necessarily fatal provided the tumor is recognized early and the operation is performed far from the seat of disease. This subject of the influence of fracture upon the development of sarcoma is one to which no extensive investigation has as yet been made and it is one which offers a rich field for original research.

Epithelioma also may develop indirectly as a result of a compound fracture; but this malignant growth has its origin from the soft tissues in connection with a sinus leading down to necrosed bone. If a sinus is not healed it becomes lined with epithelium and a discharge of ichorous pus through it from time to time sets up an irritation in the epithelial-lined sinus and a proliferation of epithelial cells takes place and epithelioma may in this way secondarily develop. While the epithelioma is not directly in connection with the seat of fracture as is the case in sarcoma, nevertheless the disease may have its origin in conditions arising from sequestration in a compound fracture. The closure of such sinuses in connection with necrosis following a fracture should always be aimed at by the surgeon. Early amputation before glandular enlargement at a point distant from the disease may offer a favorable prognosis.

Tenotomy.—Two years ago I called attention to this procedure in the treatment of compound fractures, and in a number of cases since then I have been impressed with the value of this operation in all oblique compound fractures where the fragments overlap. Division of the tendo Achillis relieves at once any contraction of the muscles, permits the fragments to be placed accurately in coaptation, and the physiological rest thus secured affords great comfort to the patient, and a valuable means of fixation to the fracture during the first ten days. The tenotomy in no way increases danger to the patient, and is easily performed. The foot should be placed in its normal position, as recommended in Dr. Reginald Sayre's most excellent monograph upon fixation of the foot, immediately after tenotomy for club-foot.

The operation is not limited to the tendo Achillis, but may be employed with advantage in exceptional cases upon the hamstrings, in fractures of the tibia or fibula close to the knee-joint. It may also be found a most valuable adjuvant after osteotomy in the anterior curvature. The same may be said in reference to the tendons of the arm and forearm, and even in fractures of the clavicle, if the clavicular origin of the sterno-cleido-mastoid muscle tends to pull the inner fragment upward and away from the outer fragment. I believe there is much to be gained by the adoption of this simple device in the treatment of many cases of compound fracture of the extremities where there is difficulty in reduction, and from the excellent results obtained in those fractures where this procedure was resorted to I can commend it as a most valuable measure.

In vertical fracture tenotomy is of no avail; but in several cases of compound fracture of the tibia, where the solution was parallel with the long axis of the bone, with considerable separation of the halves, I have found great difficulty in bringing the two long vertical fragments in contact. The Signourini horseshoe tourniquet proved a most valuable instrument in closing the long fissure. The instrument overcomes the vertical separation just as tenotomy overcomes the oblique displacement. The pad can be applied to one side of the bone, and pressure can be made by applying the other pad over a thick plaster bandage. The screw can be tightened gradually, and in a few days the bone can be approximated, and the instrument discarded. This is a safe and more satisfactory instrument than the apparatus devised by Malgaigne.

Healing by Schede's Method.—In a number of severe cases of compound fractures of the leg and skull I have observed some beautiful illustrations of this newly described method of repair. In a recent paper read before the German Congress of Surgeons this subject was ably discussed by Schede, and the views which he enunciated are somewhat at variance with the generally accepted opinions upon this pathological question. It has usually been taught that blood-clots in wounds are obstacles to repair by primary intention, and that these clots act as foreign bodies. In one case of severe compound fracture of the leg there was great hemorrhage between the fragments, and a large space left between them, which was filled with fluid blood and blood-clots. I divided the tendo Achillis to counteract the contraction of the muscle, and also in order to bring the fragments in better apposition. The leg was then dressed with the most rigid aseptic precautions, and the blood-clots became organized and furnished a most valuable medium of union. The fracture healed by primary intention, and the patient made a most excellent recovery.

Fluid blood and blood-clots, if perfectly aseptic, are valuable adjuvants in the repair of compound fractures. They are, however, most potent sources of evil if any possible infection reaches the clot through any carelessness of the surgeon. It is a most valuable contribution to the treatment of compound fractures, if the blood which escapes between the ends of the fragments can be in the future utilized as a means of hastening and perfecting union by primary intention. The reason why so important a principle in surgical pathology has been so long unknown is explained by the fact that blood-clots, until rigid asepsis was established, were recognized sources of septic inflammation. If all the surrounding parts in every compound fracture are made aseptic, blood-clots and fluid blood can be utilized for the purpose of healing. Anything short of surgical cleanliness will convert these clots and the blood into dangerous agents of infection.

Amputation.—Amputation of the member in compound fracture was resorted to formerly with great frequency in hospital practice. Until the in-

troduction of reliable and scientific antiseptics, pyæmia destroyed the life of almost every patient suffering from compound fracture who was brought to a large metropolitan hospital. The time is within my own recollection when amputation was immediately performed as routine treatment in Bellevue Hospital upon the admittance of a severe compound fracture to prevent blood poisoning; and this operation was considered by surgeons as offering to the patient the best chance of recovery. At the present time limbs are saved which were then sacrificed, and it is a rare event to witness an amputation in compound fracture. Extensive fracture of the bone with protrusion of the fragments through the soft structures would not now form an indication for amputation, unless the soft structures were badly lacerated.

A fracture into the ankle- or knee-joint was, until recently, considered an injury requiring amputation; but now the joint is washed out and provided with free drainage, and the fracture repairs, and the function of the joint is fully restored. I have recently treated a case of compound fracture and dislocation into ankle-joint, with protrusion of astragalus out of the wound. This bone was returned to its proper place, and free drainage was afforded after irrigation of the joint. The joint was perfect in all its movements after a fortnight. I have two cases now under treatment, but it is too soon to predict as to the function of the joints. Formerly the loss of a few inches of the shaft of the bone called for primary amputation. This no longer offers an indication, for the bones are brought together by silver wire, and though the limb may be shorter than the opposite one, the member is still retained and elevation of the shoe compensates for any slight irregularity in the gait. In one case which I treated where four inches of the tibia were removed, the patient made an excellent recovery, and to day has a better leg than any artificial one. In this box is the piece of the shaft which was removed from the patient to whom reference has just been made.

The limits to which amputation in compound fracture may be resorted to, are exceedingly narrow and restricted, and this conspicuous clinical fact is one of the most notable steps in the march and advance of modern and conservative surgery.

Another important point in reference to an amputation in compound fracture is the proper line of treatment to be pursued up to the time of the operation. It often happens that a patient is suffering too profoundly from shock to make it expedient to operate. In these cases I have found great benefit to be derived from deferring the amputation, even several days, until the condition was such as to justify the operation. Formerly this could not be done without subjecting the patient to a greater risk from septic infection than would be incurred in an amputation during shock. If the wound is made at once aseptic and compresses be placed over the fracture to control the hemorrhage, and these compresses do not extend any higher than the wound itself, the amputation can be deferred. It is important that these compresses be applied only over the wound, and that no form of compress or bandage be applied to the limb above the injured part, for if this is done there is danger of dry gangrene in the flaps above the wound. In one case this accident occurred from a neglect of this rule, though the compression was made before the patient was brought to the hospital, and in no way could any neglect be attached to the hospital authorities.

The complete history of the five hundred and sixteen cases of compound fractures I have here before me on this table for inspection and examination. Each case is given in full with the name of the patient, the date of his or her admittance to the hospital, the age, a description of the injury, the treatment in full, and the result. I have also here in this large roll of papers most of the temperature charts. In these glass bottles are the pieces of skull which have been preserved, and are labelled to correspond to the cases given in the table. Upon this table are the bones of the leg, thigh, arms, and forearm in which amputation was performed, also the pieces of bones from the joints, which pieces were removed by resection. I have preserved these specimens with great care. It is obvious that time will not permit the reading of these histories, amounting to 516 in all, and therefore I can only give a summary which will include them all. I would state, however, that anyone desiring to take the time is at liberty to examine each case.[1]

The list of compound fractures of the *skull* contains 107 cases, 68 of which recovered and 39 of which died; 31 of the fatal cases died within 48 hours after the receipt of the injury. Of the remaining 8 cases, 1 died one month after the operation of trephining from exhaustion and inanition, with the wound healed. The autopsy, which was made by Dr. Grauer, showed nothing in the brain to account for the death. Of the remaining 7 cases, 3 died from cerebral softening, as in apoplexy, disconnected with the original wound, and 2 cases from irreparable damage to the brain, one being extensive cerebral laceration due to the lock of a gun driven through the skull, the other being a fracture at the base of the skull. The remaining case died in 52 hours from lepto-meningitis following the operation of trephining, in which the dura mater was found injured.

The list of compound fractures of the *arm* contains 15 cases, 14 of which recovered and 1 died. The fatal case was a railroad injury, with great crushing of the parts, and the patient died in 48 hours, having never rallied from shock.

The list of compound fractures of the *forearm* contains 23 cases, of which 22 recovered and 1 died. This fatal case, which was complicated with extensive burns, never rallied from shock and expired within 24 hours.

The list of compound fractures of the *thigh* contains 53 cases, of which 48 recovered and 5 died. In the fatal cases death occurred within 48 hours.

The list of compound fractures of the leg contains 150 cases, of which 15 required primary amputation; of the remaining 135 cases, 125 recovered, 2 were

[1] [The full history of these cases, in tabular form, accompanied this paper, but we regret that the large amount of space which they would occupy precludes their publication in The News.—Editor.]

transferred at their own request from hospital immediately after admittance, and 8 died, and none of these 8 fatal cases survived forty-eight hours.

The list of compound fractures of the bones of the *hand and foot* shows 37 cases. Many of these cases of compound fracture were complicated with great laceration and crushing of the soft tissues. These injuries were caused by heavy weights falling upon the hand or foot, or by circular saw or railway accidents. In many cases the damage to the soft parts was very great. The joints were opened, the tendons exposed, the soft parts crushed, and the tissues generally torn and lacerated. These cases all recovered, with the exception of one which terminated fatally from other injuries and to which reference will be made later.

The table of compound fractures involving the *shoulder-, elbow-, and wrist-joints*, contains 23 cases, all of which recovered.

The table of compound fractures involving the *hip-, knee-, and ankle-joints* contains 43 cases, 4 of which required primary amputation, and 3 of which were fatal. Of the three fatal cases one died of tuberculous meningitis some weeks after a resection of the hip-joint, another died within twenty-four hours from shock, and the third died a week after wiring of the patella from Bright's disease which caused uræmia. The joint wound was aseptic. In none of the three fatal cases involving these major joints could septic infection have been a cause of death.

The table of compound fractures involving the *carpal and metacarpal and the tarsal and the metatarsal joints* contains twenty-four cases, all of which recovered.

The table of compound fractures of the *upper and lower jaws* contains 28 cases, 4 of which were fractures requiring suture by silver wire, and all of which recovered.

The table of compound fractures of the *ribs and nasal bones* contains thirteen cases, twelve of which recovered; the one fatal case was that of a patient who received a compound comminuted fracture of all the bones of the face and some of the skull, the result of the fall of a heavy derrick upon his head. The patient died in thirty-six hours.

The table of compound fractures of the *ilium and the malar bones* contains three cases, one of the ilium and two of the malar bones, all of which recovered.

A final summary of all of these cases of compound fractures of the different bones of the body is as follows:

Skull	107
Arm	15
Forearm	23
Thigh	53
Leg	150
Fingers and toes	37
Fractures involving shoulder-, elbow-, and wrist-joints, result of accident or of operation	23
Fractures involving hip-, knee-, and ankle-joints	40
Fractures involving carpal and metacarpal, tarsal and metatarsal joints	24
Superior and inferior maxillary bones	28
Ribs and nasal bones	13
Compound fractures of the ilium and malar bones	3
Total	516

In this total of 516 cases of compound fractures, produced by traumatism or by operation, there were 59 deaths, 19 primary amputations, and 2 cases where the result was unknown on account of the removal of the patients, at their own request, from the hospital immediately after their admittance. In the 59 fatal cases, 49 died within forty-eight hours after the accident and during shock, and consequently these deaths should not be included in any figures to ascertain the percentage of mortality, because the patients died before any plan of treatment could be adopted having reference to the repair of the fracture, or to the prevention of septic infection.

The remaining ten deaths occurred in the following manner: one from tuberculous meningitis following some weeks after a resection of the hip-joint, so that this case died from other causes than septic infection; another patient died from uræmia in chronic Bright's disease one week after wiring the patella, and the wound was aseptic, so that this case died from other causes than septic infection; another case died one month after trephining from exhaustion and inanition, with the wound perfectly healed by primary intention, and at the autopsy with no evidences in the brain of pathological changes indicating sepsis as the cause of death, so that death in this case cannot be attributed to septic infection; two other cases died from irreparable damage to the brain, in one of which a lock of a gun was driven through the skull into the brain, and in the other a fracture at the base was found at the autopsy in addition to the fracture of the parietal bone, so that death in neither of these two cases was due to pyæmia or septicæmia; three other cases died from cerebral softening which was situated at a distance from the original wound.

In reference to these cases of cerebral softening, following the injury, a word of explanation seems pertinent. These circumscribed areas of softening in every respect resembled the changes which are found after apoplexy. There was no local evidence of septic infection, and in all the three cases the autopsies were made by experienced pathologists, who coincided in this opinion. The situation of the softened areas at a point distant from the original wound, and the changes—*i. e.*, hemorrhage and softening, the perfect aseptic and healed condition of the external wounds, which are identical with those found in cerebral apoplexy—indicate that these three cases are not of septic origin from the wound.

The cerebral softening appears to be due to a molecular disintegration or laceration of brain tissue from traumatism, and this disturbance of the nutrition produces a metamorphosis and the liquefaction takes place. The external surface of the dura mater seems to possess power to prevent the entrance of septic microörganisms into the cerebral substance; while the internal surface of the dura mater, owing to its proximity to the arachnoid space, is exceedingly delicate and susceptible to the slightest influence of any septic material. Experimental work in this direction indicates that such points of softening may have their origin in traumatism and not necessarily be due to sepsis. I believe that these three cases are explained in this way, and therefore these cases may

be eliminated from the list of deaths due to septic infection derived from the wound in the skull.

I feel certain that these softenings were not the result of infection from the wounds; because the wounds were aseptic. To convince myself further of the accuracy of this conclusion I trephined the skull of a dog and planted upon its dura mater septic micrococci, which were furnished to me from cultures belonging to Dr. Biggs. Though the micro-organisms were septic, they were incapable of developing a cerebral abscess through the dura mater or even producing a meningitis.

Such an experiment, while it is not conclusive, of course carries additional evidence in favor of the non-septic origin of such cerebral softenings, though they may be due to the presence of some such micro-organisms as bacilli tuberculosis; but at the same time the traumatism may have acted as an exciting cause to develop an abscess in tissue already impregnated with a pathogenic germ. This explanation places a higher value upon antiseptic surgery, and it serves also to illustrate at the same time that an operation like trephining may be a brilliant success so far as the operation is concerned; but yet the patient perishes from causes which are as yet beyond the complete control of the surgeon.

There is still an unoccupied field for further investigation and research in this domain of surgery, and surgeons must turn the direction of their studies to those causes of death which are not connected with the details of antiseptic surgery. Perfection has been almost reached in the technique of the operation of trephining, but as yet there are circumstances which are not controlled by the practical surgeon and to a study of these causes future scientific surgery must engage.

Finally, to refer to the two remaining deaths, which may be fairly considered as septic. One of these cases died from lepto-meningitis fifty-two hours after the trephining, and the last case in ninety hours after a crushing of the foot, in a patient over sixty years of age. This makes only two deaths which could be ascribed to septic infection.

Deducting from the original 516 cases the 49 cases which terminated fatally within forty-eight hours, and the 19 cases which required primary amputation, also the 2 cases which were immediately transferred at their own request from the hospital, there remain 446 consecutive cases of compound fractures, with only 2 deaths. This shows a rate of mortality of less than one-half of one per cent. If now the 61 cases of compound fracture of the bones of the hands and feet be excluded as too insignificant, in accordance with the custom among all surgeons in their statistical reports of compound fractures, there still remain 385 consecutive cases of compound fractures, including, to the best of my knowledge, every case which has come under my treatment, with but one death, which gives a still less percentage of mortality, which is less than one-third of one per cent.

In order to appreciate what progress surgery has made during the last half century in the treatment of compound fractures, it is interesting to examine hospital reports embracing this period. Before the introduction of antiseptics the best statistical reports of compound fractures are those of Norris. He showed that in the Pennsylvania Hospital, between the years 1839–1851, there were treated 116 cases of compound fractures of the leg and thigh (excluding those cases requiring amputation), with 51 deaths, thus giving a rate of mortality of 44 per cent. This is only an approximation, as the table does not state whether any amputations were primary or secondary. In the New York Hospital, during the same period, there were treated 126 cases of compound fractures of the leg and thigh (excluding those cases requiring amputation), with 61 deaths, thus giving a rate of mortality of 48 per cent. The previous remark also applies to this percentage, but in neither case would the percentage be notably decreased.

A decade later, from 1860–1876, there were reported from the surgical clinics of Vienna and Zurich, by Billroth, 180 cases of compound fractures. Excluding those cases of amputation, there is a mortality of 31 per cent. from septo-pyæmia. In the Obuchow Hospital Reports of St. Petersburg there are reported 106 cases of compound fracture, with a mortality of 68 per cent. No particulars are given, in this high death-rate, as to whether patients died from shock, amputations, etc. In Guy's Hospital, from 1841–1861, there were reported 208 cases of compound fractures, with 56 deaths, thus giving a mortality of about 26 per cent. In other words, it is shown by these figures approximately that, before the introduction of antiseptics into hospital practice in the treatment of compound fractures, that the rate of mortality in the best tables varies from 20 to 60 per cent.

If now some statistics are examined after the introduction of antiseptics, with a view to ascertain their influence upon the rate of mortality, one is at once confronted with an astonishing fact. If, for example, Billroth's table is referred to after the use of antiseptics, the death-rate is reduced to one-tenth of what it had been formerly in the treatment of compound fractures. The influence, therefore, of antiseptics has caused the death-rate to fall from twenty to sixty per cent. to about four per cent. within a period of a few years.

In the present report of 516 cases of compound fractures, if we compare the fractures of the *extremities* only, as has been the case in the above tables, there is no death from septo-pyæmia, and thus the rate of mortality from blood-poisoning is now reduced from sixty per cent. to a figure which is represented by a cipher. It may be said, therefore, that pyæmia and septicæmia, which destroyed as many as sixty per cent. of human lives in cases of compound fractures, have been practically eliminated as causes of death.

The science of surgery has at last demonstrated to the world that it has fairly met this demon of destruction, and conquered him; and, in conclusion, in referring to this great reduction in mortality, an inquiry is not inappropriate as to the means which has brought it about, and also as to the special influence to which it is due. Without doubt, the science

of bacteriology has largely contributed to this object, and this building in which we are now convened, with its spacious laboratories devoted to this study, attests the importance in which this work is held, and also without doubt the one to whom the profession is indebted for the practical application of this science is Sir Joseph Lister, whose name can never be disassociated with the march and progress of surgery.

A PARTIAL STUDY OF THE SEASONAL RELATIONS OF CHOREA AND RHEUMATISM.[1]

By MORRIS J. LEWIS, M.D.,
of Philadelphia.

The present paper is based upon a study of the seasonal relations of chorea and rheumatism, and for this purpose the weather at Philadelphia for the years 1876–1885, inclusive, has been investigated, together with the number of storm centres, or centres of low barometer, passing across or near the United States. These data were obtained from the monthly weather reports, and from the records kept at the signal station in this city, which have been kindly placed at my disposal.

Recent investigations undertaken by me in 1881, in regard to the relation existing between the number of cases of chorea and the varying states of the weather, showed such a curious resemblance between the chorea and storm tracings that I deemed the subject worthy of further study.

The former work is embodied in Dr. S. Weir Mitchell's *Lectures on Diseases of the Nervous System, especially in Women*, and the statistics there mentioned were based upon the study of the months of onset of 170 separate attacks of chorea occurring in the years 1876–1880 inclusive, but at that time the storm records of the years 1878–1880 inclusive only were available, during which time 87 of the above-mentioned 170 attacks occurred. For the present study I have collected all the separate attacks of chorea which have been noted at the clinics of the Orthopædic Hospital and Infirmary for Nervous Diseases during the years 1876–1885 inclusive. These number in all 437, and necessarily include those previously studied.

As it is a well-recognized fact that a relationship exists between chorea and rheumatism, which, it is needless to say, is as yet imperfectly understood, I thought that it would be of much interest to compare with the cases of chorea the months of onset of attacks of acute inflammatory rheumatism occurring during the same period, and for this purpose have carefully studied the notes taken at the Pennsylvania Hospital, which have been placed at my disposal; from these I have collected 467 separate attacks of rheumatism, having excluded those that are at all doubtful, and those which occurred among sailors at sea, who were afterward brought to this port.

It must be borne in mind that while the records of the weather are complete as far as they go, the cases of disease here reported are but a small portion of those that must have occurred in this city during that decade; but, despite this fact, there is every probability that the percentage of chorea cases per month is practically correct, as may be seen by the almost exact resemblance between the two tracings of 170 and 437 attacks, respectively; Nos. 3 and 5.

To study properly the effect of the weather upon disease, there should be a *daily* record of both weather and disease taken, as has been so carefully done in the relation of pain to weather by Captain Catlin, recently reported by Dr. Mitchell before the College of Physicians (*Transactions of the College of Physicians of Philadelphia*, vol. vi.). In the diseases in question, however, the *day of onset* could only be obtained with certainty in a few cases, and, therefore, it was necessary to be satisfied with the *month of onset;* this, of necessity, destroys, to some extent, the value of the observations, but sufficient of interest remains to justify the present study. By taking the average of too long a period of weather the effect of sudden changes and all irregularities are lost sight of, and in this way some facts of importance may be overlooked.

In the present study the monthly average of the weather for ten years has been taken and compared with the monthly average of disease, but the peculiarities about to be spoken of are best seen when a table is made which shows the mean of the ten years in question, month by month.

The accompanying chart is so arranged by repeating the first half of the year, that any portion of the tracings may be studied in unbroken sequence.

Tracing No. 5 represents the *months of onset* of 437 separate attacks of chorea, and shows the actual number for each set of months, or the average number for each set, according to the manner of reading the figures; thus, January shows 36 attacks, which means 36 attacks for the ten Januarys, or 3.6 cases as an average for each January.

This tracing will be seen to be lowest in October and November, 18 and 19 attacks, respectively (4.1 and 4.3 per cent.); it then rises rapidly, until 36 attacks in January have been reached (8.2 per cent.), falls slightly in February, and again rises, reaching its highest point in March, which shows 67[1] attacks (15.3 per cent.); the line then falls in April to 38 attacks (8.6 per cent.), and after two more rises—one in May, 47 attacks (10.7 per cent.), and the other in July, 46 attacks (10.5 per cent.)—falls almost perfectly regularly to its lowest point in October. Before attempting to find an explanation for the high percentage in March, I will again draw attention to tracing No. 3, which represents the 170 separate attacks previously reported; this will be seen to resemble, in every essential particular, the tracing we have just studied. These cases I have included in the present paper. Nothing especial is seen in comparing with the chorea tracing, that of the *mean relative humidity* (No. 9), or that of the *mean barometer* (No. 2), except that there appears to be an increase in the number of attacks of chorea with a fall of the mean relative humidity and barometer tracings; neither is much seen in comparing

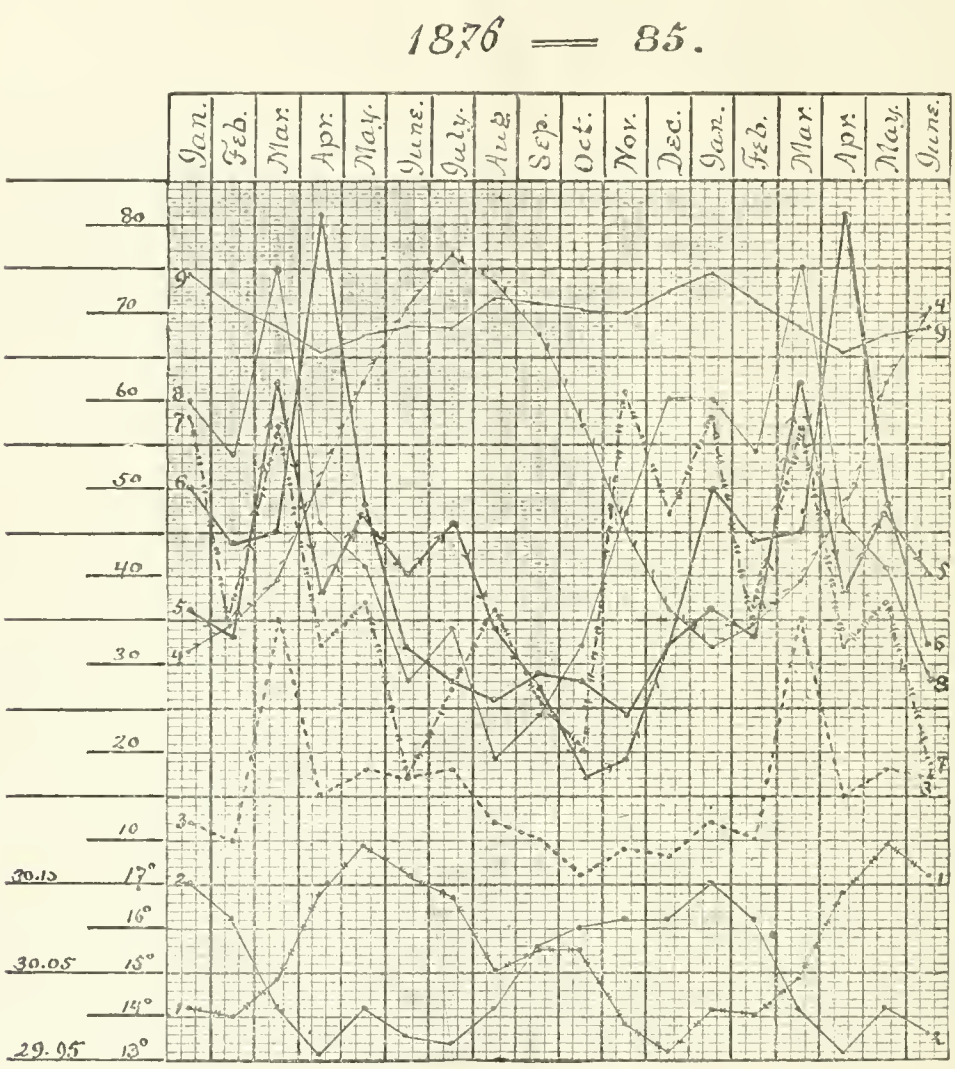
[1] Read before the Philadelphia Neurological Society, October 25, 1886.

[1] Owing to a mistake in the chart, March shows 62 attacks instead of 67.

with it the mean daily range of the thermometer (No. 1), which shows the variableness in temperature of the different months; this is greatest in May, and least in December.

to the chorea tracing. These lines are not shown on the chart.

The probable cause of the resemblances noted becomes more apparent when the storm tracing is



Tracing No. 1, mean daily range of thermometer.
Tracing No. 2, mean barometer.
Tracing No. 3, 170 separate attacks of chorea, occurring in 1876–80.
Tracing No. 4, mean thermometer.
Tracing No. 5, the months of onset of 437 separate attacks of chorea.
Tracing No. 6, the months of onset of 467 separate attacks of acute inflammatory rheumatism.
Tracing No. 7, number of cloudy days.
Tracing No. 8, storm centres passing within 400 miles of Philadelphia.
Tracing No. 9, mean relative humidity.

A resemblance begins to be apparent between the chorea tracing and the tracing of cloudy days (No. 7.) The mean temperature tracing (No. 4) does not throw much light on the subject.

The tracings of the number of days on which rain or snow fell and that showing the amount of rain or melted snow in inches also show a slight resemblance

studied, because these meteorological factors may be considered as component parts of a storm.

Tracing No. 8 represents the number of storm centres (or centres of low barometer) passing within a circle of 400 miles radius described around Philadelphia as a centre.

In studying the storms, circles of varying radii

were thus drawn around Philadelphia and the number of storm centres, as marked on the weather bureau maps, counted in each, but the closest resemblance appeared to be with the number of storms passing within the 400 mile circle, and for this reason it is the only tracing that I have placed on the chart. In the former study the great resemblance between the chorea tracing and the storms within the 750 mile circle was pointed out, but the result of the present study being more exact and more extended is the one to be most relied upon.

The smallest number of storms passing within the 400 mile circle occurs in August, a rapid rise of the tracing then takes place until December and January are reached, then there is a slight fall in February, immediately followed by a rise to the highest point in March, after which there is an irregular fall until the low point in August is reached.

Any one looking at these two tracings, as shown in the chart, will have to acknowledge that the marked resemblance which exists is more than accidental, but to decide which factor in this complex disturbance, which we call a storm, is the baneful one, or in what manner it acts, is difficult.

Let us now turn to another disease, and study its tracing, and for this purpose acute articular rheumatism has been selected on account of its well-recognized relation to chorea.

Line 6 represents the months of onset of 467 separate attacks of this affection, and, like the chorea tracing, represents the actual number for each set of months, or the average per month.

November shows the fewest attacks, viz., 24, or 5.1 per cent.; from this point the tracing rapidly rises until January, with 50 attacks (10.7 per cent.), is reached, then falls slightly in February and March, to rise to its greatest height in April, 81 attacks (17.3 per cent.); from this point it rapidly falls to 32 attacks in June (6.8 per cent.), and then gradually and slightly irregularly falls to its lowest point in November.

While the chorea tracing shows a strong tendency to keep pace, month by month, with the irregularities of the storm tracing, that of rheumatism while also strongly resembling the latter, may be seen to be exactly *one month later*, looking as if the effect of the meteorological changes was immediate in the case of chorea (as it is now acknowledged to be in some varieties of neuralgia), and preparatory only in the case of rheumatism.

From the close relationship known to exist between these two diseases, one might be led to suppose that the rheumatism tracing would precede, or at least accompany that of chorea, instead of following it, as this study seems to show.

In Zurich, according to Lebert, as quoted by Senator in Ziemssen's *Cyclopædia*, out of 220 cases of rheumatism during the years 1853 to 1859, the highest percentage occurred in January, 9.5 per cent., and in April, 13.3 per cent., agreeing exactly with the months of highest percentage in this city. A study of the storm records abroad, and their relations to rheumatism and chorea, would be interesting, and probably explain the seeming diversity of opinion.

Many of the statistics of chorea are of but little value in this connection, as the months of application for treatment, and not the months of onset, are given.

The reports of observers in different countries do not agree as to the season of the year in which chorea is most prevalent.

Angel Money (*Brain*, 1882, p. 512) reports the *months of application for treatment* of 224 cases to University College Hospital, and to the Hospital for Sick Children. The greatest number occurred in January, viz., 30 cases, and the smallest number in July, August, and September, viz., 11 cases each. Arranged according to seasons, spring shows 70, summer 47, autumn 44, and winter 63.

Germain Sée (*De la Chorée*. Paris, 1850, p. 460) is the authority for the statement that, in France, chorea is principally observed in the autumn and winter. My cases, arranged according to seasons, show the following order: Spring 152, summer 120, autumn 64, winter 101.

A comparison of the rheumatism tracing of this table with the varying states of the weather, leaving out the storm records, does not explain the reason of the highest point in April. That month shows the lowest mean relative humidity, and also the lowest barometer; but, in opposition to this, the next highest month, viz., January, gives the highest mean relative humidity, and the highest barometer. The temperature in April averages a little over 50°, and January about 32°. The most changeable month is May, so that this cannot be the explanation.

It may be well to explain that the mean relative humidity does not show the *mean actual amount* of moisture contained in the air, but the *mean per cent.* of the moisture that could be held in suspension at the *mean temperature* of each month; the amount representing complete saturation being indicated as 100.

Thus a given bulk of air at a low temperature, if saturated, and ready to drop its moisture, will become dry, if the temperature is raised, although it still holds the same amount of moisture.

This study may be considered as forging one more link in the obscure chain which binds together these two dissimilar affections.

A CASE OF PSEUDO-MUSCULAR HYPERTROPHY AFFECTING THE MUSCLES OF THE FOREARMS, ESPECIALLY THE FLEXOR GROUP.

By FRANCIS X. DERCUM, M.D.,

INSTRUCTOR IN NERVOUS DISEASES IN THE UNIVERSITY OF PENNSYLVANIA.

J. R., aged forty, an Englishman by birth, and a mechanic by profession, of robust and healthy appearance, presented himself at the University Hospital. He complained of a gradual and increasing inability to do his work, which consisted especially in filing. He stated that he had noticed the trouble for several months. An examination disclosed the grip to be somewhat diminished, especially on the right side. The muscles presented nothing unusual

beyond a slight diminution in the response to both faradism and galvanism. The case was thought to be one of muscle-tire from overwork. Intramuscular injections of strychnia, faradism, and massage, were prescribed, together with absolute rest. The treatment, though faithfully carried out, proved absolutely of no avail. After a time, it was noticed that the forearms were increasing in size, and, in fact, the patient complained of a *sense of tightness* over the bellies of the muscles.

After having been under observation for a year, the muscles of the forearms, especially the flexor group, were very much swollen and enlarged. The grip was now decidedly diminished, and became rapidly exhausted by repeated efforts. The quantitative diminution of the electrical reaction was also much more pronounced. These phenomena were all most marked on the right side.

A small piece of muscle was now removed from the flexor group of the right arm, and examined microscopically. It exhibited an undoubted increase in the nuclei. This was noted, not only throughout the tissue, but also in the walls of the capillaries. A preparation stained by osmic acid showed a decided increase in the interstitial fat.

The microscopic examination, of course, left no doubt regarding the nature of the case. There also is no *à priori* reason why pseudo-hypertrophy of the muscles should commence in, or be confined to, the lower limbs, or why it should not begin in the adult. The case before us, however, is certainly very rare. It recalls a number of cases described under the head of *true* muscular hypertrophy by Auerbach, Berger, Benedict, Friedreich, and others. The unsatisfactory character of the evidence on which these cases rest is instanced in the examination of Friedreich's case by Erb, the electrical reactions being normal, with the exception of the ball of the thumb, which had the *appearance of being atrophied.* It looks, indeed, as though these cases presented merely stages in the course of a pseudo-hypertrophy. Again, that pseudo-hypertrophy and muscular atrophy are closely related is shown by the fact of the not uncommon coexistence of both states in the same patient. Mills and Kerlin have published a number of such cases. Again, at the last meeting of the American Neurological Society, Dr. Bishop reported a case of ordinary pseudo-hypertrophy, and presented sections of the spinal cord of the same, prepared by Dr. Amidon, in which lesions of the anterior cornua existed which were in no way distinguishable from those of ordinary muscular atrophy. The lesions, too, so far as the muscles are concerned, it must be admitted, differ rather in degree than in kind. In both cases we have atrophy of the true muscular fibres, and in pseudo-hypertrophy an added interstitial deposit of fat and connective tissue.

The difference in the clinical history of the average case of muscular atrophy and that of the average case of pseudo-hypertrophy must depend on secondary factors not yet determined. It may be well to add that, in the case here described, the muscles of the upper arms and shoulders gave no decided evidence of being implicated. An examination of the legs and trunk yielded a similar negative result.

MEDICAL PROGRESS.

Influence of High Temperatures in Pregnancy.—Negri, stimulated by the labors of Runge and Doré-Doleris, has made numerous experiments upon guinea-pigs and rabbits with the following results:

1. High temperature may alone be a cause of interruption of pregnancy.

2. Temperatures of from 106.7° F. to even 109.4° F., may often be borne without harm by pregnant and non-pregnant animals, when the exposure is of but short duration, nor do they under these circumstances induce the death of the fœtus.

3. Even when exposure to high temperature is followed by abortion, the death of the fœtus is by no means a necessary consequence.—*Centralb. f. Gynäkologie*, October 16, 1886.

Is Alopecia Prematura Contagious.—At a meeting of the Chicago Medical Society, on October 18, 1886, Dr. R. W. Bishop read a paper thus entitled. He thought this disease due to microörganisms upon the shafts of the hair, and that it is contagious. He has made a series of experiments, assisted by Dr. Oscar Lassar. A typical case was that of a pefectly healthy young man whose head was nearly bald on top. The hair from the diseased surface was brittle and came out easily when pulled. Microscopic examination revealed a large number of fungi on the scalp and the shafts of the hair, the root being free from the parasite. The diseased hairs were cut and mixed with vaseline, which was rubbed on the skin of healthy rabbits, and in two weeks the hair entirely disappeared from the parts which had been rubbed. Experiments were continued, and it was found that the hairs from the inoculated animals possessed increased virulence.

The patient was treated as follows: The head was thoroughly washed for fifteen minutes with tar soap, which was removed with warm water. The head was then exposed to a warm water douche, which was gradually cooled until the water was quite cold; it was then rubbed with a rough towel until dry, and afterward washed with a solution of corrosive sublimate 1 : 500. This was removed, and a half per cent. solution of lithol applied, and, after this, one and a half per cent. carbolic oil was applied very slowly. The treatment was continued daily for eight weeks, and the result was a fine growth of new hair with beginning pigmentation at the end of three months.—*Cincinnati Lancet-Clinic.*

Potion used in Diabetic Thirst.—Duchenne gives the following formula as of value in the treatment of the excessive thirst of diabetic patients:

Potassium phosphate . . .	2 parts.
Water	75 "

A teaspoonful of this solution is given twice or thrice daily in a little wine or hop tea.—*Les Nouveaux Remèdes*, Oct. 1, 1886.

Diseases of the Skin in the Subjects of Gout.—Dr. Corlett believes that the subjects of gout are predisposed to skin diseases which have peculiarities that "may be described as a hybrid between eczema and psoriasis." Those that he has observed were: First,

scaly ; the scales were neither heaped up nor of silvery character as in psoriasis, and when detached they left an oozing surface. Second, their color was reddish, closely resembling a syphilide. Third, they showed a tendency to symmetrical distribution. Fourth, they were met with in adults usually over forty-five years old, except when the gout was inherited. Fifth, they were accompanied by other evidences of lithæmia. Sixth, they were prone to return. These eruptions were most benefited by treatment directed to the gouty diathesis. Locally most benefit was derived from alkaline baths, preparations of tar, and ammoniated mercury.—*Journal of Cutaneous and Venereal Diseases*, Sept. 1886.

Lubricant for Speculum.—Brondel commends as an antiseptic lubricant for instruments intended for insertion in the vagina a pomade thus constituted :

Boracic acid,	
Essence of eucalyptus . .	āā 10 parts.
Vaseline	100 "

For application to the hands he employs a more strongly antiseptic compound of vaseline and sublimate (1 : 1000) containing 10 per cent. of the essence of eucalyptus. The odor of the last-named constituent is found to mask that of the vaginal secretions which is occasionally so tenacious and penetrating. The mixture last mentioned is, however, inapplicable to metallic specula, as the surfaces become tarnished under its use.—*Gazette de Gynécologie*, October 15, 1886.

Fish as an Invalid Diet.—In the *Lancet*, August, 1886, p. 396, Mr. Nairne gives a series of cases in which a fish diet gave rise to very serious mischief. Several cases are related in which convalescents from typhoid fever met with a fatal relapse after partaking of some boiled fish. For some time the author excluded fish from invalid diet, as he thought it the cause of all the mischief. Lately, however, he has found that if fish be steamed it is more tender, and can be eaten with impunity.

A Cause of Indigestion in Infants.—Dr. Chas. P. Woodring, of Meadville, Pa., narrates a case of vomiting and diarrhœa in a bottle-fed infant, which had resisted all the ordinary remedies. Having given more than usual attention and care to the quality, dilution, etc., of the milk, he finally learned that the cow from which it was obtained was pastured in a wood lot. The milk was immediately discontinued, and that from the cow of a milk breeder substituted. The effect was magical ; the child recovered its usual health forthwith. Another case, the symptoms being similar to the preceding one, presented itself. On investigation, it was found that the milk was supplied by a cow that was also pastured in a wood lot, but this pasture was two miles distant from the one referred to in the first case. The hint received in the treatment of the previous patient being acted upon, and the milk from a cow pastured in an open field substituted, the result was equally happy. A third patient, under exactly the same circumstances, and treated in exactly the same way, came under observation, followed by an identical successful treatment. The water in these wood pastures was exceptionally good, but the grass was scanty, and as these three cases all came under observation within a month, the conclusion one would naturally arrive at would be that the source of irritation in the milk must have been due to the leaves of trees. Had the milk substituted been in each case from the goods of the milkman, some might credit the *carb. calcis* and the high dilution with all the benefits derived from the change of milk.—*Cleveland Medical Gazette*, October, 1886.

Iodide of Potassium in Mineral-water Menstrua. —Dr. v. Höaslin proposes, in a German medical journal, to correct the taste of iodide of potassium by dissolving it in carbonated water. He finds that by this means the nauseous taste of the iodide is almost entirely neutralized.

Quinine as an Anaphrodisiac.—Dr. J. A. McKinnon, of Selma, Ala., has found in his practice that the continuous use of sulphate of quinine will reduce the venereal desire, and that in old age it will destroy the animal propensity completely. He says that he has had cases under observation for several years who took from five to twenty grains daily, not for anti-malarial purposes, but because they had formed the quinine habit, and he has found on inquiry of such patients that the venereal desire in them was diminished, impaired, or destroyed. In most cases the subjects would become alarmed at their condition, and ask for relief. In the treatment of gonorrhœa in this malarious section, Dr. McKinnon often administers quinine in the inflammatory stage, for the dual purpose of counteracting any malarial complication and to control chordee. It must for this purpose be administered in not less than ten-grain doses at proper intervals, and it acts, he writes, in this respect more satisfactorily than camphor, lupuline, or the bromides.—*New York Medical Record*, October 30, 1886.

Fluid Extract of Marigold in Extensive Burns. —Dr. Sexton presented the following points of practical interest at the nineteenth annual session of the Mississippi State Medical Association, the *Transactions* of which meeting have just been published.

Having had a series of severe cases of burns during the past year, I have thought my experience with the fluid extract of calendula officinalis might prove of interest to the profession.

My first case was a little child, severely scalded by pulling over a pot of boiling water. This burn might be classed of the second degree. I ordered a drachm of the fluid extract of calendula to an ounce of the ordinary carbolized oil, and had the most satisfactory results. The child stopped screaming as soon as the oil was applied, and made a rapid recovery in two weeks. The skin had peeled off from the elbows down to the hand.

The second case was one where the clothes had caught fire, and was more or less burned all over the back. In some places even the flesh was charred.

The same application was made, with equally gratifying results. The carbolized oil itself is a good dressing, but its healing properties are increased tenfold by the addition of a drachm of marigold to the ounce of oil. It has another advantage of rendering the oil much less offensive to the olfactories. The odor of

marigold is pleasant, and it makes an efficient dressing in cases of severe ulcerating sores and wounds. I found it of invaluable service in treating the extensive wounds and lacerations after the cyclone at Wesson and Beauregard, and deemed it of sufficient importance to call especially the attention of members of our Association to its virtues.

Lead Poisoning by "Flake White."—Dr. D. W. Hand, of St. Paul, Minnesota, describes in the *Northwestern Lancet* of October 15, 1886, the following interesting case of lead poisoning by a cosmetic.

During the early summer a young woman called on me twice, and wanted something for a pain in her stomach, which she called neuralgia. Noticing her peculiarly pale and emaciated condition, I thought she must have a gastric ulcer, but could get no history of vomiting or any symptom except periodic pain. For this I prescribed an anodyne, and thought to investigate further, but lost sight of the case.

On August 14th, I was called in haste to see a young girl who was said to be in convulsions. On reaching the house, I found, in a badly lighted room, a girl writhing and rolling about the bed, but with no sign of convulsion. Her mother at once, with many lamentations, gave me this history: The girl was twenty-four years of age, and had been sick for over three years, being thin and weak and extremely pale. Her bowels alternated between constipation and diarrhœa, and very often she would have attacks of pain, like that which she was now suffering. The mother said they had employed many physicians, but nothing did any good. Their last physician had told them it was *spinal disease*.

I found the girl had both hands grasped tightly about the right thigh just above the knee, and she gave me to understand that was the seat of the worse pain. From her ell-like motion it was plain there was no disease of the spine; and when lights were brought, my attention was at once called to a peculiar *wrist-drop* on both sides. Examining then her mouth, I found the characteristic blue line on the gums, and at once told the mother it was a case of lead poisoning. She protested it could not be so, for they drank pure cistern water, were very careful, etc., and moreover an older daughter was affected much the same way. On calling that girl in, she proved to be the slim patient who had visited my office; and a new light was thrown on her case. She had no wrist-drop, but often some pains in her abdomen and legs, and examining her gums, I found the same blue line, even more distinct than in her sister's case.

Questioning this girl about the use of hair-dye, face powder, etc., she at once told me that for many years—in fact, ever since they were grown up—they had used "Flake White" on their faces as a beautifier. This "Flake White" is the commercial carbonate of lead, and I am told by druggists that they sell large amounts of it to women. It is used by mixing with rose-water, and then as a sort of cream spread thinly over the face. It gives an appearance like enamel to the complexion, and when persistently used must be very injurious.

After many days of intense suffering and mild delirium, the young girl was able to get up and crawl about the room. Both girls were then put on free doses of iodide of potassium; were told to eat all the watermelons they could, and to take a hot bath three times a week. Their improvement has been quite surprising, and yesterday, October 12, 1886, their mother told me they had not been so free from pain or seemed so well for nearly four years.

The Connection Between Pulmonary Phthisis and Ovarian Disease.—At the end of an extensive article thus entitled, Dr. Bedford Fenwick speaks as follows:

I would, therefore, sum up my conclusions thus: 1. Ovarian cystoma is caused in many cases by an inherited tendency on the part of the patient to degenerative changes. 2. This inherited tendency is due to a family predisposition to pulmonary phthisis. 3. Gestation and severe falls or strains are probably powerful exciting causes of the disease.

The practical lessons to be learnt from the facts I have given are great and varied, and, with increased investigation, leading to further and wider knowledge, will certainly prove greater still. For example, we should already, perhaps, pronounce against a woman of marked phthisical tendency encountering the risks of married life. The intimation we now have gained of the other dangers to which she and any future daughters will be exposed, should strengthen us in more decided expression of opinion. We shall, I think, be able to show that sterility will not increase such a woman's tendency to be affected by ovarian disease, but that pregnancy may very probably do so. Then we can clearly understand how an ovary which is or may be subject to degenerative changes, is more likely than a healthy one to evolve an ovum having within it the seeds of the same disease. So the practical rule would be—first, when an ovarian cyst is discovered, to insist that future conception must be prevented, and to remove the growth as soon as possible; and secondly, while performing ovariotomy, to extirpate the other ovary too. For I contend most strongly on every ground, moral and physical, that it is wrong to allow a patient who has already shown the clearest evidence of degenerated ovarian structure the opportunity of perpetuating in children yet unborn the same disease and suffering. And we have Mr. Lawson Tait's high authority for believing "that it is in no way more risky to remove two ovaries for cystoma, or anything else, than to remove one." And, moreover, it is a well-known fact, that in cases of an ovarian cyst it is very rare for the other ovary to be perfectly healthy.

In conclusion, I venture to believe that I have shown the distinct probability that the great predisposing cause of ovarian disease is a family tendency to phthisis, and that gestation may be the exciting cause. But in view of the immense importance of the subject, both to the profession and the public alike, as regards questions of diagnosis and prognosis, and the still greater matter of prevention, I would earnestly appeal to all who in future have to treat cases of ovarian cystoma, either to publish as complete as possible a family and previous history of each, or to favor me with the notes, which, of course, I would duly acknowledge. A thousand well-recorded histories would definitely settle the important points I have touched upon by the hard logic of manifold facts. I should not base implicit confidence upon a smaller series. Straws show how the wind blows, but mathematical precision can alone determine its force.—*The Lancet*, October, 23, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 13, 1886.

GANGRENE OF THE LUNGS.

INTERESTING questions in regard to the nature and treatment of gangrene of the lungs have recently been brought again to the notice of the profession in this city by the report of a case of this disorder by DR. JOHN H. MUSSER, before the Philadelphia County Medical Society, on October 20th. In this case a large, gangrenous cavity existed in the right lung, and death occurred suddenly from profuse hemorrhage, due to giving way of a bloodvessel in the wall of the cavity. No surgical procedure was considered advisable during life, but, in the light shed by the autopsy, it was evident that it might have been undertaken without serious risk to the patient. Dr. Musser, in reporting the case, announced his conviction that pneumonia is a frequent cause of gangrene of the lung. This view is held by many excellent clinicians, and it is said to be a settled point by CARSON, the author of the article on this subject in Pepper's *System of Medicine*. Carson recognizes croupous pneumonia, catarrhal pneumonia, bronchiectasis, embolism, foreign bodies in the lungs, alcoholism, and the extension of diphtheria, as the commonest causes of gangrene; and vitiated states of the system as strongly predisposing to it.

The opinion that croupous pneumonia is a frequent cause of gangrene can hardly be considered so well established as Carson thinks. One of the most valuable contributions to the literature of this subject is by COUPLAND, in the *British Medical Journal*, of September 5, 1885. He analyzes 38 cases, collected from the *post-mortem* records of the Middlesex Hospital, from 1875 to 1885. Of these, 14 were "associated" with acute croupous pneumonia, but Coupland says that only 8 of them could be fairly considered to be dependent on the latter, 6 were associated with chronic pneumonia, 7 with cancer of the tongue or œsophagus, 2 with cancer of the lung, 2 with bronchiectasis, 4 with embolism or thrombosis in the lung, 1 with suppurating glands and tuberculosis, 1 with thoracic aneurism, and 1 with empyema and cerebral hemiplegia. It will be seen that pneumonia was the most frequent single cause of gangrene in these cases; but the termination of acute pneumonia in gangrene can only be asserted, as Coupland says, "in a fair proportion" of the cases. When the whole number of cases of pneumonia is considered, this termination is seen to be happily very rare. Out of 1065 cases reported for 1884 to the Collective Investigation Committee of the British Medical Association, gangrene occurred in only two, both being old subjects, and one a drunkard.

A careful study of the records cited by Coupland might lead to a somewhat different classification of the cases, and especially, we think, if a fuller statement were made of the general condition of the patients, including the proportion of cases in which phthisis, syphilis, diabetes, chronic alcoholism, etc., were present. The most frequent cause of gangrene of the lung may probably be said to be septic infection by matter brought either by way of the air passages, as in case of cancer of the throat, or the aspiration of foreign bodies, or by the bloodvessels, or through the lymph channels, as in empyema, or more directly by the breaking down and putrefaction of inflamed bronchial glands, or by the putrefaction of retained secretions, as in bronchiectasis.

The treatment of gangrene of the lungs is either medicinal, or surgical, or both In the former, general supporting measures are of the utmost importance, and should be combined with antiseptic inhalations, for which purpose carbolic acid is probably the most useful drug. Thus PAUL, in the *Gazette Médicale de Paris*, No. 35, 1885, reports 7 cases of gangrene of the lungs—in regard to some of which the diagnosis is questionable—treated by inhalations of carbolized air, and all cured. DUNLOP, in the *Lancet*, of November 14, 1885, reports two cases of abscess of the lung—one of which is called a case of gangrene—similarly treated, with one recovery. BONAMY, in the *Bulletin Général de Thérapeutique*, of May 15, 1885, reports good results in one case of gangrene of the lung treated with oil of eucalyptus.

One of the most important questions in regard to the treatment of gangrene of the lungs concerns the propriety of, and the indications for, surgical interference. The history of this part of our subject is recent and somewhat obscure, as the records of cases in which the lung has been operated upon for the relief of conditions of fetid tissue destruc-

tion do not always indicate clearly whether or not true gangrene was present. If we understand by gangrene, death in mass—however small—as contrasted with molecular or cellular death, there can be no doubt that many recorded cases of fetid or putrid abscesses, and even of cavities in phthisis, should be classed as gangrene. For this reason the discussion of surgical interference in gangrene of the lungs may be regarded as only a part of the discussion of such interference in putrid cavities of any sort in the lungs. Mosler is credited with first proposing incision and drainage for these conditions nearly twenty years ago, but it was first employed, we believe, by Dr. Cayley, of London, in 1879, although Radek had opened and washed out an abscess of the lung in 1879.

We have studied the records of nine cases of this operation, four for abscess of the lung, and five for gangrene. These show that recovery took place in three cases, that distinct relief was afforded four times, although the patients' lives were not saved, and that only twice did death speedily follow the operation. The results obtained in these cases, as reported by Coupland, in the paper referred to above, and by FENGER and HOLLISTER, in an admirable paper, in the *American Journal of the Medical Sciences* for October, 1881, warrant, we believe, the conclusion that whenever the diagnosis of a putrid or gangrenous cavity in the lung is reasonably established, and the patient is losing ground under strictly medicinal treatment, surgical intervention is justifiable. This intervention should consist in an exploratory puncture, followed by incision, and even, if necessary, resection of part of a rib, drainage, and washing out with some antiseptic fluid. Potassium permanganate and carbolic acid solutions have been most frequently used, but we would suggest weak solutions of permanganate of potassium for the first washing, or for several of them, and afterward solutions of boric acid, as the most innocent antiseptic known. We believe that such measures might also prove of value, in well-selected cases, in the treatment of large cavities in phthisis.

Finally, we would suggest that these views might be put in practice earlier than some writers recommend, with advantage to the patients and with improvement in the results of the operation.

SUBPERITONEAL LAPAROTOMY.

THIS is the name given by POZZI to an operation which, he claims, is particularly well adapted to insure the thorough evacuation and drainage of those parametritic collections of blood and pus in the pelvis which constitute, perhaps, the most difficult cases with which gynecologists have to deal.

While admitting that excellent results have been obtained in these cases by the ordinary abdominal incision, especially when performed by such men as Tait, Baumgaertner, Martin, Imlach, and Prengrueber, Pozzi asserts that his method is preferable for the two important reasons, that it avoids the danger of septic peritonitis, and secures a more perfect drainage. The incision is made as if for the ligation of the external iliac, and is about four inches in length; the tissues are cut through, layer by layer, until the peritoneum is reached; this is pushed upward by the finger, the encysted collection of fluid is sought for, and, when found, freely incised; a trocar is then passed into the cyst, and through its lower wall into the vagina at the posterior vault; into the opening thus made a drainage tube of large calibre is passed, so that one end projects from the vagina, and the other from the abdominal wound, and the cavity is washed out daily.

For a certain class of cases, in which the collection of fluid is of considerable size and encapsulated, this operation would seem to be very suitable; but for small collections of pus, especially in the tubes, and for those suppurating sinuses often found in cases of long standing, it would probably not give as good results as the ordinary intraperitoneal laparotomy.

Pozzi reports in a recent number of the *Gazette Médicale de Paris*, five cases operated on by the subperitoneal method, all of which recovered perfectly from the operation, although one was not benefited by it. It cannot be said that this method of operating is entirely novel, for it was fully described by Hegar, in 1881; but it seems to have been original with Pozzi, who first saw Hegar's description after having performed several operations.

RAPID TRANSIT AND THE WAGE-EARNING CLASSES.

There are many reasons why a large city should be provided with the means of rapid transit, either by elevated or underground railroads. Not the least important of these is the benefits which it will afford to the wage-earning classes, especially such advantages as arise from the comfortable and healthy housing of this portion of the population. Under existing conditions the working classes are generally domiciled near their places of employment. The loss of time, the fatigue, and the risk of disease consequent on exposure to wet and cold in travelling long distances prevent the laborer from selecting a home far from his work. The alternative is the choice of lodgings in the neighborhood of the place of employment. The great demand for a special class of property in a restricted district results in the enhancement in value of real estate, the immediate effect of which is to promote overcrowding with its attendant evils.

In order to change the order of things and overcome the evil of overcrowding and the consequent offences against health and morality, the advantages

of cheap and comfortable houses in the suburbs, where land is less valuable, must be placed within the reach of the working classes, and the bar to their enjoyment set aside by providing cheap and rapid communication with these outlying districts. This suggestion is well worth consideration by philanthropic individuals and societies engaged in providing improved house accommodation for the wage-earning classes, as it promises to help them solve a problem which they have never successfully mastered. The tenement house system, even under the influence of sanitary reform, is disastrous to health and good morals. The proper substitute is the comfortable suburban home for the workman and his family, where the conditions of health, decency, and morality are likely to obtain—a plan which is made feasible by reducing time and space by means of rapid transit.

POISONING BY HAIR-DYE.

Every now and then the public is startled by the discovery of some new method of insidious poisoning. We learn, perhaps, that there are undreamt-of poisons in stale milk, or in the glazing of stew-pans, or in the solder of fruit-cans. Not only have many in ignorance brewed poison in the pot, and made the air of their houses unwholesome with arsenical wall-paper, but they have also fairly rubbed poison into their flesh by means of the cosmetic that promises the "bloom of youth."

The recent admirable report of the Massachusetts State Board of Health contains analyses of most of the "hair restorers" to be found in the market, among others including such well-advertised preparations as Ayer's, Allen's, Barrett's, Hall's, Chevalier's, and the "Revivum." Of these, all contained lead, Parker's and Chevalier's showing most, and Barrett's "Vegetable" hair restorative least, though the latter had the equivalent of about 0.22 per cent. of lead acetate.

As among skin cosmetics, no innocent substance has the body, the smoothness, and adhesiveness that have caused fine white lead to be preferred by those who offer to hide the homeliness of complexion, so for the hair no dressing has been found to cause the desired gradual darkening without the aid of lead. Either it is mixed with sulphur in the bottle, or trusted to find enough in the hair to form there a deposit of the black sulphide of lead.

The change of gray hair to something nearer the color of youth takes place so slowly that the user is easily duped by the assurance on the label of the bottle that the fluid is not a dye, but a tonic and restorative of hair vigor. If this were merely a case of deception, it would scarcely merit the attention we have given it. But the deceiver is also a thief and a poisoner, stealing away the health that is the basis of natural beauty, and daily increasing the need for artifice to make up an appearance like the thing stolen.

From recent periodicals and works on toxicology a list of some length could be made of cases of all degrees of slow poisoning from lead hair-dyes. The lead itself has even been recovered from the body after death in two cases of which we know. Doubtless, if all the persons who have experienced harm from lead hair-dyes could be counted, the number would be sensational enough to meet the wants of the most zealous sanitarian. The effects are often so vague that the cause is not suspected. Most physicians would not assign to a cosmetic, of the use of which they are presumably ignorant, the causation of such vague symptoms as dry and sallow skin, falling hair, dyspepsia, debility, low spirits, neuralgias, and other usual phenomena of confirmed ill-health. Yet these accompany, and may exist apart from, the sharp attack of colic, or wrist-drop, or joint pains, or brain trouble, that would first direct the physician's suspicion to lead poisoning.

General discussion a few years ago did much toward reducing the harm done by skin cosmetics, when enlightened public opinion forced the proprietors to furnish a chemist's voucher of freedom from poison. It is to be hoped that the press, lay and medical, will take notice of these recent analyses, and agitate the subject anew before the public.

In this connection two important facts are now well established: First, that serious disease may be induced by the long-continued use of lead "hair restorers." Second, that the most popular, if not all, the "hair restorers," *vegetable* and other, contain lead.

The New York State Medical Association will hold its third annual meeting at Lyric Hall, Sixth Avenue, between Forty-first and Forty-second Streets, New York City, on Tuesday, Wednesday, and Thursday next. The most notable feature of the programme is a discussion on the treatment of gunshot wounds of the belly, which will be participated in by Drs. Charles T. Parkes, of Chicago, C. B. Nancrede, of Philadelphia, Surgeon-General Hamilton, of the Marine Hospital Service, J. D. Bryant, W. T. Bull, and F. S. Dennis, of New York, T. R. Varick, of Jersey City, W. S. Tremain, of Buffalo, and E. M. Moore, Jr., of Rochester.

At the stated meeting of the New York County Medical Association, to be held on Monday evening, at the Carnegie Laboratory Dr. T. Gaillard Thomas will read a paper on "Laparotomy as a Diagnostic Resource," and Dr. Ira B. Read will make some remarks on "Rupture of the Aneurismal Sac of the Aorta," and will illustrate them by a specimen.

On last Monday Harvard University concluded its celebration of the Two Hundred and Fiftieth Anniversary of its foundation. The occasion was honored by the presence of the President and his Cabinet, the Governor of the State, with numerous other high public functionaries, and many delegates from institutions of learning at home and abroad. Mr. James Russell Lowell delivered the oration, and Dr. Oliver Wendell Holmes read a poem. At its conclusion President Eliot conferred the degree of Doctor of Laws upon thirty-five persons who had been selected for this distinguished honor. The list included three eminent representatives of medicine, and their selection by the Harvard authorities will meet the cordial approval of the profession. They were presented to President Eliot for the conferring of the degree, in the following language:

"Joseph Leidy, anatomist, biologist, a leader and exemplar among American naturalists, professor of anatomy in the University of Pennsylvania.

"Silas Weir Mitchell, physician, physiologist, author.

"John Shaw Billings, surgeon in the United States Army, student and teacher of public medicine, medical bibliographer."

We learn that the West Virginia State Board of Health has determined hereafter to register the graduates of the Columbus (Ohio) Medical College on their diplomas, thereby revoking their former action. We are further informed that the graduates of this College are entitled to be thus registered in all States in which this procedure is required.

Dr. W. H. Draper will deliver the Anniversary Discourse before the New York Academy of Medicine next Thursday.

Dr. F. J. Shepherd, of Montreal, on Saturday week, removed by a lumbar incision a large calculus weighing nearly five ounces from the left kidney of a man aged twenty-six. No tumor was discoverable before the operation. At last accounts the patient was doing well. We hope to present a full report of the case at an early date.

The death of Dr. Julius F. Miner is announced at the age of sixty-three years. He was eminent in his profession, and ranked for many years as one of the ablest surgeons in Western New York. He was born in Peru, Mass., in 1823, was graduated at the Albany Medical School in 1847, and settled in Buffalo in 1855. He was for several years Professor of Special and Clinical Surgery in the Buffalo Medical College, and editor of the *Buffalo Medical and Surgical Journal.*

REVIEWS.

Practical Human Anatomy. By Faneuil D. Weisse, M.D. 8vo. pp. xii. 456, pl. 222. New York: Wm. Wood & Co., 1886.

The first thing that strikes one upon opening this volume is the large number and the excellent quality of the plates. They form half the work. They are partly lettered on each organ or tissue, a method first popularized in *Gray's Anatomy*, and partly by clear reference lines. The lettering is unusually well done, and it would be hard to excel in the delineation of superficial fascia in several of the plates, but especially in plate 6. There is hardly an error in the whole number, unless we cite one of omission—that no plate shows the hymen—an omission in which nature, however, has sometimes set us the example, and which the index follows.

The author's use of "section" as a verb is peculiar and indefensible, and his adoption of odd names such as "pollex eminence" and "minim eminence," for "thenar" and "hypothenar," has not only no advantage in clearness, but is positively confusing. We fear that some not over-bright students might think that "minim" had some pharmaceutical foundation. So too in describing the levator ani et prostatæ, he speaks of "the prostatæ portion," and "the ani portion."

The book, however, is good—thoroughly good—and we commend it most highly.

SOCIETY PROCEEDINGS.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, October 25, 1886.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. Morris J. Lewis read a paper on

A PARTIAL STUDY OF THE SEASONAL RELATIONS OF CHOREA AND RHEUMATISM.

(See page 541.)

Dr. Wharton Sinkler said that this paper was valuable and interesting because it showed the close relation between chorea and rheumatism which has been denied by some authors. For instance, Sturgis had 219 cases of chorea in the Hospital for Sick Children in London, of which number twenty per cent. also had rheumatism; but he did not attach much importance to this connection, because, as he stated, fifteen per cent. of all children have rheumatism. Other writers have expressed the same views. This paper seemed to prove the relationship between the storm centres and attacks of rheumatism and chorea.

Dr. G. E. de Schweinitz reported

EIGHT CASES OF TOBACCO-AMBLYOPIA, ONE COMPLICATED WITH DISEASE OF THE SPINAL CORD.

Since 1854, when Mackenzie showed that defective vision might be produced by tobacco smoking, and since, ten years later, when the subject was renewed and enlarged by the observations of Hutchinson, tobacco amblyopia has become one of the well-recognized facts of ophthalmological science. As is well known, pro-

gressive and usually equal failure of vision, unimproved by optical therapeutics; a feeling of wretchedness on the part of the patient; an ill-defined ophthalmoscopic picture; and a symmetrical, oval scotoma in the fields of vision, lying between the fixing point and the blind spot, and often including both, in which the perception of green and red is especially defective, constitute the marked symptoms of this affection.

Case I.—A. G., æt. forty-nine, a book-keeper, presented himself in the University Hospital, because his vision was failing and because of sleepless nights. He was a large, dark-haired man, with a restless, irritable disposition. Vision in the R. E. $\frac{20}{C}$, L. E. $\frac{20}{CL}$. Pupils about normal in size and reaction. Vision best in the early morning. Both optic nerves slightly hazy and gray in their deeper layers. The refraction H., but vision unimproved by the correcting glass. The fields of vision for white and red about normal. Between fixation—*i. e.*, the macula and the blind point, the optic nerve entrance—there was an oval, slightly sloping, relative scotoma, including both. In this area green appeared dirty white, and red could not be distinguished as such. For twenty years he had smoked excessively, averaging two pounds of Cavendish a month. He drank one pint of spirits a day. He was ordered to stop tobacco absolutely and to diminish his daily quantity of spirits. In a month his vision had improved to $\frac{20}{XXX}$ in each eye, and with his correcting glass he could read with fair ability.

Case II.—B. E., æt. fifty-three, laborer, came to the University Hospital for failing vision. He was a small, dark-skinned man, with fairly steady nerves. Vision, R. E. $\frac{20}{LXXX}$, L. E. $\frac{20}{L}$. Pupils normal in size and reaction. Vision worse in a bright light. Both optic nerves were gray-red, and the veins full and dark. The fields of vision showed no marked peripheral change, but perfectly characteristic oval scotomata were present. This man had smoked two pounds of "hard tobacco" a month for many years, and was accustomed to drink one quart of spirits a week. The usual order to stop tobacco was given. Sufficient time has not yet elapsed to prophesy how successful the case will be.

Case III.—J. M., æt. thirty-five, a mechanic, came to the University Hospital because of defective vision, headache, and great nervousness. He was a short, thick-set man, tremulous and despondent. Pupils exhibited no abnormalities. Vision, R. E. $\frac{20}{LXXX}$, L. E. $\frac{20}{C}$. The nasal edges of the optic nerves were hazy and the temporal sides gray; arteries rather small. The fields for white and red were not far from normal, those for red being slightly contracted. In the right eye from fixation and including it and passing outward there was an oval scotoma for red and green which reached to the blind spot, but did not embrace it. In the left eye a similar, rather more irregular scotoma. Up and out from the fixing point a small area of the scotoma was absolute. This man for fifteen years had smoked about six ounces of coarse tobacco a week, and occasionally cigars and cigarettes. He denied taking anything to drink, except a little beer or ale. In eight days his vision in right eye had become $\frac{20}{XXX}$, and in the left eye $\frac{20}{L}$. He then passed from observation.

Case IV.—Ida J., æt. twenty-seven, came to the University Hospital because of failing vision and great "nervousness." She was a finely formed brunette, of rather pallid countenance and excitable temperament. Vision in R. E. all of $\frac{20}{XL}$ some of $\frac{20}{XXX}$. The L. E. had been removed years ago for disease. Pupil responded freely to the change of light and shade and was about medium size. The optic nerve was pallid, edges clear, arteries rather small. The field of vision both for white and red was somewhat contracted and surrounding fixation in a band-like manner, but not extending to either side, there was a relative scotoma in which this color appeared "brownish" or rather "dull colored." The girl used no tobacco, but had worked for some years in a tobacco factory. On this account she was advised to get other employment and also to take one twenty-fourth of a grain of sulphate of strychnia three times a day. In two weeks the scotoma was no longer demonstrable and in about one month the vision had returned to normal and is now above normal.

Case V.—H. H., æt. fifty-eight, a shoemaker, came to the Dispensary of the University Hospital because his eyesight was so poor he could no longer see to do his work. He was a medium-sized man, with dark hair beginning to turn gray, tremulous and easily startled. Vision in the R. E. $\frac{20}{CC}$, the same in the L. E. The pupils were small and failed to respond to the changes of light and shade, although they contracted in the efforts of accommodation. The optic nerves showed a large, shallow excavation, widening of the scleral ring all around and were of a distinctly gray color. There were no changes in the central circulation. The fields of vision showed slight contraction for white, distinct limitation for colors and oval scotomata from fixation to blind spot, including both. The man smoked three ounces of tobacco weekly and drank whiskey, but not to excess. Further examination developed the fact that the patellar reflexes were absent, that with closed eyes the upright position was maintained with difficulty, and on attempting to walk the gait became staggering, if not positively ataxic, and that preceding the time of failing vision there was a history of diplopia. These symptoms, together with the state of the pupils rendered the presence of sclerosis in the posterior columns of the cord a fair inference. There was no history of syphilis. Examination of the urine revealed it normal. The patient was ordered to stop the use of tobacco and take iodide of potassium. Although two months have elapsed since he applied for treatment no improvement in his vision has taken place, nor have the scotomata changed or lessened.

Case VI.—W. H., æt. fifty-eight, a farmer, applied for treatment in the University Hospital, because of a "cloud" before his vision and inability to do even ordinary coarse eye-work. He was a well-preserved, large-framed man, with iron-gray hair and presented no noteworthy unsteadiness of the nervous system. Vision in the R. E. counts fingers at two feet, in the L.

E. $\frac{10}{cc.}$ The pupils were small, they responded to the changes of light and shade and also to the efforts of accommodation. Both optic nerves were small, surrounded by a halo, and their edges and the surrounding retina hazy. The disks were gray-red in color. In the neighborhood of each macula were slight patches of choroiditis. In the R. E. the field of vision for white was contracted, but not markedly so, and the fields for blue and red showed similar slight limitations. Between fixation and the blind spot, a large irregular scotoma for all colors. In the area surrounding the fixation, and for a small distance toward the blind spot, the loss of color was absolute, from there to blind spot relative. In the L. E. the field for white was limited above, and the fields for red and blue irregular and constricted. A similar scotoma, absolute near its centre, extended between fixation and blind spot and included both. This man smoked four to six cigars daily and drank "an occasional glass of whiskey." The patellar reflexes were prompt and greater on the right than the left side. His urine has as yet not been examined.

Cases VII. and VIII.—These cases occurred in private practice, and were both men over forty years of age, of active business habits, who complained of indistinct vision. In both the vision was not far from normal, viz., $\frac{15}{XX}$, and in both the eye-grounds presented no abnormal features. There were no true scotomata, only slight dimness of the perception of green and red between the macula and the optic nerve. These men were inveterate smokers. The difficulty of vision disappeared in one patient when he ceased using tobacco, the other declined to abandon his habit. While tobacco was evidently producing deleterious effects, these cases can scarcely be classified as true instances of tobacco amblyopia.

In three of the cases reported, the ophthalmoscopic examination revealed "hazy disks" either with or without full, dark retinal veins (Cases I., II., and III.); in two, if the last record be included in the list, there were no fundus changes (Cases VII. and VIII.). In one the optic nerve was pallid, the arteries rather small, perhaps the appearance of beginning atrophy (Case IV.), and in one the nerve showed evidences of gray atrophy (Case V.), while in another the appearances were those of a subsiding neuritis (Case VI.). Three of these cases are perfectly typical instances of tobacco amblyopia (Cases I., II., and III.); and two of them, if not characteristic cases, at least show the result of tobacco impression (Cases VII. and VIII.). Case IV. is an atypical one, inasmuch as the scotoma surrounded the fixation but did not include it or pass to either side, and, furthermore, is noteworthy because of the fact that the tobacco found its entrance into the system by absorption through the skin. This woman worked in tobacco, but did not use it. Case V. may be one of those rare instances in which a central scotoma appears with a spinal atrophy of the optic nerve, but inasmuch as the man used tobacco, although moderately, its influence cannot be excluded. An almost precisely similar case is recorded by Gowers (*Med. Ophthalmoscopy*, p. 111). In Case VI. it is doubtful if the use of tobacco produced the scotoma, although, as in the last instance, the patient was accustomed to its use, and hence its influence cannot be excluded. The whole subject of tobacco amblyopia has so often and so thoroughly been discussed, notably by Mr. Nettleship (*St. Thomas's Hospital Reports*, 1878), that it is useless to do more than report these cases and point out the features that are interesting.

Dr. B. Alex. Randall remarked that some ophthalmologists disbelieve in the existence of tobacco amblyopia. Very few cases have been put on record in which the influence of alcohol could be wholly excluded; but the combination of alcohol and tobacco is certainly a serious disturbing element in a number of cases. This affection is constantly coming under notice—occurring some eight or ten times in a thousand cases. While the scotoma is usually of an oval form, he had seen it distinctly annular (as in Case IV.) in a case typical in other respects.

It has recently been claimed that the absolute quantity of nicotine used does not bear that relation to amblyopia that we should infer, and that those who smoke the finest cigars are more liable to this affection than those who smoke the poorest and strongest.

Dr. Jas. Hendrie Lloyd asked if this affection were due to neuritis or to some disturbance of the intraocular circulation? The cases reported suggested an interesting analogy between tobacco amblyopia and peripheral neuritis, especially that form due to toxic agents. Is this a form of toxic neuritis of a special nerve?

Dr. J. Madison Taylor, referring to one of the cases reported, asked if it were not possible to have a powerful effect from the absorption of tobacco by the skin and lungs? In children working or living in tobacco shops, he had, in several instances, seen profound disturbance of the heart as the result of absorption.

Dr. Louis J. Lautenbach remarked that there had always been an element of doubt about these cases, and that of late this had become stronger. There are cases reported in which alcohol has been stopped, while the tobacco has been continued, and the patients have gotten well. Dr. Minor, of Memphis, reports eight such cases. In addition to the discontinuance of alcohol, he administered in these cases either iodide of potassium or strychnia. Nettleship, Foerster, and a few others, have succeeded in curing some of these amblyopia cases by the discontinuance of tobacco alone. About two years ago, at the Philadelphia Eye and Ear Dispensary, he had experimented in this matter, and had cured a number of cases by removing alcohol, allowing them to use tobacco, without the use of any medicines. The same treatment had resulted satisfactorily in two cases treated in private practice. One case was that of a professional base-ball player, who was in the habit of drinking thirty-five or more glasses of whiskey, and smoking from eighteen to twenty-five cigars a day. When examined, both eyes gave V.= $\frac{3}{LX}$?. The patient was directed to stop the use of strong liquors, but to keep on with his tobacco. In four days later V.= $\frac{3}{XXXV}$. Vision continued to improve, although no medicines were used.

The condition which causes this amblyopia may be a slight grade of retro-ocular neuritis, involving only the macula lutea fibres, which may be induced not only by tobacco but also by alcohol; lead occasioning it in some few cases. Depressed conditions of the system may probably cause it. This amblyopia with central scotoma,

is coming to be looked upon not as a special symptom of tobacco abuse, but rather as an indication of the depression of the general system which may be brought about by various poisons.

Dr. Wharton Sinkler referred to a paper published in one of the New York journals by Drs. Roosa and Ely, giving the results of the examination of a large number of workers in cigar factories, many of those examined smoking a great deal. Only a very small proportion of these cases was found to present any defect of vision or any disorder of the nerve. He asked if in the experience of other members they had found that a large proportion of nervous diseases were attributed to tobacco? He saw but few patients at his clinic at the Infirmary for Nervous Diseases with nervous disorders which could be directly attributed to the use of tobacco.

A point to be remembered in the consideration of this subject is that a person who takes alcohol will use more tobacco than one who does not. If he stops his alcohol he will take less tobacco.

Dr. Morris J. Lewis stated that in studying the subject of writer's cramp, he had found that in the majority of cases the use of tobacco increased the difficulty. A few out of forty-three cases said that it did no harm, and three said that it was of service.

Dr. Francis X. Dercum asked if those who used tea or coffee to excess, especially tea-tasters, presented symptoms analogous to those presumably caused by tobacco and alcohol?

Dr. B. Alex. Randall said that there were some cases in which alcohol *could* be entirely excluded in the causation of this affection. As to the pathology of the trouble, it is interesting to note that he knew of no case on record of true neuritis in the sense of anything like a choked disk, which had any apparent relation to tobacco abuse; although such cases are not rare in lead poisoning and other toxæmic conditions. In all cases of actual neuritis of the optic nerve, as in inflammation of other nerves, strychnia has to be carefully avoided in the acute stage. In most cases reported the use of strychnia had no injurious effect, and in fact caused, or was followed by, improvement. In some cases where strychnia has been given and the alcohol and tobacco both continued, recovery has taken place. The amount of poison required to produce a certain effect probably depends upon the constitution and condition of the patient. If the general condition is brought up a given amount of the poison no longer has the same effect.

Dr. Charles K. Mills, referring to the question of Dr. Sinkler, stated that his experience agreed with that of Dr. Sinkler, that nervous disorders are rarely attributable to the use of tobacco, although some cases of tremor and general nervousness, and a few other affections, undoubtedly originate in this way.

Dr. George E. de Schweinitz, in closing the discussion, said that he believed that in these cases there was an axial neuritis. He has had no experience with the poisonous effects of tea and coffee. Some of the cases reported had recovered, although the free use of spirits was continued. One of the patients continues to drink a pint of whiskey a day, and yet his vision has remained normal since the discontinuance of tobacco. The only way to reach a satisfactory explanation of this subject is to continue the experiments.

One object in presenting this series of cases was to call attention to the importance of a careful study of the field in nervous cases. If this were done more frequently, many interesting discoveries would probably be made.

Referring to the question of Dr. Taylor, he said that tobacco is freely absorbed through the skin, but inasmuch as it is rare to find scotomata under such circumtances he had reported the case.

Dr. Francis Dercum reported

A CASE OF UNUSUAL PARESIS OF THE FOREARMS.

(See page 543.)

Dr. Charles K. Mills referred to three cases which had been reported a few years ago, by Dr. Kerlin and himself. These cases were studied at the School for Feeble-minded Children at Elwyn. The patients were brothers, and in them was a marked combination of pseudo-hypertrophy and muscular atrophy. One of the boys who has since died, presented in the calves the typical appearance of pseudo-hypertrophy and also in one or two other isolated portions of the body. In the back, however, were all the distinctive signs of progressive muscular atrophy. In the second case the changes were principally those of progressive muscular atrophy. In the third there was a combination of the two conditions. Why in one case we get the pseudo-hypertrophic form, and in another the atrophic form, he was not prepared to say. He believed that in all cases there are cord and nerve lesions, but he did not know which of these was primary. In the treatment of such cases, that pursued in the present instance would seem to offer the most hope. He was in the habit of putting these cases on strychnia, iron, cod-liver oil, and similar tonic and nutrient remedies. He had never seen much benefit from local treatment, but if myositis was present he thought it worthy of a trial.

Dr. James Hendrie Lloyd said, with reference to the age at which this affection may develop, that he had recently seen a case in which a married woman, thirty years of age, who had been under treatment on several occasions without a positive diagnosis having been made, returned after an interval of four months with hypertrophy of the muscles of the calf, lordosis, and other characteristics of pseudo-muscular hypertrophy. This was the first case which he had seen in which the disease had apparently occurred as a primary disease in an adult with no hereditary tendency.

Dr. William Osler remarked that some observations had been made by an English physician with reference to the atrophy which follows great use of the muscles. After examining the microscopic specimens, he agreed with Dr. Dercum in regard to the condition present in this case. There is no essential difference between the atrophic and the pseudo-hypertrophic form of the disease, and both may be present in the same case.

Dr. William Osler exhibited the following specimens:

PACHYMENINGITIS.

J. K., was admitted to the drunkards' ward of the Philadelphia Hospital, on August 26th, with delirium tremens, and died September 4th. I did not see him

during life, but from the account given by the Resident Physician, he appears to have had an ordinary attack of delirium tremens without any paralysis, local or general. He was not in a condition to give a satisfactory account of himself. Death took place from exhaustion. The post-mortem showed an extensive pachymeningitis of the right half of the dura mater. The specimen presents layers of exudation two lines in thickness over the central portion of the dura, gradually becoming thinner toward the tentorium or the orbital surface. In these regions there was a delicate uniform sheeting on the dura mater and no hemorrhage had as yet taken place; but on examination with a low power lens there could readily be seen a plexus of wide vessels. In the central part there were several layers of altered blood, alternating with colorless firmer exudation. The surface of the pia mater of this hemisphere was a little stained, but there had evidently not been any pressure upon the convolutions. There were no other lesions.

PHTHISIS; TUBERCULAR MENINGITIS; APHASIA.

J. McD., æt thirty-six, laborer, was admitted to the Philadelphia Hospital, June 5th, with phthisis. There was nothing special in his family history; five of his brothers and sisters had died from causes unknown to him. He had been ill for over eighteen months with cough, fever, chills, and sweats. Had brought up blood and had had severe diarrhœa. When I saw him first, on September 4th, there were signs of extensive disease in both lungs. Ten days before, he had two convulsions, after which he had some difficulty in talking. On the 4th he looked bright and intelligent, the pupils were dilated and there was no paralysis. Expressed himself with difficulty; when asked his name, said *Joseph Mac*, but could not say the *Donald*. After several attempts and a good deal of worry, he did so, and seemed much pleased. Some words he said clearly, others he could not. Thus he could read the letters of the word *shaken*, but could not pronounce it. He was delirious at times during the next two weeks, and one night he got from the ward on the fire-escape. The aphasic condition improved somewhat. The eye-grounds were examined twice, with negative results. At the time of my visit on September 10th, he had an epileptic seizure, strong spasm of respiratory muscles, and great lividity. Tonic spasms of arms gradually relaxing and becoming choreic. Facial muscles in violent action; face drawn to the left, eyes to the right (strongly) and upward. He became unconscious the next day and died on the 14th. The autopsy showed extensive disease of the lungs. The brain was large; at the base the membrane was thickened and infiltrated and tubercles existed along the vessels. On exposing the Sylvian fissures, the pia on the left side covering the insula was very thick and studded with tubercles the size of a pin's head. The process was most advanced upon the three or four posterior gyri of the insula. The gray matter was reddened and soft. The third left frontal convolution was not specially involved; there were a few isolated tubercles on the pia, but the membrane was not thickened. In the right Sylvian fissure there were tubercles scattered along the vessels, and the arteries of the anterior perforated spaces presented many bead-like and oval swellings. The ventricles were dilated and their walls softened.

EMBOLISM OF RIGHT MIDDLE CEREBRAL ARTERY; CHRONIC NEPHRITIS.

J. W., laborer, aged forty-nine, was admitted to the Philadelphia Hospital, Oct. 7, 1886. No special history could be obtained, as he was very dull and heavy. When I saw him on the 9th he was apathetic, answered questions with difficulty. The face was anæmic, and he had a decidedly renal look. The pulse was slow and hard, sixty to the minute. No increased heart dulness, possibly a murmur at apex, but it was not at all distinct, and at base very ringing. Albumen and hyaline casts were present in the urine. The case was regarded as one of chronic interstitial nephritis.

On the morning of the 12th he had a hemiplegic attack. I found him at 1 o'clock P.M., comatose, with puffing respiration and complete left hemiplegia, including face. Right pupil larger than the left. He died during the night.

The autopsy showed cirrhotic kidneys, slight atheroma in large vessels, moderate hypertrophy of left ventricle. The mitral valve presented recent vegetations, three in number, on the auricular face of segments, freely movable, and on the posterior flap a flattened area looking as if eroded. The right hemisphere of the brain looked fuller than the left, and the vessels were not so full, particularly in the central region. The vessels of the circle of Willis were denuded *in situ*, and the right middle cerebral just beyond the first two branches (temporal) was found plugged with the firm embolism here shown. It was very evident before opening the vessel, as it showed grayish-white throughout the coat, while on either side of it were dark clots, and the branches beyond it were very small. The embolus was firmly adherent, and had a small pale clot on its proximal, and a firm dark one on its distal side. Examination showed it to be an endocardial vegetation, and it doubtless came from the rough spot on the posterior segment. The convolutions of the central portions of the hemisphere were swollen, and œdematous, particularly the gray matter, and softer. There was a light gray yellow tint, but there had not been time for much change. The right anterior cerebral was greatly enlarged, three times as big as the left, doubtless a compensatory process.

Dr. Charles K. Mills remarked that cases of pachymeningitis hemorrhagica were somewhat common in the Philadelphia Hospital. He had met with a comparatively large number of cases in making autopsies in that institution. A form of hemiplegia met with in the wards of this hospital, is undoubtedly due to pachymeningitis hemorrhagica. These cases make partial recoveries, and then again break down, and at the autopsy is found the condition exhibited to-night. He had reported one case five years ago, with a number of other cases, in the English journal *Brain*. This condition is sometimes mistaken for embolism, hemorrhage, or some other form of disease producing hemiplegia. In some of the cases he had seen there had been distinct naked-eye flattening of the convolutions of the motor region, which he supposed accounted for this peculiar, variable form of hemiplegia.

Adjourned.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, October 22, 1886.

The President, James C. Cameron, M.D., in the Chair.

SUBMUCOUS INJECTION OF LACTIC ACID FOR THE CURE OF THE EARLY STAGE OF LARYNGEAL PHTHISIS.

Dr. George W. Major, in a short paper, related his experience of lactic acid as a local application in the ulcerative stage of laryngeal phthisis. He said that it was probably the most speedy and most efficacious plan of treatment yet introduced. Ulcerations healed under it most kindly, and tuberculous deposits underwent absorption more rapidly than by any other means. But it was of lactic acid employed as a submucous injection into the substance of the laryngeal tissues that he wished to speak. In the early swellings and œdemata it had rendered very remarkable results in Dr. Krause's (Berlin) hands. Dr. Major had the privilege, during the past summer, of seeing many of Dr. Krause's cases and he was happy to be able to endorse all that had been maintained by Dr. Theodore Herring, of Warsaw, and Dr. Krause in its favor when used as an injection. Dr. Major employed a twenty to thirty per cent. solution of the remedy, and inserted at one sitting from fifteen to twenty minims of the liquid. Very trifling pain followed, and but little after-irritation was induced. The swellings disappeared in periods varying from twenty to thirty days and ulcerative changes were avoided. A case undergoing treatment by injection was exhibited to the members of the Society, and the result was deemed very satisfactory and encouraging. Dr. Herring's syringe, as modified by Krause, was the instrument employed for the injections. Altogether, Dr. Major regarded the lactic acid treatment of laryngeal tuberculosis as the greatest advance yet made in the treatment of this disease and looked forward to a great future for it.

Dr. R. J. B. Howard said that he had listened with interest to Dr. Major's paper and was delighted to know that such a distressing disease as laryngeal phthisis could be so successfully treated by such simple means. He had seen several cases of this affection lately, and improvement had followed treatment by application of solutions of nitrate of silver and other means. He would like to ask Dr. Major whether the frequent puncturing of the laryngeal structures would not cause inflammation of those parts.

Dr. F. W. Campbell said that it was important, whilst treating such a disease as tuberculosis locally, not to omit general constitutional remedies, such as cod-liver oil, hypophosphites, etc.

Dr. George Ross was glad to hear of a successful method of treating that most painful affection, laryngeal phthisis. He, however, thought that the cases in which tubercle is first deposited in the throat are extremely rare, and although apparently in many cases the disease first appears there, yet it turns out afterward that the lungs themselves were involved also. In cases of tuberculous disease of joints and glands, the removal of the disease from these centres is most beneficial, and so, also, would this benefit be great if the disease localized in the larynx could be removed. In the treatment and cure of tuberculous laryngitis in the early stage by any remedy, there is always an element of doubt as to the diagnosis, and many cases might be recorded as cures which were never affected with tuberculous disease at all. However, he considers that great benefit is conferred by improving the condition of the larynx, even though the ultimate result of the cases is unfavorable.

Dr. Cameron asked whether there was any tendency to relapse in the cases cured by lactic acid.

Dr. Major, in reply, stated that no inflammatory action followed the punctures; also that no relapses, as a rule, occur in cases of laryngeal phthisis. He did not think that tuberculous disease often occurs primarily in the larynx. The advantage of this method of treatment is that the case can be treated before ulceration takes place.

TUMOR OF THE OPTIC NERVE.

Dr. Buller exhibited a tumor of the optic nerve removed from the orbit of an otherwise healthy female child aged seven years. He also showed a photograph representing the appearance of the child before operation. There was considerable prolapse in a forward and slightly downward direction. The protrusion of the eyeball had commenced to be noticeable about six months previously, and had gradually increased without pain or signs of inflammatory action. The movements of the eyeball were only slightly impaired, but the eye was totally blind. The blindness had been discovered by a physician who had examined the eye some two months previously. There was a high degree of papillitis (choked disk), but no other ophthalmoscopic changes. These facts seemed to warrant a diagnosis of tumor of the optic nerve, and an attempt was made to remove the growth without removal of the eyeball, but during the progress of the operation it was found that the enlargement of the nerve extended quite to the optic foramen, and in order to guard, as far as possible, against a recurrence of the growth, Dr. Buller thought it expedient to remove the eyeball and apply chloride of zinc to the apex of the orbit. The patient made a good recovery from the operation, and returned to her home ten days after. A few days ago (six months after the operation) she was reported to be in excellent health, with as yet no signs of recurrence of the growth. The microscopic examination of the tumor showed it to be a round-celled sarcoma—possibly a glioma.

ANEURISM OF THE AORTA.

Dr. M C. McGannon, of Brookville, Ont., exhibited a specimen of aneurism of the aorta removed from a patient aged forty-eight, who had died from pneumonia, induced by pressure of the aneurismal tumor on left bronchus. At first, patient never suffered from severe pain, the only symptom pertaining to aneurism being an irritating cough; there was no dulness or percussion or bruit.

Some time before death, however, the patient had intense pain in the back, and pulsation became visible on the right side of the sternum. After death, the left lung was found to be consolidated, right lung normal.

Dr. Gardner exhibited the following specimens obtained during the previous ten days.

1. SUBMUCOUS MYOMA.

Removed by enucleation; the patient, a lady of forty-

five years, the mother of several children, the last born five years ago, had suffered from internal hemorrhage ever since. After dilatation by Tait's dilators, the capsule of the tumor was slit with a bistoury, the tumor grasped with vulsellum forceps, separated by the finger, and dragged from its bed. The shreds of the capsule were next clipped off, the uterine cavity well douched with hot water, and Churchill's solution of iodine freely applied. No drainage or irrigation was practised. The patient made an easy and rapid recovery.

2. CYST OF THE LEFT LABIUM.

Tumor had been five years growing, and was the size of a hen's egg; it was easily enucleated.

3. EXTIRPATION OF THE UTERUS BY THE VAGINAL METHOD.

The vagina was incised all around the cervix, the bases of both broad ligaments ligatured in sections, the Douglas pouch opened, and the bladder separated; the remaining portions of the broad ligaments were then clamped with Ferrier's forceps devised for the purpose, after which the uterus was completely extirpated. A few bleeding points required ligature. The operation was completed by placing a T-drainage tube on the Douglas fossa. The clamps were removed at the end of three days, and the drainage tube a day later. The patient recovered without a bad symptom.

4. TWO CASES OF MULTILOCULAR OVARIAN CYSTOMA.

In the first case the patient was aged sixty-eight; the operation was a simple one, and there were never any adverse symptoms referable to the operation, but forty-eight hours after she developed pleurisy of the right side, which extended to the left two days later. The pulse reached as high as 175. After four or five days the serious symptoms abated, and rapid convalescence took place.

In the second case, that of a young lady aged twenty-two, there were no adhesions, but some troublesome bleeding took place from a rent in the broad ligament; slight oozing continued after application of a continuous silk suture and a drainage tube was used for forty hours. The left ovary was as large as a hen's egg and was cystic. It was also removed. Patient did well. Dr. Gardner remarked, with reference to Schröder's practice of saving a portion of the ovary in such cases when the condition seemed to justify it, that while on a visit to Berlin, during the past summer, he was told, on inquiry, that the professor had discontinued the practice.

Dr. Trenholme said that during the past summer he had twice extirpated the uterus. In these cases he first opened Douglas's fossa and then ligated and separated the uterus from the bladder with the finger, although at the time of operation the disease was confined to the cervix; in both cases it has recurred after four months. He is not now in favor of removing the uterus for cancerous ovaries, and thinks that on account of the large amount of lymphatics in the neighborhood, recurrence is almost always certain to take place.

Dr. Kennedy agreed with Dr. Trenholme in thinking that the number of lymphatics in the broad ligament gave slight hopes of radical cure of the disease after extirpation. He thought that the use of Terrier's forceps would greatly simplify the operation.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting November 4, 1886.

The President, A. Jacobi, M.D., in the Chair.

THE ERNST KRACKOWIZER PRIZE.

The President, as Chairman of the Committee appointed by the Council in reference to the Ernst Krackowizer Prize Fund, the accumulated interest of which is to be devoted every third year to an award for an essay, the standard and merit of which are to be determined by a committee composed of the Presidents of the New York Academy of Medicine, of the Bellevue Hospital Medical College, of the Medical Department of the University of the City of New York, and of the College of Physicians and Surgeons (unless the Academy should direct otherwise), announced that the first subject selected by the committee was "New Observations on Osteomyelitis," and that all competing essays should be sent in on or before the first day of January, 1889.

Dr. Wm. Gilman Thompson read a paper on

THE MOVEMENTS OF THE HEART AND INTESTINES ILLUSTRATED BY PHOTOGRAPHY.

He said that several years ago he had been much interested in reading the account of a series of photographs of the horse, taken while the animal was in motion, and that this had suggested to him the practicability of securing similar views of the movements of the heart under various conditions. Carrying this suggestion out, he had been enabled to take photographs of normal hearts in full systole and full diastole, and also as affected by various stimuli, such as heat, and different drugs.

In his early experiments he employed an ordinary camera; but more recently he had devised a form of apparatus which rendered the work much easier as well as more accurate. The difficulty about the ordinary camera was that only one view could be taken at a time, and then the plate had to be changed. By the aid of his improved apparatus, however, he was able to take no less than six successive views on the same plate, in the space of one second, a feat in photography which had never before been achieved. The problem was to revolve the plate, which was circular, and stop it six times in the second, each time exposing one-sixth of the surface, and this he had succeeded in accomplishing by means of an arrangement of cog-wheels turned by a handle. Each image was clear and distinct, without any blurring. The animal of which the heart was to be photographed was anæsthetized, and an incision having been made in the median line, the heart was exposed, and a collar of celluloid slipped behind it in order to secure a light background, which was a matter of no little importance. The light used was strong sunlight, and the animals experimented on were cats, kittens, rabbits, rats, frogs, and pigeons.

The results were very interesting, and the movements, changes of form, and pulsations of the heart were distinctly shown. The shape of the apex was found to be greatly affected by different drugs, and of the various stimuli employed, heat was found to produce the strongest systole. Of the chemicals tried, glonoin, either painted over the surface or used hypodermatically, was also very active in producing a similar effect; while chloral caused marked diastolic distention.

In photographing the movements of the intestines the same methods were employed. He had been able to demonstrate positively that two peristaltic waves sometimes occurred, moving simultaneously in opposite directions; although the preponderance of motion was toward the anus.

In summing up his observations, Dr. Thompson alluded to the accuracy of the photographic method he had devised, the rapidity and ease with which data for scientific conclusions could be accumulated, and the facility with which the action of various cardiac and intestinal stimuli could be illustrated before classes of students.

In regard to the movements and form of the heart he said: (1) The long diameter may or may not shorten in systole; but it usually shortens from one-fifth to one-thirteenth.

(2) The transverse diameter usually shortens at least one-fourth.

(3) The apex does not in all cases cause the impulse-beat; and this very frequently is produced by the hardened anterior wall of the heart pressing against the thoracic walls. The form of the apex varies greatly under the influence of different drugs.

(4) The contractile power of the right ventricle may outlast that of the left, and pathologically the two ventricles may contract independently.

(5) The lumena of the ventricular cavities are capable of being entirely occluded by the circular fibres acting independently of the longitudinal and transverse; thereby demonstrating the immense reserve contractile power in all the cardiac fibres.

Dr. W. Gill Wylie read a paper on

TWO OPERATIONS FOR INTESTINAL OBSTRUCTIONS.

He said that out of the sixty-seven laparotomies which he had performed since June, 1885, six were not gynecological. In only two of these, however, was the diagnosis made before the operation. In order to make the list complete, he gave a *résumé* of all the six cases.

Complete intestinal obstruction. The first was that of a female patient, fifty years of age, who had had three children and one miscarriage. Her last pregnancy was twenty years ago, and the menopause occurred four years ago. She had a uterine fibroid, and after the passage of the sound on one occasion an attack of peritonitis was set up. Afterward she had great trouble in getting her bowels moved. Previous to the 7th of October last she suffered from colicky pains and distention of the abdomen. On that day she had much more severe pain, and suffered greatly from vomiting. In order to relieve the pain, large quantities of morphia were required. Ox-gall enemata and other means entirely failed in causing an evacuation of the bowels. Dr. Wylie saw the patient in consultation with Drs. F. N. Otis and Ward, and it was agreed that if a movement could not be secured laparotomy should be resorted to. The pulse and temperature were nearly normal, and the matter vomited was not stercoraceous. The patient was found to be very listless, but this could not be attributed to the opiates which she had been taking, since the pupils were not contracted.

On the 10th of October he operated. A short incision was made in the median line, and a number of small peritoneal cysts were discovered. A large uterine fibroid was found, and on one side of it was a mass of intestines closely matted together. The incision was then extended, and a large part of the intestines turned out of the abdominal cavity, when the cause of the obstruction at once became apparent. A loop of the ileum was found to be firmly bound down by a strong band of adhesions; and the obstruction thus caused was so complete that the intestines in the vicinity had turned black, and the lumen of the canal was destroyed. This firm band was cut, and the lumen was at once restored. The fibroid involved not only the uterus, but both broad ligaments; but as the patient had passed the menopause, it had already begun to atrophy, and it was not disturbed. The wound was closed in the usual way, and ten hours after the operation she had a copious liquid stool. The temperature never rose above 101°, and the patient did perfectly well. Now, at the end of three weeks, her bowels move more freely than they have for ten years past.

A point of interest in connection with this case was the normal temperature and pulse, notwithstanding the presence of such a grave local condition, and Dr. Wylie said that he was convinced that many cases of laparotomy are followed by intestinal obstruction, which is generally mistaken for peritonitis. Until very lately it had been the universal practice to keep the bowels confined for five or six days after laparotomy, notwithstanding the presence of tympanites and vomiting. He would not go so far as the laparotomist who said that a brisk purge was the best treatment for peritonitis; but he felt sure that a turpentine or ox-gall enema was often of great service after abdominal section. He had adopted the plan of always opening the bowels after the first twenty-four hours, if there were any indications for it; and in all cases he did this at the end of three days, at all events.

Partial intestinal obstruction. The second case was that of a widow, twenty-five years of age, who was admitted to Bellevue Hospital in June, 1885. She was sent in as a "tumor case." There was a swelling in the left side of the abdomen, and the bowels were obstinately constipated. The uterus was firmly bound down by adhesions; but no very accurate diagnosis could be made on account of the distention of the abdomen. On the 28th of June an abdominal incision was made, when it was found that there were extensive peritoneal adhesions, with partial intestinal obstruction. The glands were found to be greatly enlarged, and this was attributed either to syphilis or to malignant disease. In the other cases which he had had, the obstruction was due simply to pressure from a tumor or adhesion due to the same cause.

Laparotomy for peritonitis. The third case was one of laparotomy for peritonitis. The patient was a negro, who was admitted to the Bellevue Hospital August 24, 1885. Two weeks before, he had had an attack of severe pain, and noticed that his abdomen was enlarged. He afterward had a number of chills, followed by high fever. After his admission the temperature was 103°, and the abdominal wall in the vicinity of the crest of the ilium, was found to be indurated over a space of several inches. He made the diagnosis of suppurative peritonitis, and prepared to perform laparotomy; but Drs. Janeway and L. H. Stimson, who saw the case in consultation, did not think the operation called for. After-

ward, however, the late Dr. T. H. McBride saw the patient, and agreed with Dr. Wylie, that laparotomy should be performed. Accordingly he did the operation. A cavity was found which contained ten ounces of pus, and the intestines were matted together. The cavity was kept well washed out for several days, and the patient made a good recovery.

Exploratory laparotomy. The other three cases were admitted to the hospital as "tumor cases." In the first he made an exploratory incision, and found tubercular peritonitis present. The patient was a married woman, thirty years of age, who had had five children and one miscarriage. There was a small tumor in the left inguinal region, and he operated April 12, 1886. Two quarts of yellowish and comparatively clear fluid were evacuated, and he then found a semi-solid mass. There were also many grayish-white nodules; the tubercular deposit involving both the intestines and mesentery. Drainage was kept up as long as any fluid came away, and the operation was followed by very marked relief in the patient's sufferings. A sinus was finally established in the site of the wound, and ulceration followed. She died about the middle of July.

The fourth case was also one of tubercular peritonitis. The patient was a female, fifty-four years of age, who had had five children; and an exploratory incision was made in the same way.

The sixth, last case, was that of a patient twenty-five years of age, admitted to Bellevue Hospital October 22d. The abdomen was distended with fluid, and there was some jaundice. On October 23d an incision was made in the median line, and a trocar inserted into the peritoneal cavity; when three gallons of fluid were withdrawn. The nodulated condition of the liver then found showed that there was cancer of that organ.

In Germany, Dr. Wylie said that permanent drainage had recently been resorted to in cases of tubercular peritonitis, and in the two cases related in which he had tried it, the relief afforded the patients had been very great. He stated that in a large number of cases of abdominal dropsy exploratory laparotomy was far less dangerous than tapping, and he contended that laparotomists in this country will never succeed in obtaining as good results as European operators so long as the mischievous practice of tapping continues in vogue. Patients with ovarian tumors, on account of the temporary relief afforded them by tapping, are very apt to delay applying to competent operators for their removal until a stage of exhaustion is reached which leaves but a meagre chance of recovery.

NEWS ITEMS.

Inter-State Notification in Infectious and Contagious Diseases.—The following resolutions, presented by the National Conference of State Boards of Health, were adopted by the American Public Health Association at Toronto, October 8, 1886:

Whereas, It is necessary for the protection and preservation of the public health that prompt information should be given of the existence of cholera, yellow fever, and smallpox; be it

Resolved, That it is the sense of the National Conference of State Boards of Health that it is the duty of each State, provincial, and local board of health, in any locality in which said diseases may at any time occur, to furnish immediately information of the existence of such disease to boards of health of neighboring and provincial States, and to the local boards in such States as have no State board.

Resolved, That upon rumor or report of the existence of pestilential disease, and positive definite information thereon not being obtainable from the proper health authorities, this Conference recommends that the health officials of one State shall be privileged and justified to go into another State, for the purpose of investigating and establishing the truth or falsity of such reports.

Resolved, That, whenever practicable, the investigations made under the preceding section shall be done with the coöperation of the State or local health authorities.

Resolved, That any case which presents symptoms seriously suspicious of one of the aforenamed diseases, shall be treated as suspicious, and reported as provided for in cases announced as actual.

Resolved, That any case respecting which reputable and experienced physicians disagree as to whether the disease is or is not pestilential, shall be reported as suspicious.

Resolved, That any case respecting which efforts are made to conceal its existence, full history, and true nature, shall be deemed suspicious and so acted upon.

Resolved, That in accordance with the provisions of the foregoing resolutions, the Boards of Health of the United States and Canada represented at this conference, do pledge themselves to an interchange of information as herein provided.

Salicylated Beer.—The custom of employing salicylic acid to prevent deterioration of beer is the subject of active discussion in French journals. The quantity of the acid employed is by no means inappreciable. It is computed that the salicylated beer of Paris contains more than 20 centigrammes per litre, so that a considerable quantity is taken by a thirsty beer consumer. A contemporary commenting upon this fact, says: There are grounds for believing that the rate of elimination of the antiseptic drug is by no means rapid, and any congestion of the kidney or liver would certainly retard its excretion in great degree. Again, we are not sure, even supposing that the substance were excreted completely, that constantly having the tissues bathed by a weak solution of salicylic acid would be unattended with danger. Salicylic acid is a member of a dangerous group of chemical bodies, the best known of which, carbolic acid, is a most rapid and fatal poison.

The Length of a Step.—Dr. Gilles de la Tourette has recently published a monograph upon normal locomotion and the variations in the gait caused by diseases of the nervous system. He found, from a comparison of a large number of cases, that the average length of a pace is, for men, 25 inches, for women 20 inches. The step with the right foot is somewhat longer than that with the left. The feet are separated laterally in walking about 4½ inches in men, and about 5 inches in women. The ataxic gait is characterized by an actual shortening of the pace coinciding with an apparent lengthening, and by a considerable increase in the lateral separation of the feet.

Criterion of Intoxication.—Dr. T. E. Wright has carefully investigated the question: "When is a man drunk?" and decides as follows: "When consciousness becomes modified, in any degree whatever, through the influence of alcohol, and when, or as long as no exercise of independent nervous force is adequate to restore it to a normal state, the man so affected is drunk."

Cardiac Lymphatic Gland.—Dr. E. Baisrtrocchi has demonstrated the existence of a lymphatic gland of the heart. The gland is situated where the fold at the beginning of the aorta touches the pulmonary artery. He finds the gland to be constant in many of the lower animals and has observed it five times in the human subject.

Homœopathy in the United States.—It is stated that, in the United States, there are more than 10,000 homœopathic practitioners, and that there are fourteen colleges for educating students in homœopathy. The homœopaths set forth their views in 143 societies and twenty journals, and give their valuable services to the public at fifty-one hospitals and forty-eight dispensaries. Our usually well-informed contemporary, the *New York Medical Record*, appears to accept these figures as at least approximately correct, though at the same time it expresses the belief that Americans are outgrowing their curious love for this worn-out theory.—*British Medical Journal*, Oct. 23, 1886.

A New Hybrid.—Before the St. Louis Medical Society Dr. Funkhouser exhibited a specimen of an embryo five days old, the result of the union of a rooster and a duck. This was the only fertile specimen of sixteen such eggs hatched in an incubator. The doctor thought his experiment tended to upset prevailing ideas about species, general orders, and classes. All sources of error with regard to the roosters and ducks had been carefully avoided. He regarded it as an extraordinary event that a member of the order of swimmers, being crossed with the order of scratchers, should have produced a living result, thus jumping over not only species, but also further. The duck and the rooster are of the same class, but belong to different orders.

Diphtheria and Pigeon-keeping.—At a recent meeting of the Anatomical and Pathological Society of Brussels, M. Destrée called the attention of the members to the fact that cases of croup had been greatly and steadily on the increase in Brussels, so that croup and diphtheria were now endemic there; and he ventured to suggest that there might be some connection between the keeping of pigeons and the occurrence of these diseases. He pointed out that Emmeriels, of Munich, had found the microbe of diphtheria in these birds, and he himself had met with three cases of croup in families where pigeons were kept, in all of which cases signs of the disease had appeared in the pigeons. M. Destrée hoped that members would bear this matter in mind, in order that it might be further elucidated.

Venereal Infection pronounced a Crime.—Some consternation may be caused among a certain class by a recent judgment of Justice Wills, of the Central Criminal Court, England. The charge against the prisoner was on two counts, one with having had carnal knowledge of an imbecile woman, aged eighteen, and another, under 24 and 25 Vict., c. 100, s. 47, for a "fraudulent assault" upon the same woman, occasioning her actual bodily harm. The harm done was the wilful infection with syphilis. The prisoner was found guilty on both heads, and sentenced to two years' imprisonment for the first, and five years for the second. The more remarkable piece of information is that a man who has immoral sexual connection with a woman, knowing himself to be suffering at the time from gonorrhœa or syphilis, is liable to prosecution and penal servitude.

Female Drug Clerks in Holland.—In Holland ladies are gradually usurping the occupations of the pharmaceutical assistants. Out of a total of 55 candidates, 19 out of 31 females, and only 8 out of 24 male candidates were successful, in the recent State examination.

The Disinfection of Books.—The health authorities of Aberdeen have ordered that all books taken from the public library, which are known to have been in the hands of those suffering from any contagious disease, must be sent to a disinfecting establishment before being returned to the shelves. The librarian is provided with a list of the families in the town where there any cases of contagious disease.

Absence of Ill Results from Consanguineous Marriages in Japan.—An interesting contribution to the study of consanguineous marriages occurs in the paper of Dr. Baelz on the Japanese, in the *Sei-I-Kwai*. He says: "Near the bathing resort, Atami, there is situated a small island named Hatsushima. The inhabitants of that island, nearly three hundred in number, have for more than two hundred years exclusively married amongst themselves; strange blood has never entered the island. Those people live by fishing, and from the proceeds of a small trade with the neighboring coast. They are physically and mentally quite normally developed, and their statistics show a larger number of births, and a smaller number of deaths in proportion than any other part of the Japanese empire."

The Action of Water on Lead.—Prof. Crookes and Drs. Odling and C. Meymott Tidy contributed a valuable paper on "The Action of Water on Lead" to the proceedings of the recent meeting of the British Association. They find that the action of a soft water on lead pipes does not depend upon its degree of softness, but to the amount of silica it contains. When the silica was as low as 0.3 grain per gallon, the water dissolved the lead; but where it was more than 0.5 grain, the water had no solvent action on the lead pipes. It is therefore recommended that the water should be filtered at the works, and that where necessary the filter-beds be so modified as to insure the silication of the water. They are inclined to the belief that when the amount of lead in the water does not exceed 0.05 grain per gallon, it will not produce any hurtful effect.

A New Diagnostic Sign of Imbecility.—Dr. Giné, of Barcelona, has published in the *Independencia Medica* an article on what he terms "phrenopathic uranostomatoscopy," and in which he maintains that

all congenital mental deficiencies are accompanied by a depression of greater or less profundity in the centre of the palatine vault; and further, that this depression is in direct and constant proportion to the degree of mental deficiency. It is, for instance, comparatively small in simple dulness or retardation of the faculties, deeper and more marked in imbeciles, and deepest and largest in idiots. He therefore suggests the exploration of the palatine arch as a method of diagnosis in such cases.

Fluorine.—The element fluorine, which has heretofore defied all efforts to isolate it from its compounds, has at last been produced by a French chemist, M. Moissan. It was obtained by decomposing, by an electric current from twenty Bunsen cells, a quantity of anhydrous hydrofluoric acid contained in a platinum U-tube, at a temperature of —23° C. Hydrogen gas was given off at the negative pole, and was readily recognized; while the other arm of the tube became filled with gas which was undoubtedly pure fluorine, as the results of an analysis show that it contains no hydrogen. As might have been anticipated, fluorine is extremely active, violently attacking organic substances, and uniting with various elements to form fluorides. Water is decomposed by it into ozone and hydrofluoric acid. M. Moissan was at work upon the problem for nearly a year before his efforts were rewarded by this brilliant discovery.

Obituary.—Dr. W. D. Stewart, late Acting Assistant Surgeon U. S. Marine-Hospital Service, died on October 31, 1886, at Vineyard Haven, Mass., of chronic intestinal catarrh, which he had contracted during his service in the late war, and from which he never entirely recovered.

Dr. Stewart was born in Trimble County, Kentucky, in 1820. He was a graduate of the University of Louisville, of the class of 1846, at the time when the late Professor S. D. Gross occupied the Chair of Surgery, and was under the preceptorship of that distinguished teacher. He was also a graduate of the University of the City of New York. After the completion of his medical course, he commenced the successful practice of his profession at Fort Wayne, Indiana, where he remained until the beginning of the War of the Rebellion. Proceeding to Washington, he obtained the position of Brigade Surgeon of Volunteers, August 3, 1861, with the rank of Major, and was assigned to duty on the Military Governor's Staff at Washington, D. C. At the close of the war he was mustered out of service, and for honorable, meritorious services was brevetted Lieutenant-Colonel.

In the year 1869, he was appointed Inspector of U. S. Marine Hospitals, and was later associated, in this capacity, with Surgeon John S. Billings, U. S. Army, by whom he was afterward succeeded. He was then selected as Medical Sanitary Inspector of the Board of Health of the District of Columbia, which position he retained for six years. After the severance of his connection from the Board of Health, he accepted the appointment of Assistant Surgeon, Marine Hospital Service, and was ordered to duty at Vineyard Haven, Mass.

He was a man of fine physique, affable in manner, and entertaining in conversation, and his death will be lamented by a large circle of friends to whom he had endeared himself by his honor, integrity, and cheerful deportment. His body will be temporarily interred at Vineyard Haven.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 6, 1886.

Neilson, J. L., *Surgeon U. S. N.*—Ordered to receiving ship "New Hampshire."

Drennan, M. C., *Surgeon U. S. N.*—Detached from receiving ship "New Hampshire" and granted one year's leave.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 2 TO NOVEMBER 8, 1886.

Clements, B. A., *Major and Surgeon.*—Died November 1, 1886, at Fort Leavenworth, Kansas.

Wright, J. P., *Major and Surgeon.*—From the Department of Texas to the Department of Missouri for duty as attending surgeon at Leavenworth Military Prison, Fort Leavenworth, Kansas. —*S. O. 257, A. G. O.*, November 4, 1886.

Forward, W. H., *Major and Surgeon.*—From duty as attending surgeon at Headquarters of the Division of the Missour and examiner of recruits at Chicago, Ill., to the Department o Dakota.—*S. O. 257, A. G. O.*, November 4, 1886.

Hubbard, V. B., *Major and Surgeon.*—From the Department of Arizona to duty as attending surgeon at the Headquarters o the Division of the Missouri and as examiner of recruits at Chicago, Ill.—*S. O. 257, A. G. O.*, November 4, 1886.

Perley, Harry O., *Captain and Assistant Surgeon.*—Granted leave of absence for four months on surgeon's certificate of disability.—*S. O. 257, A. G. O.*, November 4, 1886.

Ives, Francis J., *First Lieutenant and Assistant Surgeon.*—Ordered to proceed to and take station at Fort D. A. Russell, Wyoming Territory.—*S. O. 145, Department of Platte*, November 4, 1886.

PROMOTION.

O'Reilly, Robert M., *Captain and Assistant Surgeon.*—To be Major and Surgeon, November 1, 1886, vice Clements, deceased.

APPOINTMENTS.

Clendenin, Paul, First Lieutenant and Assistant Surgeon, November 5, 1886.

Anderson, Charles L. G., First Lieutenant and Assistant Surgeon, November 5, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING NOVEMBER 6, 1886.

Ames, R. P. M., *Passed Assistant Surgeon.*—Relieved from duty at Marine Hospital, New York, N. Y., to assume charge of Marine Hospital, Vineyard Haven, Mass., November 1, 1886.

Urquhart, F. M., *Passed Assistant Surgeon.*—To proceed to Norfolk, Va., for duty, November 4, 1886.

Yemans, H. W., *Passed Assistant Surgeon.*—Relieved from duty at Marine Hospital, San Francisco, Cal., to assume charge of the Service at Galveston, Texas, November 1, 1886.

Wasdin, Eugene, *Passed Assistant Surgeon.*—When relieved, to proceed to New York, N. Y., for duty at Marine Hospital, November 1, 1886.

Williams, L. L., *Assistant Surgeon.*—Relieved from duty at Marine Hospital, Wilmington, N. C., to proceed to Pittsburg, Pa., for temporary duty, November 5, 1886.

Perry, T. B., *Assistant Surgeon.*—Relieved from duty at Marine Hospital, St. Louis, Mo., to proceed to San Francisco, Cal., for duty at Marine Hospital, November 1, 1886.

ORIGINAL LECTURES.

ON INSUFFICIENT DIET, AND THE HYGIENIC TREATMENT OF OBESITY.[1]

A Lecture on Hygienic Therapeutics.

BY PROF. DUJARDIN-BEAUMETZ, M.D.,
OF PARIS, FRANCE.

GENTLEMEN: In a preceding lecture we have considered the bases of dietetics. We have also ascertained the sum of foods which suffice for the necessities of nutrition. When the daily diet becomes insufficient, there supervenes a series of phenomena described under the name of inanition, the effects of which have been so well described by Bouchardat and Chossat.

In inanition we see successively disappear fat and muscle, and man becomes *autophagic*—living on his own substance; the proportion of urea excreted diminishes every day; the temperature falls; and the individual soon succumbs to the progressive depravement of his organism.

This inanition may be due to several causes: sometimes it results from insufficiency of food; sometimes, on the contrary, the diet is sufficient, but special conditions of the economy oppose the healthful nutrition of the tissues. It does not enter into the plan of this course for me to consider the mechanism and causation of inanition, and I have only to point out the applications which may be made of spare diet in the treatment of disease.

Spare diet, or *negative diet*, as it has been called, has been recommended in the treatment of numerous affections. Valsalva urged its utility in aneurisms of the aorta; he employed in the treatment of these aneurisms a very heroic method, which was based on abstinence and bloodletting. The patient was allowed only half a pint of soup in the morning, a little less in the evening, and no drink but water flavored with quince jelly. To this was added repeated venesections, and this treatment was continued until the patient was so reduced as to be unable to leave his bed, or even raise his arms. If certain medical authorities[2] have reported cases of cure by this method, it must be admitted that the failures have been so numerous as to stigmatize this system as detestable, and he would be a foolhardy man who would propose it in our day.

From aneurisms of the aorta the transition was easy to what has been described as *aneurism of the heart*, and which was nothing, but hypertrophy of this organ, and we have seen Corvisart and even Laennec vaunt the advantages of spare diet in the treatment of affections of the heart. I have no need to insist here on the perniciousness of this treatment, which, if carried out, could only aggravate the troubles of the circulation in cardiac patients.

The spare diet regimen has also been employed in diathetic affections, and it is especially in the treatment of syphilis that clinical authorities have made use of what has been described under the name of *cura famis*. Ulrich von Hutten, in 1677, and afterward Astrac treated syphilitic diseases by guaiacum and low diet. For about two months the patient was confined in a room where no food was allowed him but a little bread, a few grapes, a little chicken broth, and he was still further debilitated by successive sweats. In this vegetable treatment, so extolled by the antimercurialists, guaiacum and the other sudorific medicaments played only a secondary part, and it was chiefly the severe dietary regimen to which the patients were subjected which was regarded as the curative element. This mode of treatment has been taken up again in our day in Sweden, and we have only to go back to 1811, to find Osbeck, of Stockholm, physician to the Hospital St. Seraphin, claiming that by this means he could arrest the most stubborn manifestations of syphilis.

Lastly, surgeons, and even obstetricians, have utilized the low diet system; the former to cause fatty tumors (lipomata) to disappear, the latter to reduce the volume of the fœtus in some cases of narrow pelvis, so that parturition might be more easily accomplished. Although Merriman, Baudelocque, Moreau, and even Depaul, have reported cases where wonderful results of this kind have been obtained, I confess that I believe it to be a dangerous method, which, while having but a hypothetical value in diminishing the size of the child's head, must considerably debilitate the mother, and place her in unfavorable condition for a successful delivery, and a good convalescence.

To these supposed advantages derived from low diet, we may add the hypothetical influence of abstinence in promoting absorption of certain inflammatory products. I have seen my master, Nonat, employ frequent bloodlettings and low diet, with the intent to "discuss" perituterine phlegmons. It has been supposed that pleuritic and other effusions might be made to disappear more rapidly by "starving" the absorbents. But all these methods are to-day abandoned, as both useless and pernicious.

In applying a spare diet regimen to the treatment of obesity, more logical good sense has been shown. Nothing seems to be more reasonable, for one of the first effects of inanition is to cause consumption of the fat which has accumulated in the tissues.

The etiology of obesity is very complex. I cannot here enter into all the details connected with this vexed question of pathogeny, and what I have to say under this head will be brief; for a more complete consideration of this subject, I must refer you to an important

[1] Translated, from advance sheets, by E. P. Hurd, M.D., of Newburyport, Mass.

[2] Notably Stancario, of Bologne; Luke, of London Hospital; Pelletan, in France.

chapter on the "Pathogeny of Obesity," in Bouchard's work on *Diseases by Retardation of Nutrition*.[1]

The diet has very much to do with obesity, and we have first to note the important *rôle* which fatty foods have in the production of polysarcia. In this respect all physiologists are agreed, and if each animal species makes its special fat, adipose tissue is derived chiefly from fatty substances ingested, and the recent experiments of Debove confirm fully this view.

Fat is also derived from carbohydrates, and here zoötechnic experiments are absolutely demonstrative, most animals fabricating their fat out of amylaceous food substances. Lastly, fat may also be formed from azotized food; and Henneberg has shown that an ounce of albumen may furnish half an ounce of fat. But we are not to look for the sole cause of obesity in alimentation, and if Etmuller was able justly to say, *In stomacho prima rudimenta obesitatis*,[2] it must be admitted that heredity has much to do with corpulence. There are families characterized by their obesity, and just as in zoötechnics we find varieties of animals that are more easily fattened than others, so among mankind we find lean races and races that naturally take on adipose development.

In those disposed to develop fat, this substance accumulates little by little in the cellular tissue, impedes the respiration and circulation, and hinders muscular exercise, so that the corpulent person eventually lives in a sort of vicious circle. The more the adipose tissue develops, the less exercise he takes, and the want of exercise favors *embonpoint*. But I am ready, with Ebstein, to admit that we must make a difference between obesity, properly so-called—that is, simple fatty deposition in the tissues—and fatty transformation or degeneration of organs.

Ebstein, in his work on obesity (lately published) divides into three periods of degeneration or retrogression the life of a corpulent person. In the first period the individual is *envied;* every one admires his corpulence. In the second period he is a being that is laughed at; he is a Silenus, a Falstaff, or some other big-bellied hero of a comedy. In the third period the obese person becomes an object of commiseration; he is a patient whom everybody pities.

Obesity may be general, but oftener it is met with in that partial and limited form in which great ventral development is coincident with small or ordinary sized limbs and a moderate thorax. There are three factors in this abdominal *embonpoint:* accumulation of fat in the omentum and abdominal walls, distention of the intestines and stomach, and weakness of the abdominal walls, which readily yield to the pressure resulting from these two causes. Brillat-Savarin, who has given us a curious chapter on obesity and its treatment (see his *Physiologie du Gout*), calls those affected with this kind of corpulence gastrophorous or big-bellied, and says of himself that though enormously "pot-bellied," yet his arms were well muscled and graceful, and his legs were as slender as those of an Arab steed.

To combat obesity three sorts of means have been advised; pharmaceutical means, exercise, and a special diet. I shall first consider the dietetic treatment.

From early antiquity attempts have been made to oppose obesity. The Grecians, in particular, who attached so much importance to beauty of person, multiplied means to diminish corpulence, and Hippocrates in his numerous writings returns repeatedly to the subject. Permit me to transcribe one passage from Hippocrates which is of great interest as pointing out one principle in the treatment of obesity on which Ebstein has so much insisted of late years. I refer to the use of fatty food in the dietary of the corpulent. This is the way in which the Father of Medicine expresses himself on this subject: "Fat people, and all those who wish to become lean, should do much hard work while fasting, and should take their meals while still fatigued, and without resting, and after having drunk a little weak wine: their meats should be prepared with sesamum and suitable seasoning, *and should be fat;* in this way appetite will be satisfied with a smaller quantity. The obese person should eat but one meal a day, should not bathe, should sleep on a hard bed, and should walk as much as possible."

You will find, moreover, in the interesting and curious thesis of Worthington,[1] a multitude of references which show how much this question of obesity interested our ancient forefathers. At the same time, it is not til of late years that the treatment of obesity has taken a definite scientific shape, and it is to Dancel, a French military physician, that we are indebted for the first principles of the new therapy of corpulence. Dancel's first writings appeared forty years ago. This physician, who belonged to a regiment of cavalry, had remarked the influence of water and frequent drinking on the development of the abdomen of horses, and he had deduced from these observations one of the fundamental bases of his hygienic treatment, which consists in reducing as much as possible the water of drinks and of food. He permitted only one, or at the most two, glasses of liquid with each meal, or a quantity scarcely exceeding half a pint. He discarded soups and aliments containing a considerable quantity of water; he suppressed also from the diet all fats and starchy food, frequently purged his patients, and made them take long walks daily.

In an interesting communication made by my friend Constantin Paul,[2] and from which I have drawn largely for material for this lecture, he has shown the progress of a case which he has watched since 1876, and in which the method of Dancel has caused a very marked reduction of weight, only by dint, however, of carrying out the treatment with rigorous exactness.

Dancel's method has been adopted in England, where it has taken the name of Banting's method, in honor of the patient who first put in practice this treatment, and published the report of his own case. This individual was a man sixty-five years of age, by the name of Banting, five feet six inches in height, and weighing, in August, 1862, two hundred and two pounds. Banting submitted to the Dancel regimen prescribed by his phy-

[1] Bouchard: Maladies par ralentissement de la Nutrition, 2d ed., 1885, p. 107.

[2] Obesity originates in the stomach.

[2] On the Treatment of Obesity. (Bull. et Mém. de la Soc. des Hôp., May 24, 1886.)

sician, Harvey, and with such success that in May, 1863, his weight was reduced to one hundred and fifty-six pounds.

I transcribe, literally, the account of the course pursued by this man to obtain diminution of his weight, from his "Letter on Corpulence addressed to the Public," published in London, 1874.

"*Breakfast* at 9 o'clock in the morning; five or six ounces of either beef, mutton, kidneys, broiled fish, bacon, or cold meat of any kind except pork or veal; a large cup of tea or coffee without milk or sugar, a little biscuit, or one ounce of dry toast; making together six ounces of solids and nine of liquids. *Dinner* at 2 P.M.: five or six ounces of any fish except salmon, herrings, or eels; any meat except pork or veal; any vegetable except potato, parsnip, beet root, turnip, or carrot; one ounce of dry toast; fruit out of a pudding not sweetened; any kind of poultry or game, and two or three glasses of claret, sherry, or madeira—champagne, port, and beer forbidden; making together ten or twelve ounces of solids and ten of liquids. *Tea*, at 6 P.M.: two or three ounces of cooked fruit, a rusk or two, and a cup of tea without milk or sugar; making two to four ounces of solids, and nine of liquids. *Supper* at 9 P.M.: three or four ounces of meat or fish, similar to dinner, with a glass or two of claret or sherry and water; making four ounces of solids and seven of liquids. A little unsweetened punch, or a glass of sherry, if desired, on retiring."

As you see, Harvey followed the method of Dancel, with some abatement in the quantity of food permitted. He allowed only 170 grammes (or 5⅔ ounces) of albuminoid matters, 10 grammes (or ⅓ ounce) of fatty matters, and 80 grammes (2⅔ ounces) of cabohydrates; while Dancel, on the other hand, gave the patient leave to eat all he wanted of articles of food which were not prohibited.

From England, this method passed over to Germany, where it was perfected, and, in the hands of Ebstein, Dancel's and Banting's system has undergone modification in a new direction. Struck with the fact that fatty substances are with difficulty assimilable, and that moreover they assuage both hunger and thirst, he permits them to his corpulent patients. This does not imply, as he rightly says in his work, that he treats obesity by a fatty regimen, but he simply restores to fat the rights which belong to it as an aliment.

This is the substance of Ebstein's regimen, which, in a man forty-four years of age, causes a very notable diminution in his obesity. He allows three meals, breakfast, dinner, and supper. Breakfast at 7.30 A.M. in winter, at 6 A.M. in the summer; a half pint of tea, without milk or sugar; one and two-thirds ounces of dry toast well buttered. Dinner, the principal meal, at 2 P.M.; soup of beef's marrow, four ounces of fat meat with some rich sauce, vegetables in moderate quantity. Ebstein forbids starchy foods, and vegetables containing sugar. As a drink, two or three glasses of light white wine, and after dinner a large cup of black tea without milk or sugar. Supper at 7.30 P.M.: a large cup of tea without milk or sugar, an egg, or a little roast beef well streaked with fat; an ounce of fine flour bread well buttered.[1]

In 1885 Professor Œrtel, of Munich, published a very complete work, in which this question of obesity is treated in its entirety. He makes a distinction, accepted by Professor Sée, between obese persons with fatty heart, and those who have no trouble of the circulatory apparatus; like Dancel, he suppresses from the dietary fatty matters and carbohydrates.[1]

Schwenninger, in applying the method of Œrtel to the son of the Grand Chancellor, gave it a great notoriety; but while adopting as a basis the precepts of Dancel, he considerably modified the method by the absolute suppression of drinks with the meals. The patient was not allowed to drink until two hours after meals; he was then allowed to drink all he wanted.

In two important communications made last year to the Academy of Medicine, Professor Germain Sée has taken up anew this question of the physiological treatment of obesity, and, like Œrtel, he makes a distinction between the obese with fatty degeneration of the heart, and those with sound heart.[2]

Prof. Sée, while sanctioning the reduction of fats, and especially of starches in the dietary of the corpulent, parts company with all previous authorities in allowing the free use of drinks, and especially of tea and coffee. He, in fact, considers water as denutrient, and thinks it promotive of the combustions of the economy. He thus sums up the treatment of obesity:

"1. The physiological regimen comprehends 120 to 130 grammes (4 to 4½ ounces) of azotized principles, derived from 250 to 300 grammes (8 to 10 ounces) of muscular flesh or of albuminoids; 100 to 120 grammes (3 to 4 ounces) of neutral fats, plus 250 grammes (8⅓ ounces) of carbohydrates furnished by 300 to 400 grammes (10 to 14 ounces) of starch or sugar; these proportions should be modified in such a way that the musculo-albuminous substances shall not much exceed the normal ration, for meat in excess, in breaking up, forms fat. The fats which are of easy digestion may without harm be used in the proportion of 60 to 90 grammes (2 to 3 ounces); the carbohydrates should be reduced to a minimum; as for herbaceous vegetables, they contain nothing nutritive.

"2. Drinks, instead of being suppressed should be augmented, in order to facilitate the gastric digestion, and promote general nutrition. It is necessary, however, to eschew alcoholic liquors, especially beer, as well as mineral waters; tea and coffee (drunk as hot as possible) may be used instead.

"3. Muscular exercise of all kinds is imperative on the obese; exception may be made of riding, which is passive exercise.

"4. Sweats, vapor baths, warm baths, and hydrotherapy in all its forms may present certain advantages.

"5. Among medicines the most useful are the iodides in small doses, and the sodic chloride waters, which act only temporarily. Alkaline waters and alkalies generally, which act so powerfully in the diabetes of fat people, have no well-defined action in ordinary obesity. Every other medicinal treatment is quite inefficacious."

Lastly, in a communication made to the Society of the Hospitals, my colleague, Albert Robin, has endeavored to lay down the rules which should direct the drink-regimen of the obese. You have, in fact, just seen how widely authorities differ on this point. While almost all physicians who have studied this question of obesity have adopted Dancel's view, and reduced to a

[2] Germain Sée: Traitement physiologique de l'obésité et des transformations graisseuses du cœur. (Académie de médecine, Sessions of 29th Sept. and 6th Oct., 1885.)

minimum the water to be taken with meals, even going so far as to proscribe it altogether, as Schwenninger has done; others, as Prof. G. Sée, permit drinks to be taken freely.

Albert Robin, after having verified on himself the experiments of Genth, and after having noted the augmentation of urea under the influence of increase of drinks, divides the obese into two classes: those attended with excess and those with deficiency of urea; this division he bases on the quantity of urea excreted daily. If the figure exceeds the average, the obesity is *with excess*, if less than the mean, it is *obesity with deficiency*.

In cases where the quantity of urea is an average, the clinician will be guided by what Robin calls *the coefficient of oxidation*, which is the relation which exists between the solid materials of the urine and the urea. If this coefficient is higher than the normal, the obesity comes under the first head (*i. e.*, by excess); if lower than normal, it belongs to the second class.

In all cases where there is obesity by excess, we should permit drinks, and even counsel them to be taken very freely; in all cases, on the contrary, where we have to do with obesity with deficiency of urea, the amount of drinks should be restricted. In support of this view Robin refers to several interesting cases in which the application of this method produced a notable reduction in weight. But it is worthy of note that all these patients, obese by excess or deficiency of urea, were subjected to an insufficient dietary regimen, which consisted in giving them from 300 to 400 grammes of meat, 100 grammes of fresh vegetables, and from 100 to 150 grammes of bread.

When once all these data are mastered, you will be able to compare these regimens and decide as to their relative merits. Whatever may be the method adopted, you will bear in mind that the regimen of the obese is always an insufficient regimen. Cast your eye over the following table, which I borrow from Constantin Paul's communication, and compare it with the normal regimen, the bases of which we have established, and you will find this conclusion force itself upon you.

Average Regimen of the Obese.

Authorities.	Albuminoid matters.	Fatty matters.	Carbohydrates.
Voit	118	40	150
Harvey	170	10	80
Ebstein	100	85	50
Œrtel	155–179	25–40	70–110
Normal ration	124	55	435

This insufficient regimen explains why there is always autophagism in the obese; it is this self-consumption which causes the lessening of the obesity, and when you attentively examine each of these regimens, you see that by variable artifices they all arrive at the same end—reduction of the daily rations.

If Ebstein advises fatty foods, it is because they diminish the sensation of hunger, and by the satiety which they produce, they prevent the obese person from eating too much. If Dancel discards sauces and all condiments, it is because meats when well seasoned excite the appetite. If others, as Bouchard, order a uniform regimen of eggs and meat and exclude everything else, it is because the very uniformity of the regimen produces a certain fatigue of the digestive powers and a certain disrelish. If Schwenninger forbids the use of fluids at meals, it is because he knows well that it is difficult to eat without taking drink.

In a word, what you have to do is, by some one of the approved means, to diminish the alimentation of the obese, and especially to reduce to the minimum the quantity of amylaceous and hydrocarbonaceous elements of the dietary. It is for you to choose the regimen which seems most appropriate for the case which you have to treat.

The corpulent are, in fact, divided into two groups; the one are strong and vigorous, and are great eaters; the others, on the contrary, are weak and debilitated, with soft and flabby flesh. It is impossible to adapt the same dietetic regimen to both groups, and in his excellent article on regimen in sickness, the late Edward Smith insisted especially on this point.[1] Those of the first group may undergo all the rigorousness of reduced diet with impunity, those of the second group will only be injured thereby. You will be obliged then, as you see, to adapt your dietary regimen to the different cases.

As for drinks, you should take as your guide the indications furnished by Albert Robin; but if you may modify according to circumstances the quantity of water daily ingested, you ought absolutely to proscribe alcohols, and, as a general rule, allow only water. This is the opinion of our excellent friend and colleague, St. Germain, who has shown by an experiment made on himself, the happy influence of regimen and exercise in the treatment of obesity. St. Germain would allow neither bread nor wine.

To reduction of diet should correspond an increase of exercise. Here there is unanimity of opinion; eat little and work till greatly fatigued, are the essential points in the hygienic treatment. When I come to speak of gymnastics, of massage, of sudations, and of hydrotherapy, I will show you the happy effects of these agents in the cure of polysarcia. Among these exercises, I insist especially on the benefits of *the wall exercise*. The patient stands with his back firmly fixed against a wall, then he raises his arms above his head and keeps them firmly extended, at the same time swinging them back and forth, and describing a half circle. This exercise develops the abdominal muscles, and gives increased rigidity to the abdominal walls.

Lastly, there is a pharmaceutical mode of treating polysarcia, and we have seen vaunted the good effects of acids, and vinegar in particular, the Fucus vesiculosus, iodine, and the iodides. All these means have but a secondary place in the treatment of obesity, but it is not so with purgatives and alkalies.

Purgatives of whatever kind, and in particular purgative waters and drastic cathartics, are all applicable to the treatment of polysarcia. In fact, in corpulence the development of the intestine plays a considerable part, and by our purgatives we not only obtain for the patient the benefits of a "white bleeding," but we diminish the intestinal tympanism.

As for the alkaline waters, they have a real influence on the march of obesity, especially when they are slightly purgative. There are special treatments for reduction and emaciation practised at Driburg, at Ems, at Kissin-

[1] Edward Smith: On Diet in the Treatment of Disease. Lancet, May 14 and 21, 1864.

gen, and especially at Carlsbad and at Marienbad. Note that in all these stations, besides the administration of the waters and a rigorous diet, joined to prolonged exercise, the presiding physicians make their patients take "reduction pills" or powders, which all consist of drastic purgatives.

In France, Philibert, who was able to test on himself the good effects of the reducing treatment of Marienbad, has instituted at Brides, in Savoy, a course of treatment similar to that pursued in Germany.[1]

To sum up, this is my usual procedure: I begin by a thorough examination of the patient who claims my care for the cure of obesity. I take note whether there exists in him any organic vice which explains or complicates the obesity; for, as Bouchard has well remarked, in a great many cases the polysarcia constitutes a secondary disease. I examine attentively the heart and circulation; fatty degeneration of the heart is, in fact, a complication which is often found in the polysarcous, and the existence of such degeneration should considerably modify the rigorousness of our treatment. When once these points are settled, and after having satisfied myself as to the soundness of the organs, I order the following regimen:

As for drinks—either the patient drinks at his meals, or he pledges himself to drink nothing at all at meal-time. In the first case I limit the quantity of liquid to a tumblerful and a half, or about ten fluid-ounces. This drink shall consist of red or white wine, diluted with an alkaline water, Vals or Vichy. In the second case—*i.e.*, where only drinking between meals is practised—the patient may drink more abundantly, but he must drink nothing until two hours after meals; then he may take weak tea without sugar. I proscribe absolutely beer, bitters, and spirits. In some cases I allow a little strong coffee after breakfast.

As for foods, I forbid soups, and authorize fish, eggs, meat, green vegetables and fruits, but I reduce to a minimum starches.

As for bread, I prefer the light baker's loaf of which the crust forms the principal part, such loaves as are known in Paris by the name of "Peter's flute bread;" the American rusks and light pilot biscuits are also to be commended, while pastries should be utterly interdicted.

I require that the patient shall weigh all his food, and that he shall keep within the following limits:

Breakfast at 8 A.M.: one ounce of bread; two ounces of cold meat (ham or beef); seven ounces of weak tea without sugar. Lunch at noon: two ounces of bread, three ounces of meat or ragoût, or two eggs (the egg without its shell weighs from eleven to twelve drachms); three and one-third ounces of green vegetables, half an ounce of cheese; fruit *ad libitum*.

Dinner at 7 P.M.: two ounces of bread, three and one-third ounces of meat of some kind, or ragoût, four ounces of green vegetables, half an ounce of cheese, fruit *ad libitum*.

I join to this treatment the employment of purgatives, whether under the form of purgative waters, or of laxative pills or powders. I order physical exercise appropriate to the subject, and lastly, I enjoin massage.

I have obtained remarkable results from this regimen. Only a short time ago I saw, with Dr. Francis, at Ivry, a man thirty-five years of age, of short stature, and weighing two hundred and fifty pounds. This patient had arrived at such a state of corpulence that life was to him a real burden and a difficulty; moreover, he had got into a torpid state which nothing could overcome. All the functions of the economy seemed to be impeded, and asphyxia was imminent. To-day this man, by following my regimen, is sixty pounds lighter, and he is still losing several pounds a week. You will find this interesting case reported, along with others, in the thesis of my pupil Geoffroy.

Are we always as successful as this? Unhappily, no! Age, in fact, plays a considerable *rôle* in the prognosis of obesity, and by as much as you are warranted in assuring a cure in patients under thirty-five years, by so much will you be likely to find your efforts of little or no avail if your patient has attained the age of forty-five or fifty years. The results of treatment depend also on the cause of the obesity, a disease which is generally secondary; the pathogeny of obesity is not limited to one or two causes, and for that very reason it resists more or less the treatment directed against it. The state of histological integrity of the organs should influence your prognosis, and when, for instance, there is fatty degeneration of the heart, you can do nothing by a reducing treatment, which is a treatment of inanition, and is sure to enfeeble and damage the heart, and thus shorten the life of the patient. Lastly, the result of the treatment will depend very much on the willingness of the patient to comply strictly with all the rules of the regimen prescribed. You should, in fact, never forget that in undertaking the treatment of obesity it is not enough simply to lay down precise and rigorous regulations; you must see that these are carried out, and this will often be a trying and difficult matter; for the obese person, notwithstanding his great desire to become thin, easily tires of the regimen which you prescribe, and as soon as he obtains a slight amelioration, he is very likely to transgress, and go back to his former diet, and in a few days all your gain, so dearly purchased, is lost.

Such, gentlemen, are the indications which I desired to furnish relative to the treatment of obesity. In the next lecture I shall consider the opposite side of the question, and shall take up the subject of superabundant diet.

ORIGINAL ARTICLES.

LAPAROTOMY IN THE TREATMENT OF SPONTANEOUS GLUTEAL AND SCIATIC ANEURISMS.

By FREDERIC S. DENNIS, M.D.,

PROFESSSOR OF THE PRINCIPLES AND PRACTICE OF SURGERY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK CITY.

The surgical treatment of spontaneous gluteal and sciatic aneurisms has always been extremely unsatisfactory. The results of the various operations for the cure of this special form of aneurism have been attended with a high rate of mortality. The reasons for failure and the fatality by the older operations were obviously due to causes which may be said to be avoidable at the present time. Among the obstacles to a successful issue in the treatment of gluteal

aneurism by former methods may be mentioned the occurrence of secondary hemorrhage, the presence of purulent œdema of Pirogoff in the subperitoneal tissue, the puncture of the veins and injury to important structures owing to the limited space, the ligation of the ureter, the onset of peritonitis, the formation of pelvic cellulitis, and other like complitions which made the mortality upward of fifty per cent.

The present unsettled opinion among surgeons as to treatment of this aneurism indicates that as yet no unanimity exists, and a review of the various methods which have been recommended, clearly demonstrates how wide is the breach. For example, Mr. Timothy Holmes in his college lectures claims that in gluteal aneurism the operation of Antyllus or Anel offers the best chances of success. In five cases in which the operation of Antyllus was performed four recovered and one died, and of four cases in which the operation of Anel was performed two recovered and two died; thus showing a death-rate of thirty-three per cent.

Fischer, of Hanover, concludes that the operation by injecting perchloride of iron into the sac affords the best chance of success. In six cases in which this operation was resorted to, four recovered and two died, thus giving a death rate of thirty-three per cent.

Ribert recommended proximal pressure on the aorta, and direct compression over the sac. This was tried in one case. The patient's condition improved; but in a few months the aneurism returned and the patient died.

Hamilton recommended ligation of the internal iliac artery by an incision parallel with Poupart's ligament, and pushing back the peritoneum. In eleven cases in which this operation was performed, six recovered and five died, thus giving us a rate of mortality of about forty-four per cent.

The plan of treatment by rest and expectancy has been suggested by several authors. This method was adopted in six cases, five of these died and one was cured, but only temporarily, as the aneurism returned in a short time.

Galvanopuncture has also been recommended, but in the one case in which this method was tried the case terminated fatally.

It is evident, therefore, from an examination of the treatment at present in vogue that much is to be desired in the way of perfecting a plan of treatment which will permanently cure the aneurism, and at the same time reduce the present high rate of mortality. Nothing is to be expected from non-interference.

Gluteal aneurism, as a rule to which there is but one recorded exception, progresses steadily and rapidly to certain death from hemorrhage. Among all writers this opinion prevails, and among all the cases of gluteal aneurism which have been collected from various sources there is only one case in which a spontaneous cure has taken place. When the great difficulties of a positive diagnosis from other diseases is taken into consideration, the one recorded case of spontaneous cure admits of doubt; but still, on the other hand, it can be said that the anatomical relations of gluteal aneurism afford certain conditions favorable to the accomplishment of this object. Whether it is admitted or not that spontaneous cure ever occurs, no surgeon can place any reliance upon this process of cure, and refuse, on this account, to take active steps to cure the disease.

The performance of laparotomy as an initiative and necessary step in the ligation of the internal iliac artery seems to meet the exigencies of the case. That laparotomy may appear to be a severe measure as a preparatory step no one can deny: but, while it may seem a desperate measure, it must be remembered that the disease is a uniformly fatal one, and, therefore, calls for heroic measures to overcome the dangers which await the patient.

After carefully reviewing the literature of spontaneous gluteal aneurism, and investigating the high rate of mortality following the operations for the cure of this variety of aneurism, and after considering thoughtfully the unsatisfactory results and the causes which brought about these results, there seemed much to be desired in reference to an operation which would effect a permanent and radical cure, and which would diminish the high rate of mortality. With these important questions in mind, a new operation was necessary to make the treatment of gluteal aneurism satisfactory.

With a view to the settlement of the first question, namely, the accomplishment of a permanent and a radical cure in gluteal aneurism, it would seem that the application of the principle of John Hunter in the treatment of aneurism in general would be especially adapted to this form of aneurism. The ligature of the main artery on the proximal side in healthy arterial tissue yields the best results. The principle of compression is not applicable here, though in the form of Esmarch's bandage in certain aneurisms this plan has met with most brilliant success. The injection of coagulating fluids into the sac, and all the other operations are obviously not suited to the gluteal aneurism. While in theory and practice the Hunterian method is the best operation in those forms of aneurism in which compression by elastic bandage is inadmissible, the same principle holds good in gluteal aneurism. If it can be shown that the ligation of the internal iliac on the proximal side of the aneurism can be performed with immunity from those accidents which have caused death, the difficult problem of a safe and permanent method of cure has been solved. It remains, therefore, to show that when the Hunterian operation has been performed the causes of death have been attributed to certain defects in the method of ligating the internal iliac artery, and that if any plan can be adopted which will not only effect a radical cure in the aneurism, but at the same time which will be free from danger to the patient, an ideal operation has been established for the treatment of this fatal disease.

An examination into the causes of death after ligation of the internal iliac artery, shows that in the majority of the cases death resulted from secondary hemorrhage, laceration of the peritoneum, wound of the contiguous vessels, tying the ureter, pelvic cellulitis, abscess, and purulent œdema. In

other words, excluding uræmia, nearly all the deaths may be attributed to some fault in the method of operation in the surgeon's attempt to secure the internal iliac artery.

If now it can be demonstrated that the internal iliac artery can be reached and ligated without incurring the risks common to the older operation of Abernethy or Cooper, the science of surgery can point to a means of saving life in these desperate cases, where heretofore human lives were sacrificed.

No argument is needed to prove that the internal iliac artery can be tied with safety and with no damage to the surrounding and adjacent structures, if the surgeon can pass the aneurism needle around the vessel with all the pelvic viscera removed. This is obvious; but the question upon which everything hinges is the safety of the opening of the peritoneal cavity and removal of its contents, in order to expose the artery. If this procedure can be proved to be free from danger, then the complete operation in each of its several stages will form a new method of cure for the relief of spontaneous gluteal aneurism, which cannot but commend itself to the sound judgment of every surgeon.

With regard to the proof of the safety of laparotomy, as a preparatory step to ligation of the internal iliac artery, for the application of the Hunterian principle in the treatment of spontaneous gluteal aneurism, it becomes necessary to study the rate of mortality attending an ordinary laparotomy. A reference to the statistics of laparotomy will not afford reliable data from which to draw conclusions; because, if the laparotomy is performed for ovariotomy, the death-rate has become so low that it need not offer any barrier to the operation. A reference to Lawson Tait's one hundred and thirty-nine consecutive ovariotomies without a death, is corroborative of this statement. On the other hand, if the laparotomy is performed for gunshot wound, or stab wound, or intestinal obstruction, or malignant disease, the death-rate is comparatively high, and thus the mortality of laparotomy would preclude the adoption of this measure as a preparatory step to tying the internal iliac artery. A laparotomy in which the contents of the abdominal cavity are removed, is an operation of greater severity than most ovariotomies and of less severity than abdominal section would be in perforating wound of the abdomen, or in intestinal obstruction. Laparotomy for removal of a portion of the intestinal canal, however, has one very favorable condition, and that is the absence from shock, as is the case where abdominal section is attended with a high rate of mortality.

Laparotomy as a preparatory step to ligation of the internal iliac artery for the cure of spontaneous gluteal aneurism thus may be said to stand midway between these two extremes with regard to its mortality. In the future, as the technique of abdominal section improves, the small fractional death-rate which now attends the operation will be reduced to that of a simple oöphorectomy, which is practically no death-rate at all. In the laparotomies which I have performed I have never had a patient die during the operation: but, invariably, I have noticed that the symptoms were improved after the operation. In the cases of perforating wound to which this statement is applicable, it must be remembered that shock existed before the laparotomy, and that in those cases where an exploratory laparotomy was performed without the presence of shock, the patients invariably reacted, and their condition was in every respect satisfactory as regards the reaction.

Laparotomy performed under suitable antiseptic precautions, and in a patient whose condition before the operation is in every way satisfactory, may be said, in the light of present statistics, to be free from any danger which would render it inexpedient to perform the abdominal section.

When the paramount advantages are considered in regard to the safe ligation of the iliac arteries, and with an immunity from all other accidents so common by the older methods, laparotomy as a preparatory step to securing safely the internal iliac artery in this special form of aneurism seems to be an ideal operation for the cure of a surgical disease which formerly was attended with a death-rate of nearly fifty per cent. The internal iliac artery has been tied four times for spontaneous gluteal aneurism: three of these aneurisms occurred in my hospital service during the past year, and one of which belonged to Dr. W. Locke Chew, of Alabama. The history of each of these operations will be given with remarks.

Case I. *Double gluteal aneurism; laparotomy, and ligation of both internal iliac arteries simultaneously; death from suppression of urine on the fourth day.*—I. McC., æt. sixty, admitted to St. Vincent Hospital February 5, 1886. Patient was sent by Dr. Carpenter, of Boonton, New Jersey. Patient has always enjoyed good health until three years previous to date, when she complained of pain along the course of the sciatic nerve upon the right side. The pain was not relieved by medication, either general or local. A year and a half later a swelling became apparent on this buttock, which was accompanied by throbbing, and the tumor steadily increased in size, with no abatement of the pain. As these symptoms increased, the patient began to lose flesh and strength. The diagnosis of gluteal aneurism was made by Dr. Carpenter.

Upon admission to St. Vincent Hospital there was found a large, tense, pulsating tumor occupying the entire gluteal region, and tapering down to the trochanter major of the right femur. The skin over it was natural in color, but very tense; a thrill was felt on palpation, and a distinct bruit heard on auscultation; pulsation very marked. Tumor measured thirteen inches from the tuberosity of the ischium to the trochanter major. On the opposite side, measurement from the same points seven inches. Right leg was somewhat swollen and œdematous. On the left buttock a slight tumor was found on palpation. It was situated along the course of the gluteal artery at about its middle. A distinct pulsation was here felt, accompanied by a bruit. Patient had pain here for a week before she was admitted to the hospital, and now feels a throbbing in the same situation. Good nourishment was

given, and stimulants were administered according to indications.

February 15th, patient has improved somewhat in general health, but pain still continues.

Operation.—February 18, 1886, the abdomen, perineum, and thighs were thoroughly scrubbed with warm water and soap. After this ablution the parts were irrigated with a solution of bichloride of mercury (1 : 1000). Especial attention was given to the purification of the umbilicus, which is most important to observe in all cases of abdominal surgery, as infection has been known to originate from a neglect of this precaution. The hair was cleanly shaven from the abdominal wall. A saturated solution of ether and iodoform was now poured over the abdomen, and the parts were thus made aseptic. Clean towels, wrung out in warm bichloride, were now placed over the abdomen, and the ether was administered.

In all capital operations requiring the patient to be kept under ether for any indefinite length of time, I have always adopted the rule of making the parts aseptic before the patient is anæsthetized. This saves the time during which it is necessary to keep the patient under ether, and in abdominal surgery especially this is important; because the surgeon can never form an idea of how long it may take to complete the operation. I have never found that the disinfection of the parts ever caused any discomfort to the patient; but, on the other hand, it often attracts the attention first before taking the ether. In this way the time during which the patient must take ether is shortened by an appreciable period of time.

The median incision was made, beginning at the umbilicus and extending downward to the symphysis pubis. Each layer was divided under continuous irrigation, and all vessels were ligatured, and the peritoneum was now exposed, which was carefully divided the length of the cutaneous incision. Everything was now in readiness for the removal of the intestine, and the hand was introduced into a warm solution of bichloride of mercury (1 : 5000). Towels and the elephant-ear flat sponges were now dipped into this mild warm antiseptic solution, and the contents of the peritoneal cavity were removed outside of the wound and wrapped at once into these towels and sponges, which were renewed from time to time to keep up equable and uniform temperature. Having removed the pelvic viscera as far as was necessary, my index finger felt the pulsation of the aorta, then the common iliac, then the external and internal iliacs. The peritoneum and the sheath were scratched and divided only sufficiently to admit the point of the aneurism needle. With scarcely any disturbance of the parts, the ligature of twisted catgut was passed around the vessel from within outward, care being taken not to include the ureter, which was double upon this side, as well as other important structures. The same procedure was immediately performed with reference to the other internal iliac artery; a little iodoform was dusted over the ligatures, and the intestine was now carefully returned into its proper cavity, and the peritoneum, deep fascia, muscles, aponeurosis, and the two layers of superficial fascia, with the skin were united by catgut and silver sutures. The entire incision was then dusted over with a thin layer of iodoform, and the superficial drainage tubes were introduced; but no tube was used to drain the cavity. The patient was under ether only about thirty minutes. I am indebted to Dr. Charles Phelps for his kind assistance and advice during the operation. The patient was removed to an adjoining room, and placed in bed.

4 P. M. Patient has not come fully out from the ether, as yet; moans continually, and is very restless. Pulse fair force, temperature normal. External heat applied to body, and morph. given hypodermatically. During the evening reacted nicely from the shock.

19th. Patient in a condition of mild delirium; temperature elevated; tongue dry; pulse rapid and feeble. Nutrient enemata given; morph. hypodermatically; water drawn by catheter.

20th. The dressings were removed and wound was perfectly aseptic. No tympanites; tongue dry and brown; temperature elevated. Peptonized milk given by enemata, also one drop tincture of digitalis every two hours.

21st. Patient sinking steadily, and vomited several times during day. The rectal temperature one degree lower than in the axilla.

22d. Patient died to-day.

Autopsy.—Rigor mortis well marked. On removing the dressing the abdominal wall had healed by primary intention. There was a little pus in the pelvis, about one of the ligatures, probably the result of her poorly nourished condition; the amount was very small, and there was lymph exudation. There was no peritonitis. The incision over the right buttock exposed the aneurismal sac extending from the origin of the gluteal from the internal iliac to a point below the trochanter major. An aneurism was found also upon the opposite hip. The aneurism upon the right side was very large, and was filled with laminæ of fibrin. The sac had, previous to operation, ruptured upon its inner surface, and had produced erosion of the ilium. The aneurism upon the left side was fusiform in shape, and was about four inches in length. The iliac vessels were both occluded by thrombi, and the ligatures included nothing but the internal iliac vessels. The kidney upon the right side had two ureters extending to the bladder. The kidneys showed a mild grade of diffuse parenchymatous nephritis. The suppression of urine was in all probability due to the acute congestion produced by ligation of the internal iliac arteries, and this condition was engrafted upon a chronic disease of these organs. The specimens are preserved in the museum of the Carnegie Laboratory.

Remarks.—There are some points of special interest connected with this case that seem to be worthy of consideration. The patient's mother, who is alive, is now considerably over one hundred years, and the patient herself was over sixty years. The aneurism was not single, as is the rule; but was double. This is the first case ever reported with both gluteal aneurisms developing simultaneously. The case is also the first one in which the internal iliac has ever been ligated with laparotomy as a preparatory step. It is also the first time in

the history of surgery that both internal iliacs have been tied at the same time. The patient reacted nicely from the operation, thus showing that even in a patient of sixty years a laparotomy can be performed without serious shock.

Another clinical fact of interest in connection with this case is the perceptible diminution of temperature in the rectum, as compared with the axilla. This is due, without doubt, to the fact that all the pelvic organs were poorly supplied with blood in comparison with the amount previous to the ligation of the internal iliac arteries.

Case II. *A case of spontaneous gluteal aneurism, diffused by manipulation; laparotomy; ligation of the internal iliac; cured.*—(By W. Locke Chew, M.D., of Birmingham, Ala.) W. T. S., a negro, aged forty-six years, a native of Georgia; residence for fourteen years in North Alabama; occupation an iron-ore workman, gives the history that seven months ago while going rapidly upstairs, felt a sudden stitch in the buttock and back part of the thigh. This pain was very intense at times, but never wholly absent. For the past seven weeks has been unable to walk, and the past four weeks has been confined to bed. About two and a half months ago noticed a marked swelling of right gluteal region, which "thumped as if my heart beat there." Dr. Cooper was called to see the case, and treated it only palliatively. Suspecting the tumor to be aneurismal, I was called to see the case in consultation with Dr. Cooper, on the morning of June 14th, at 11.43 A.M., and found the patient as follows: Right thigh flexed on abdomen and leg on thigh, adducted, and toes everted, violent spasms of the muscles of the calf and foot, considerable spastic rigidity of same parts; less violent muscular spasms in the posterior portion of the thigh; gluteal region of right hip very much distended, tense, and firm. Tumor as large as a fœtal head at sixth month. No increase in local warmth. On grasping tumor evenly with expanded hands, and making gentle pressure there was detected a very slight, indistinct, wavy expansion. Auscultation over tumor revealed an obscure bruit, but at the sacro-ischiatic notch and slightly lower a loud, grating bruit was noted. By pressure on the abdominal aorta both bruit and expansion could be readily stopped.

Dr. Cooper here gave the history that the swelling had been circumscribed, and thought it probable that it had been ruptured the day before by manipulation at the hands of a friend he had invited to see it. The diagnosis being arrived at, nothing more was done than to order the patient's bowels thoroughly opened by salts and warm enemata; the patient thoroughly washed, and clean linen placed on him and the bed; the room, a new one, was rendered as neat as possible. It had been necessary to administer twelve grains of morphia sulphate in the preceding twenty-four hours to secure the least quiet.

On the morning of June 15th, in the presence of Drs. Wheelan, Dozier, Dnncan, Wyman, Shoemaker, Drennan, Dr. Brice M. Hughes and myself assuming the case—which Dr. Cooper kindly proffered us—immediately proceeded to do a laparotomy to secure the internal iliac artery for relief and cure of the aneurism. The patient being anæsthetized, and the abdomen being shaved and thoroughly cleansed, the usual curved, lateral incision was made. The muscles and fascia having been divided carefully, at the inferior angle of the incision, the epigastric artery, displaced a very little to the right, was seen pulsating strongly, which was doubly ligated before section. The peritoneum was carefully divided on the finger as a director, and the hand was passed into the abdomen. The arteries could be felt in their usual places pulsating strongly, trunks in good condition. That of the common iliac was normal, while that of the internal iliac was about two inches long, the trunk large, and the walls in fine condition. The aneurismal tumor did not extend into the pelvis. Such being the condition, we determined to place a strong silk ligature on the internal iliac. So violent were the efforts of the patient, and such the difficulty of manipulation within the cavity that a few coils of intestines were taken out and swaddled in cloth, saturated in a warm carbolized solution. While I exposed and guarded the parts, Dr. Hughes divided the arterial sheath, which I separated from the trunk as he passed the armed needle. The ligature was then tightened, and all present satisfied themselves that all blood-flow through the tumor was checked. The artery was then firmly ligated, and the peritoneum approximated over the ligature. The cavity was next thoroughly cleansed and closed by six deep silver-wire sutures and six small superficial catgut sutures. There were a few points in the divided muscles that gave us a little trouble from oozing, but this was controlled by warm water and torsion. The incision was dusted with iodoform, while adhesive strips to support suture, antiseptic cotton, and binder applied evenly constituted the dressing.

Progress of the Case.—Morphia sulphate in quarter-grain doses were administered every four hours subcutaneously. Crushed ice with a little milk was allowed during the first week; patient kept in the dorsal-decubitus position strictly. The temperature on the evening of the operation reached 100.5°, but never again reached that point; after the evening of the fifth day it was absolutely normal; pulse ranged from 90 to 108. The incision united by adhesion throughout, and the dressing, which was removed on the sixth day, was perfectly clean, except at a single point where there was a clot of dried blood as large as a split pea. Sutures removed on the ninth day, union firm. A free, natural movement of the bowels on the tenth day. A small abscess formed on the thirteenth day, a little to the right of the incision, due to the hemorrhage from the veins above mentioned, most probably; all pain immediately stopped in the tumor, and it has gradually diminished in size and tenseness. The condition of spastic rigidity never returned after recovery from the anæsthetic, nor did the muscular spasm; leg became freely movable after the tenth day. On the twentieth day tumor about one-third of original size. Patient walking on crutches, free from pain, cured.

In reviewing the history of this interesting case as it is given, it seems that the operator did not intend, before the operation, to do a laparotomy in the sense of removing the contents of the peritoneal cavity as a preparatory step to the ligation of the internal iliac, but that this most important feature of the whole plan was an after-thought, or the result of an accident. The incision which he mentions as "the usual curved lateral incision," must be either Sir Astley Cooper's or Abernethy's, as it is not the one which would be made if it were intended first to remove the intestine before ligating the artery. Later on the operator mentions, "so violent were the efforts of the patient, and such the difficulty of manipulation within the cavity, that a few coils of intestines were taken out," thus giving his readers to suppose that it was not his intention to remove the intestine, which is the main feature and first stage of the operation of tying the internal iliac artery by the new method. It is the intentional removal of the intestine by the median incision, for

the purpose of fully exposing the pelvic vessels, that laparotomy is recommended as a preparatory step. The case, however, stands as one of the few successful, and places on record another case of cure of a spontaneous gluteal aneurism by the application of the Hunterian principle.

The friendly criticism which I have offered in no way detracts from the credit due to the operator or to the successful issue of the operation, but it has been made only to impress clearly the fact that the great object of the laparotomy is to remove the contents of the peritoneal cavity, and thus enable the surgeon to ligate the vessel without incurring any of the risks so common by the older incisions and by the older methods.

As many of the causes of death in these cases of ligation of the internal iliac artery are due to the fact that the operation cannot so safely be performed without the removal of the intestine, it therefore follows that the removal of the intestine preparatory to ligating the vessel is an essential feature in the entire plan to be carried out in the treatment of gluteal aneurism.

Case III. *Gluteal aneurism, associated with an aneurismal varix; laparotomy; ligation of left internal iliac artery; recovery.*—M. F., aet. eighteen, domestic; admitted to St. Vincent Hospital, August 26, 1886. Family history good and no evidence of specific disease. Patient has noticed for many years that her left buttock was much larger than the right, and that in this enlarged buttock she experienced a good deal of pain. Until three weeks previous to admittance to hospital, patient was able to work about; but at that time the skin became ulcerated over the left buttock. The patient now began to have great pain, and was unable to assume the sitting posture. Whenever she tried to sit down she felt a throbbing in the tumor.

On admission patient is well nourished and muscular. Complains of heat, throbbing, and pain, but more especially of the latter, which is no longer localized, but shoots down toward the knee. She states that her bowels are usually constipated, but in other respects physical condition is good. Heart and lungs normal.

On examination the left buttock is found to be considerably enlarged, the ulcer mentioned above being situated about the centre of the tumor. The veins are visibly dilated, those situated at the most dependent part of the tumor are markedly engorged, and upon gentle palpation the blood is felt surging through the vessels, which shows that a communication exists between the artery and the vein. With each systole of the heart an expansile pulsation is quite evident. Upon auscultation a very loud bruit is heard, which follows closely upon the first sound of the heart.

Examination by the abdominal wall and rectum negative.

Aug. 27. Potassæ iodidi grs. xv t. i. d.; liq. morph. n. s. ʒj, when needed.

Sept. 7. Examination of urine negative. Pil. colye. co. iij. Light breakfast.

8th. Patient etherized. Abdomen thoroughly cleansed and shaved. An incision was made in the median line, starting at the umbilicus and extending downward to within two inches of the symphysis. Having dissected down to the peritoneum, all the vessels that required attention were ligatured. The peritoneum was now lifted up and snipped, a director being introduced, the membrane was divided upon it. The incision was not at first extended beyond the umbilicus; but the abdominal walls were so very thick with adipose tissue that the original incision was extended some distance above the umbilicus. The contents of the peritoneal cavity were easily removed, and abundance of room was obtained for the subsequent steps of the operation.

In the first case of gluteal aneurism the patient was emaciated, and the walls could be drawn aside without extending the incision higher than the umbilicus. The intestine was removed outside of the abdomen sufficiently to allow the exposure of the vessel, the bowels being protected by the application of towels and flat zymoca sponges soaked in a warm, weak solution of bichloride of mercury. The index finger felt the pulsation of the common iliac, then its bifurcation, and the external and internal iliac. The ureter was drawn aside, the peritoneum and sheath opened sufficiently to admit the point of the aneurism needle, which was passed from within outward. A double twisted catgut ligature was employed, and the ends cut off, after which a thin layer of iodoform was dusted over the knot of the ligature. The intestine was carefully replaced, the peritoneum and the other structures were stitched. A small drainage tube was introduced between the lips of the wound, iodoform was sprinkled over the linear incision, and antiseptic dressings were then applied. In closing the abdominal wound deep and superficial sutures of catgut, and three interrupted sutures of silver wire were employed.

No nausea or vomiting followed the operation. At six o'clock patient had recovered from the shock and appeared to be in a most comfortable condition.

9th. Patient had a good night and slept after a hypodermatic injection of morphia was given. During the day patient complained of some pain, and there was some tympanites. The ice coil was placed over the abdomen, and her pain was diminished. The urine was passed without the use of the catheter; it contained fifteen per cent. in bulk of albumen. The tongue was dry.

10th. Patient had another good night. Tongue cleared up and moist. The amount of urine passed during the day was nearly two pints, and it contained only a trace of albumen.

11th. The pulse and temperature to-day are below one hundred. Patient has been fed on peptonized milk, which was administered in the form of an enema during the first twenty-four hours subsequent to the operation. The urine contained no albumen and the quantity was normal.

12th. Dressings removed. Wound appeared healthy, with only a slight discharge upon the deep dressings.

13th. Patient had a normal movement from the bowels.

15th. Patient's condition is in every way satisfactory. The wound healed by primary intention,

except near the centre for a little distance, where the incision healed by granulation. The bowels moved after the 13th instant at regular intervals, and with the exception of cramps occurring after the movement, there is nothing of importance to note.

Remarks.—This patient rallied quickly after the operation, and on the fifth day following the laparotomy the bowels moved, and continued after this time to assume their normal function. The albumen, which was not present in the urine previous to the operation, amounted to fifteen per cent. in bulk within twenty-four hours, but all traces of it quickly disappeared from the urine. This acute albuminuria was due to congestion of the kidney, as a result of the ligation of the main trunk of the internal iliac.

With regard to the aneurism, no pulsation ever occurred after the ligature was applied. The aneurismal varix was also completely cured. The ulcer healed, and the parts returned to nearly their normal size and shape. The patient is now discharged from the hospital cured, and expresses herself as feeling perfectly well.

After recording in detail the history of these interesting cases, a final summary seems appropriate in regard to the advantages of this method of treatment over the older methods, restricting, of course, this method of operating to the cases of spontaneous gluteal aneurism.

First. Laparotomy in no way increases the dangers of the operation of ligation of the internal iliac artery.

Second. Laparotomy prevents a series of accidents which have occurred during the performance of the operation of ligation of the artery by the older methods. Among these accidents may be mentioned the division of the circumflex and epigastric arteries, wounding the vas deferens, including the ureter in the ligature, puncture of the iliac or circumflex veins, tying the genital branch of the genito-crural nerve, stripping up and tearing the peritoneum, injury to the subperitoneal connective tissue, and other accidents of a like nature.

Third. Laparotomy enables the surgeon to apply the ligature at a point of election, and affords him an opportunity of obtaining information as to the exact extent of disease in the main arterial trunk.

Fourth. Laparotomy averts the dangers which were likely to follow ligation of the internal iliac artery by the older operations, among which may be cited peritonitis resulting from tearing up the peritoneum posteriorly, cellulitis, purulent œdema, pelvic abscess, septicæmia, and pyæmia.

Fifth. Laparotomy occupies much less time for its performance in order to expose the internal iliac artery than was occupied to reach the vessel by the incision of Abernethy or Sir Astley Cooper.

Finally, it may be said that the only real obstacle to the successful issue of the operation of ligation of the internal iliac artery for the cure of spontaneous aneurism of the gluteal artery lies in the prevention of acute albuminuria. To this point in the clinical history of the operation the attention of surgeons should be directed. The solution of the difficult problem is only to be obtained by experimental observations made upon the lower animals, and when measures are discovered that will obviate and remedy this unfavorable complication, the treatment of spontaneous gluteal aneurism by laparotomy and ligation of the internal iliac artery may be considered under the control of the surgeon.

THE RELATIVE VALUE OF CULTURES IN LIQUID AND SOLID MEDIA IN THE DIAGNOSIS OF BACTERIA.

BY THEOBALD SMITH, PH.B., M.D.,
OF THE BUREAU OF ANIMAL INDUSTRY, UNITED STATES DEPARTMENT OF AGRICULTURE.

THE marked progress recently made in the study of microörganisms as the cause of certain diseases is, without doubt, due to the more thorough application of various solid culture media by Koch and his pupils. To-day the microscope does not hold the chief place in the study of these minute organisms. It is their mode of growth upon gelatine, blood serum, agar-agar, potato, in meat infusions, milk, etc., or the absence of growth in one or more of these substances and in these fluids which aids in confirming the microscopic examination. For this frequently yields results so indefinite that, without the media mentioned, it is impossible to come to any satisfactory conclusions as to the kind of bacteria under consideration. Besides these various tests, inoculation experiments upon animals are of essential importance in the investigation of pathogenic forms.

In connection with the cultivation of bacteria for diagnostic purposes, it is again desirable to call attention to liquid media and their uses. The statements of Koch and others, several years ago, concerning the unreliability of liquids, have almost driven them from the field in Germany, and in our own country.

Pasteur, the founder of this new and brilliant branch of pathology, made cultures in meat broths or decoctions exclusively. That grave errors may arise in this way through contaminations which cannot be easily detected, is self-evident. When gelatine and other solid media were introduced by Koch, he discarded cultures in liquids, except for very special purposes. Since that time they have been looked upon with distrust, and results obtained with their aid suspected and questioned.

If there were some means of keeping liquids free from contamination, it is not unfair to say that they would be better adapted as a natural medium of bacterial life than any solid media ever suggested. This is self-evident for germs endowed with motility. One of the advantages of solid media consists in the fact that any after-contaminations are quite easily detected with the unaided eye. This is not so readily done in the case of liquids. There are two ways of overcoming this difficulty: 1. By the use of a culture-tube in which the parts are so adjusted that a momentary exposure for purposes of inoculation, etc., is practically without any danger whatever. 2. By frequently testing liquid cultures on solid media, preferably on nutrient gelatine. My experience with the culture-tube devised by Dr. D. E. Salmon has been entirely satisfactory. Its efficiency may be considered quite perfect. As it has been

fully described,[1] I need not dwell upon it here. The testing of liquid cultures is very simple, and quickly accomplished. Either a minute portion is shaken up with liquefied gelatine, and the mixture poured on glass plates, or a platinum wire, previously dipped into the culture liquid, is drawn several times across a layer of gelatine not yet congealed. In either case, the developing colonies will determine the purity or impurity of the liquid culture. I have almost invariably found the thirteenth or fourteenth generation as pure as the first, when tested in this way. I should be surprised to find one out of every hundred tubes impure.

I will grant unreservedly that test-tubes plugged with cotton-wool are not fit for liquid cultures. For gelatine in such tubes, when frequently exposed, is invariably invaded after a time by fungi or bacteria. The plug being a nidus for dust, its removal is always attended with danger. Because a culture-tube which eliminates the use of a large, removable plug is more costly, it does not follow that it is not valuable in scientific research. We know that in the departments of physics, chemistry, and physiology, the most advanced work is of necessity performed with the most complex apparatus. That there are those who do not succeed in keeping liquid cultures pure, does not concern those who do. It behooves the former, in the interest of a true scientific spirit, to improve their apparatus and technique, instead of condemning the method.

Conceding then, for the present, that cultivations in liquids can be kept free from contamination, the point at issue is the employment of liquids for diagnostic purposes. Whoever has paid any attention to the multiplication of bacteria in nutritive fluids has, no doubt, been surprised at the variety of features which present themselves, and at the regularity with which the same ones appear in cultures of the same microbe. To illustrate how many different characters may be used in determining the kind of bacteria, and the purity of the cultivation, I will briefly outline a few of the most important ones, as they have come under my own observation, referring the reader to Miquel[2] for the characters of bacteria obtained from the air, soil, and water.

Every cultivation made in a tube shaped like a test-tube presents three regions for observation—the liquid itself, its surface, and the bottom of the tube. In other words, there may be a membrane covering the liquid, and a deposit in the bottom. With reference to the liquid itself, it may remain clear or become clouded. In the former case, the growth may appear as a membrane, or a deposit, or it may be disseminated through the fluid in minute granules, flakes, or cloud-like masses. The cloudiness may be very faint—a mere opalescence—or it may be very dense, approaching a turbidity. When shaken the cloudiness may be, as it were, set in motion, and thus show itself composed of elements indistinguishably minute, or as granular and flocculent masses: or it may be impossible, by shaking, to disturb the uniform opalescence. The liquid may become colored. There may, or may not, be a membrane on the surface of the liquid. When present, it may vary from a mere iridescent pellicle to a thick, creamy layer. Its formation and growth should be carefully noted, together with its color, consistency, and structure, when fully formed. The deposit may be absent, very scanty, or quite abundant and colored. When agitated, it will rise from the bottom in coarse or fine flakes, as a viscid, ropy mass, or as a fine powder. In connection with these characters, it is necessary to take into consideration the composition of the culture liquid, and its reaction. The temperature to which the culture is exposed has a marked effect on the rapidity with which these characters appear. The odor and reaction of the culture of a certain age are also instructive in many cases.

When these various features, and many others not given above, are taken alone and in combination, we have, for most cultures, an almost positive means of diagnosis, as well as a ready method of detecting contaminations, for these features are, as a rule, constant. In order to illustrate this statement, I will write down a few features of the growth of *bacillus subtilis*[1] in a neutralized infusion of beef, to which one per cent. of peptone has been added.

In a temperature of about 35° C., the liquid becomes opalescent in from six to eight hours. When agitated, rolling, cloud-like masses are outlined by a condensation of the suspended bacteria. Within twenty-four hours an interlacing network, or islands of a whitish, gelatinous deposit, appear on the surface, which, within another day, are fused into a white, papery membrane, covering the entire surface. This membrane, which is not smooth, but puckered and pouched in a peculiar way, soon pushes its border up the sides of the tube, resembling, at this stage, the cup of an acorn. The liquid itself gradually clears up in the meantime, until it is quite as limpid as before inoculation. This clearing up of the liquid, together with the puckered, cup-shaped, papery membrane, is very characteristic of this bacillus, certainly as reassuring to the observer as the stellate growth of its colonies on gelatine. For, if another microbe be present, the liquid remains clouded, and the membrane is modified. There are many other points of interest in connection with the membrane, and the deposit forming later, which I forbear to mention here, as their value for diagnostic purposes is limited by their tardy appearance.

If we now turn our attention to solid media, we shall find that diagnosis often fails when the bacteria do not liquefy the substratum. The colonies then are apt to develop very much alike, and any modifications may as well be credited to change in the consistency of the gelatine, due to variations in temperature, to drying, etc. These same changes will modify the appearances of colonies of the same microbe. Tube cultures in gelatine of radically

[1] First Annual Report of the Bureau of Animal Industry, Department of Agriculture, 1884, p. 229. American Monthly Microscopic Journal, 1884, p. 185.

[2] Annuaire de l'Observatoire de Montsouris pour l'an 1885, pp. 577 et seq.

[1] This bacillus can be obtained pure at any time, by boiling in a water-bath, for from one-half to three-quarters of an hour, a filtered infusion of hay, contained in a flask plugged with cotton-wool.

different bacteria are frequently almost identical in appearance, or the slight differences are found not constant. In such cases, cultures in fluids are frequently of great service. In a paper[1] recently read before the American Association for the Advancement of Science, I called attention to two pathogenic forms, identical microscopically, and in their effect upon animals, though found in widely separated sections of our country. One of the few differential characters was the presence of a membrane in the liquid culture of one germ, its absence in the other.

The great importance of solid media in isolating bacteria, and testing the purity of cultivations, is conceded by all engaged in this field of research. The advantage of starting cultures from a single germ, by inoculating them from the colony, its progeny, is inestimable in obtaining accurate and reliable results. But that liquids have also a place, and a very important one, the facts above stated will, I hope, demonstrate beyond a doubt. It seems a pity, therefore, that we should be blindly following in the wake of some general statements which tend to deprive the study of microörganisms of an exceedingly valuable accessory.

That they have as yet but little recognition in the country where microörganisms are receiving most attention to-day, is illustrated by the recent issue of a book,[2] in which are given all the well-known culture reactions, excepting those in liquids, of the best known bacteria. I venture to maintain that the characters of the liquid cultures of some of the bacteria there tabulated are worth as much from a diagnostic standpoint as all the rest combined. It is, in fact, a matter of common observation, that, for many bacteria, cultures on agar-agar and blood serum offer scarcely anything different from what is observed on gelatine. In the first two editions of Hüppe's *Bakterienforschung*, very little is said of liquid media. In the third edition there is a decided improvement. Several pages are added, giving recipes for the preparation of nutritive meat infusions. The author also quotes from Miquel a number of characters which liquid cultures may present, and which may serve as a means of differential diagnosis. It is to be hoped that a fourth edition of this very excellent and impartial handbook will give a still ampler space to this subject.

I am happy to quote from an author so well versed in bacteriological technique as Miquel,[3] in support of the statements made in these pages. In fact, they would appear as a mere echoing of his own, if the conclusions there recorded had not been reached before the publication of his remarks, and in part written before my attention was called to them. He says: "I have been one of the first to recognize that solid substrata offer a ready means for the separation of species. But I consider it puerile to apply a particular method to all kinds of experimentation." After giving some of the diagnostic characters of liquid cultures referred to above, he concludes by saying: "I fear that I shall abuse the patience of the reader in continuing still farther the enumeration of the advantages which it (bouillon) offers over gelatine for the microscopic diagnosis of species. . . . . It is said that species are easily recognized in cultures on gelatine with the unaided eye, and that cultures in liquids do not possess this advantage. Such a statement denotes profound ignorance. To my knowledge there are not two bacteria that develop alike in beef broth, for example."

That every one studying microörganisms should familiarize himself thoroughly with the manipulation of cultivations in liquids, and the characters which they present, so that impurities may be detected, becomes self-evident when we reflect that most of the biological properties of bacteria can be observed only in liquids. "With cultures in liquids it is possible to study the biological phenomena of fermentation, to analyze gases set free, to collect the soluble ferments diffused through the fluid, to determine the formation or disappearance of certain substances. I doubt very strongly whether such things could ever be done with liquid cultures.[1]" To these may be added the study of ptomaines, of such great interest to the pathologist. Inoculation experiments are also much simplified, and the dose is very easily regulated.

Considering these important facts, the views of the unbiassed investigator should be directed to the employment of whatever is truly serviceable, whether it be of French, German, or American origin. The future will decide still more clearly the relative merits of solid and liquid culture media, and range them side by side, for both have become indispensable.

THE NASAL REFLEX.
A NEW METHOD FOR DETERMINING THE LOCAL SENSORY ACTION OF DRUGS.
A PRELIMINARY NOTE.

By THOS. J. MAYS, M.D.,
of Philadelphia.

It is not, as it is generally believed to be, comparatively easy to distinguish between the local sensory and motor action of drugs; and it becomes especially difficult when, in other respects, the action of two drugs is quite analogous. The methods hitherto in use of applying a solution of the drug to the skin of a frog, and then testing the reflex irritability of the same; or of immersing one leg in the solution and then comparing its reflex sensibility with the other by means of mechanical, thermal, or electric stimulation, do not always yield satisfactory results. Hence, in the hope of adding something that may facilitate research in this new field of medicine, I submit the description of a method which is both simple and reliable.

Five or six drops of a one or two per cent. solution of the drug to be tested are slowly dropped, either from a dropper, or from a hypodermatic syringe into one nostril of a good-sized frog at intervals of from three to five minutes, and the nasal reflex

[1] Loc. cit.

is tested by introducing the end of a very light wire (such as is used to keep a hypodermatic needle pervious) into the nostril under the influence of the drug, as well as into its fellow on the opposite side and the effects compared. The nasal reflex is extremely sensitive, and shows the slightest interference with its integrity. As soon as the wire comes in contact with the inner surface of the nostril in its normal state the frog will wink and wince, and make efforts to brush the offending body away with the front foot; while after the instillation of ten or fifteen drops of a drug solution which has the power of obtunding sensibility, the frog will not only allow the wire to remain in the nostril, but will endure considerable boring with it before he evinces the slightest pain. After the nostril is fully under the influence of the drug, reflex sensibility is annihilated on that side, while the sensation of the opposite nostril remains intact.

This method, which I have called the nasal reflex method, has been used by me in determining the difference between the local action of theine and of caffeine, and this, I think, is a sufficient guarantee of its delicacy and accuracy.

MEDICAL PROGRESS.

SHOEMAKER'S ULCER.—DR. DANFORD THOMAS has called attention to this peculiar form of industrial disease. While holding an inquest recently on the body of a shoemaker who had died suddenly at Queen's Road Station, Bayswater, from the bursting of an ulcer in the stomach, Dr. Thomas said it was a pity that shoemakers persisted in pressing the boot to the stomach when engaged on their work, for the pressure was apt to produce an ulcer. We are informed by Dr. Lomas, an excellent authority on the subject, that a very large number of shoemakers suffer from stomach diseases. Some years ago an upright bench for shoemakers was exhibited by the Society of Arts, which, it is believed, is now used in many boot factories. The repairers of boots and shoes are the people who still carry on their work in the old way. In hospitals and dispensaries, he has met with some cases of hæmatemesis from pressure over the stomach. As a class, shoemakers are not healthy; many of them become very feeble at the age of forty or fifty.—*British Medical Journal*, October 30, 1886.

ON URÆMIC HEMIPLEGIA AND HEMORRHAGIC OTITIS IN THE COURSE OF BRIGHT'S DISEASE.—DEWÈVRE, in the *Lyon Médical*, No. 40, Oct. 3, 1886, records the following case: A tall muscular soldier, aged twenty-one years, was struck with complete left hemiplegia and aphasia. There was no history of any hereditary taint or excesses. Two years previously he had suffered from scarlatina, with nephritis and anasarca. At the end of fifteen days the urine was normal, but he felt constant dyspeptic troubles, cramp of the limbs and back of the neck, and palpitation on exertion. The left arm was less affected than the leg, and the face only slightly paralyzed. Taste and sight were not affected, but the pupils were greatly dilated. There was intense frontal headache, nausea and dryness of the tongue, with constipation and suppression of urine. The heart and circulation were normal, but the respiration was anxious and of Cheyne-Stokes character, and crepitant râles accompanied a difficult expectoration streaked with blood. Frequent epistaxis took place, and a week after the attack there was some bleeding from the left ear, and the patient complained of tinnitus and of distressing pulsation on the left side of the head. There was complete deafness of the left ear, and the membrana tympani very red. The mastoid was red and œdematous, but not painful to the touch. The sero-sanguineous discharge from the ear became purulent. Two months later a perforation was observed, but the hearing returned and all pain ceased. The urine contained a little albumen.

Various authors have called attention to the occurrence of hemorrhage in the middle ear during Bright's disease and diabetes, and Dr. Dewèvre points out that the symptoms are in exactly the reverse order to purulent affections producing secondary cerebral complications.

CONTRACTURE DIATHESIS, PARTICULARLY THE CONTRACTURE PRODUCED IN HYSTERICS BY THE APPLICATION OF A LIGATURE.—Charcot has given the name of *Diathèse de contracture* to a special nervous state which is neither contracture nor paralysis, but which at the same time contains a little of both. The author of this paper, M. Berbez, says they were led in the following manner to note the frequency of the contracture diathesis in hysterics at least. M. Charcot gave a lecture on intermittent limpness (*claudication*), caused by obstruction, more or less complete, of the arteries of a limb, and ascribed to local ischæmia, the rigidities, the contractures more or less prolonged, which supervened in the ischæmic muscles. Wishing to verify this hypothesis, M. Charcot applied on many of the *externes* Esmarch's band without obtaining contractures. In this state of ischæmia the muscles were exhausted by the patient being made to squeeze the dynamometer, but even then contracture did not supervene. Very different, however, were the results obtained by experimenting on hysterics. All, or nearly all, of them developed contracture with the first turn of the band. This led Charcot to think that ischæmia was not the cause of the contracture. They applied the band from the tip of the fingers to the wrist, then at the elbow, then the band was carried as high as the insertion of the deltoid. In all these cases the contracture was produced, and rose with the height to which the band was carried. Then the band was applied to the middle part of the forearm or limb, and contracture followed in the same way. The contracture which the circular band produced disappeared nearly always after its removal. In two cases it became more generalized—once over the whole body, in another to the right side. In some minutes the contracture invaded the four limbs in a young woman, who came as an out-patient, and to whom the band of contracture was applied in the middle part of the right forearm. General massage used at once made the rigidities disappear completely. This forms an easy and prompt method of discovering the contracture diathesis and hysteria in cases of difficult diagnosis.—*Edinburgh Medical Journal*, November, 1886.

ANTISEPTIC OBSTETRICS IN VIENNA.—From an elaborate paper by EHRENDORFER (*Archiv f. Gyn.*, XXVII.

2), we reproduce here simply the results from Spaeth's Clinic, where the antiseptic means depended on are carbolic acid and iodoform. The figures from this clinic are analyzed with great care, the history of each septic or otherwise fatal case being given in abstract. We reproduce the figures for each year separately:

In 1882 there were 2898 confinements. Total corrected mortality for clinic, 0.51 per cent.

Since the puerperal mortality in any clinic will, in a measure, go hand in hand with the abnormalities and complications occurring, we note a few of these:

116 miscarriages; 35 twin labors; 16 face presentations; 59 forceps operations; 23 versions; 3 embryotomies; 2 decapitations; 1 Cæsarean section; 12 craniotomies; 7 placentæ prævíæ.

And further we note that, during this year, 211 students had the privileges of the wards, and were instructed in the touch and in delivery.

In 1883, there were 2669 confinements. Mortality, 0.33 per cent. Of complications and interference we note: 54 forceps; 90 extractions pelvic extremity; 24 versions; 21 manual removal of placenta or secundines; 8 craniotomies; 90 miscarriages.

During this year there were 381 students in attendance.

In 1884, there were 2788 confinements. Mortality (corrected), 0.32 per cent. (including two Porro cases and one Cæsarean section—uterine suture).

The complications, etc., were similarly large, and the students in attendance numbered 324.

The figures for puerperal morbidity during these three years were: 1882, 4.31 per cent.; 1883, 3.59 per cent.; 1884, 3.08 per cent. In particular, were the results for 1883 better than those for 1882, seeing that in the former year there were 390 operations against 340 in the latter, and the number of students in attendance was also greater.

(The above results, be it remembered, were obtained in a clinic in an old hospital, and where the material was largely used for purposes of instruction.)

Ehrendorfer then describes Spaeth's clinic, and formulates the antiseptic rules which are rigidly adhered to. (It seems profitable to reproduce briefly these rules here, since, in all probability, the good results obtained may fairly be said to depend on the antisepsis resorted to. And whilst we do so, we do not mean to imply that just as good results may not be obtained in private practice without such rules. Indeed, we believe them unnecessary in private practice, where all that is requisite is through cleanliness, which may be obtained without antiseptics. There is a vast difference, however, between private and hospital practice.)

The rules in brief are: Before any vaginal examination, hands must be cleansed with soap and brush, and then dipped in from one to five per cent. carbolic. Examining finger smeared with three per cent. carbolized vaseline. Neither before nor after an examination is vaginal douche given, unless there be special ground therefor, fever and bad discharge, etc. After a normal, spontaneous labor, the external genitals are washed with one to two per cent. carbolic. After intrauterine manipulation, the uterus is washed out with one or two litres warm, one to two per cent. carbolic. After dead-born fœtus (decomposed), or difficult instrumentation, an iodoform pencil is, in addition, used. Episiotomy wounds, if not deep enough for suture, are simply dusted with iodoform, and similarly slight perineal ruptures. During the puerperium, unless especially ordered, neither vaginal injections nor antiseptic compresses. As soon as the lying-in woman has elevation of temperature, she is isolated. Each ward is carefully disinfected when empty. In case of rise of temperature, if there are wounds of the outer genitals, vaginal injections, one to two per cent. carbolic; if the lochia are bad-smelling, intrauterine douche twice daily, or else iodoform pencils. The douche is stopped as soon as the lochia become normal. Continuous irrigation never used. Iodoform freely on all wounded surfaces.

At Spaeth's clinic, in brief, the puerperal uterus is not considered in similar condition to an amputation wound. The aim is to prevent infection from without, and this is attained by cleanliness, weak carbolic solutions, iodoform, and *leaving the patient alone* unless operative measures have been resorted to, or symptoms arise calling for the vaginal or intrauterine douche.

A valuable summary of the literature of puerperal fever, and clinical reports bearing on this disease, are appended.—*American Journal of Obstetrics*, Nov. 1886.

A Case of Tubercular Inoculation in an Infant.—Syphilis has frequently been conveyed by the process of sucking the wound in ritual circumcision, but the communication of tuberculosis in the same manner has been met with more rarely, and is less known. There are on record two cases observed by Lindmann and twelve by Lehrmann, but without examination for bacilli. Elsenberg, a Polish doctor, relates the following: A priest suffering from tubercle of the lungs and of the larynx, with bacilli in his sputum, had circumcised an infant. When seen, at the age of five months, the wound in the penis had become transformed into an ulcer, covered with a yellow and adherent deposit. There was a hard nodule in the prepuce near the foreskin. On both sides the inguinal glands were much swollen, and from an opening in the left side there escaped an opaque serous fluid, containing caseous particles. In the mastoid region in the right side was a large fluctuating abscess. The other lymphatic glands were unaltered. The child died of erysipelas and tetanus, after the removal of the caseating glands and the opening of the mastoid abscess. Numerous tubercle bacilli were found in the ulcerated prepuce and caseous lymphatic glands.—*Edinburgh Medical Journal*, November, 1886.

The Duration of Infectiveness in Scarlet Fever.—In the Section of Public Medicine at the annual meeting of the British Medical Association in Brighton, Dr. H. Ashby spoke as follows:

In reviewing the character of the cases discharged which have apparently infected others, one finds a certain number in which it is very difficult to explain the cause of their retaining their infectiveness beyond the usual time. Some cases have occurred in which especial pains have been taken to free them from infection, and who have been retained till the end of the seventh week, and in one or two cases beyond this period, on account of their belonging to a family in which there were many children, and yet a reinfection of the household followed in a few days after their return home. These exceptional cases it is difficult to explain, unless one takes refuge in the belief that the infection must, in some way or other, have been conveyed from the fever

ward to the household by means of the person or clothes, rather than by any infection given out by the patient himself. Our experience plainly shows that cases of fever attended by such complications as nephritis, empyema, otitis with discharge of pus from the ears, and suppurating glands, retain their infectiveness for a longer period than do uncomplicated cases of slight or medium severity. On one occasion, a case of empyema following scarlet fever was transferred from the fever to the general wards on the forty-ninth day; and on opening the chest antiseptically, and evacuating the pus, was followed, within forty-eight hours, by the nurse who attended it having an attack of scarlet fever, and two other cases in the ward. As an interval of several days elapsed after removal and before operating, it seemed most probable that the pus contained infecting materials. In some of our cases which have inadvertently been sent out with discharges from the ears or glands, it has appeared to me to have been the means of infecting others. I believe, also, that cases of scarlatinal nephritis retain their infectiveness for a lengthened period, the infection being, doubtless, given out in the urine. I have seen such cases which were quite free from desquamation, and having suffered from a mild attack of scarlet fever many weeks before admitted to a general ward, their admission being followed by an outbreak of scarlet fever. In such cases, however, it must be remembered that their urine is carefully saved, standing about in the ward for many hours, and is, consequently, more likely to infect than if thrown away at once, as urine would be in cases where no albuminuria exists. Concerning the desquamation, I may add that, while I believe in the importance of baths and ointments in order to remove the epidermis which has detached, yet I believe in the importance of removing every little tag of skin, or of rendering smooth a more or less roughened skin as having been much exaggerated. Probably the poison is stored up in the epidermis, and the exfoliating skin is capable of communicating the poison to others, but it can hardly be held that the skin monopolizes the whole of the poison to the exclusion of the internal organs, and, moreover, baths and external applications must assist in rendering the epidermis innocuous, while the internal organs more slowly give out the poison by means of the secretions and breath.

In conclusion, I venture to summarize my paper as follows: 1. If desquamation is complete, convalescent scarlet fever patients may be discharged at the end of the sixth week, though, in order to secure absolute immunity from infection, it is wiser to delay till the end of the eighth. 2. Cases complicated with nephritis, empyema, otitis, or glandular abscesses should be detained until the cure is complete. 3. That while it is important that desquamation should be as complete as possible, the detention of patients beyond the eighth week, in order that the epidermis should be removed upon the soles of the feet, etc., is unnecessary.—*Brit. Med. Journal*, Oct. 30, 1886.

Fatal Result of Peroxide of Hydrogen Injections.—A Norwegian surgeon, Dr. Laache, has reported a case in which a fatal result followed an injection of peroxide of hydrogen into the pleural cavity. The patient was a man twenty-eight years of age, who had had a portion of the ninth and tenth ribs resected for empyema. The operation had been successful and the wound progressed favorably, and two months after the operation there remained only a fistula about an inch and a half long. In order to hasten the healing of this, hypodermatic injections of a three per cent. solution of peroxide of hydrogen were resorted to, as this method of treatment had given very satisfactory results in two somewhat similar cases in which it had been tried. Six injections, each containing 0.8 cubic centimetre of the solution, were administered without any particular effect. At the seventh, however, the patient complained of pain and faintness, the pulse failed, the respiration became oppressed, clonic contractions occurred in the right arm, the head turned to the left, the jaws became tightly set, the face became cyanotic, and the patient died in ten minutes. The necropsy, which was not made till forty-eight hours after death, revealed nothing very striking. The heart was dilated, and contained liquid blood without air bubbles; some ecchymoses were found in the parts of the left lung which were adherent to the chest walls. In the fourth ventricle of the brain an ecchymosis the size of a pin's-head was seen. A number of air-bubbles were present in the blood of the hepatic veins, and some were seen on cutting into the spleen and kidneys. The cause of death was, therefore, by no means clear. Dr. Laache suggests that it may have been the small extravasation in the fourth ventricle or shock. Dr. Wulfsberg, who took part in the discussion on the case at the Christiania Medical Society, thought it was probably due to the introduction of the drug into the circulation. He stated that the strength of the blood-current might have carried the peroxide, if introduced into a vein, through the right heart and lungs almost unchanged, but that afterward more oxygen might have been disengaged than the blood could absorb, and bubbles were thus produced, which may have been the immediate cause of death. Where animals have been subjected to injections of air into the veins bubbles are not always found in the blood. In these cases Dr. Wulfsberg thinks that death has been due to paralysis of the heart, for when examinations have been made immediately after death bubbles have been found in the coronary arteries. As so long a time had elapsed before the necropsy in Dr. Laache's case, these might have been absorbed.—*Lancet*, October 9, 1886.

Measurements of Body Surfaces.—According to some measurements made by P. Putilov, of Omsk, the surface of a man's head is 27 times as large as that of an average child at birth, while the trunk and the upper and lower limbs have respectively 7.5, 7, and 10.8 times the superficial area in the adult that they have in the infant. The mucous membrane of the respiratory apparatus appears to increase much more than that of the œsophagus, the former measuring 13.5 times as much in the adult as in the infant, while the latter only measures 4.7 times as much. The stomach is 50 times, and the small and large intestine 18 and 22 times, as large. The internal surface of the digestive canal is given as 1200 sq. cm. in the baby, and 18.300 sq. cm. in the adult, and the surface of the liver is 199 and 774.5 sq. cm. in the two bodies respectively, that of the adult being 3.9 times that of the baby.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 20, 1886.

CASTRATION OF WOMEN IN NERVOUS AND MENTAL DISEASES.

A LITTLE more than ten years ago, Battey in the United States and Hegar in Germany almost simultaneously removed the ovaries in order to determine the menopause, with the hope of curing serious disease that had baffled other treatment. Although this operation is so recent, it has been performed hundreds of times, and its literature has become vast. Removal of the ovaries, or of the tubes, is a frequent subject of discussion in medical societies and journals, both at home and abroad, and indeed, some of the obstetrical societies are becoming chiefly remarkable for the comparative absence of consideration of obstetric subjects, while the monthly *ménu* is almost sure to include ovaries or tubes, or both, until one becomes somewhat weary of these articles, or is ready to suggest that there might be tubo-ovarian societies organized.

In the midst of many experiences and differences of opinion as to the castration of women, it was a wise and happy thought to combine, as has been recently done in the *American Journal of the Medical Sciences*, the views of three great masters in regard to the suitableness of the operation in mental and nervous disorders. In this symposium SIR SPENCER WELLS speaks first, then HEGAR, and, finally, BATTEY. For obvious reasons, we will in this brief notice begin with the statements of the last. We might truthfully add that he alone of the three "sticks to the text," Sir Spencer Wells's observations being, especially in some parts, quite discursive. Further, Battey alone presents facts, while the others deal in arguments and opinions. Yet, notwithstanding these undoubted merits of his contribution, it is somewhat disappointing. He has forsaken the position taken in his first communications upon the subject; he no longer holds to "normal ovariotomy," but claims that the ovaries which he removes are diseased, though, on the other hand, both Wells and Hegar regard castration as including removal of the normal ovaries.

Battey mentions the evidences of disease found in the ovaries which he had removed, but he gives only the gross appearances, and there is presented no study of the more minute pathological changes which establish the nature of the affection. Indeed, when we read in connection with his statement that of Emmet which is included in his paper, there is obviously needed a more complete demonstration of the alleged fact. Emmet's statement, referring to hundreds of post-mortem examinations which he had made, is that "Cystic degeneration was very common, and often the ovaries were found bound down by old pelvic adhesions, when, during life, not the slightest symptom had been given of any unusual local disease."

Battey gives the results in 36 cases upon which he has operated for epilepsy, mania, and ovaralgia: of which 23 were cured, 7 improved, and 6 not improved. He claims that patients who are not benefited the first year after the operation may, at the expiration of two or three years, prove soundly cured. This, we think, a very weak point, especially when such a claim is made in behalf of cases of ovaralgia. If one suffers from toothache, and the pain is not removed, but continues unabated after the dentist extracts a tooth, our conclusion is that he pulled the wrong tooth; and if we must wait two years for the pain to cease, we must naturally conclude that the cessation was spontaneous. Again, unless ovaralgia be different from neuralgic affections of other organs, it has no pathological anatomy yet demonstrated, and, therefore, if the ovaries removed in these cases presented obvious evidence of disease, may there not be some doubt as to the diagnosis of ovaralgia? Then, too, after the removal of the aching organ, is it right to call the pain still felt ovaralgia?

When we read the statistics given by the ardent friends of removal of the ovaries for mental or nervous diseases, the testimony being so generally favorable, we feel somewhat like the man who, after seeing virtues universally recorded upon tombstones, wondered where the bad men and women were buried; so we wonder who does the unsuccessful operations. Certainly there are very many of them; more, probably, than Dr. Battey is aware of: these unhappy women, in their disappointment and despair, do not return when they find their ovaries have been removed without the slightest benefit, to those who have removed them, but seek other counsellors, while the operators may honestly believe, because the

patients do not again consult them, a year or two afterward, that the cures have been complete. The danger of error from this source is real and great.

Battey gives as one of the forms of disease presented by the ovaries "a sort of sclerosis of the investing tunic," and "the stroma also presents a sort of fibrous degeneration." If we compare these statements of the gross appearances of the diseased ovaries with those given by Sappey of their normal structure, the necessity for microscopic study of the former is evident.

Hegar holds that "castration is indicated in a psychosis evoked or maintained by pathological alteration of the sexual organs, and in a neurosis originating from the same source, as soon as this imperils life or hinders all occupation and all enjoyment of life." He regards castration, too, as indicated when a psychosis is maintained by the anæmia resulting from hemorrhage in consequence of a uterine myoma. Now in regard to the results arising from the operation in cases of bleeding myomata, unfortunately he gives no statistics, and we may supplement the deficiency by those of Winckel in his recent admirable work upon diseases of women. Fifteen per cent. of women who have had their ovaries extirpated for bleeding myomata died; twenty per cent. of those who survived were not benefited; and, hence, the operation cured sixty-five per cent. This is by no means a favorable showing, even including those cases in which mental disorders resulting from the anæmia were cured.

In reading Hegar's article one is struck with the admitted difficulties in determining the cases in which castration is indicated; a most commendable frankness characterizes the author's utterances, and while he regards the operation with great favor, having had from it, in suitable cases, most brilliant results, he cautions against resort to it without clear indications. He concludes his able contribution by a consideration of "the causes of the mishaps which unfortunately are not rare, and which have brought the operation, otherwise so beneficial, into discredit."

The most brilliant of the series is Sir Spencer Wells's contribution, but we have only space to refer to his conclusions. The first is that the "removal of normal ovaries may be advised in some cases of uterine fibroids, and in uncontrollable uterine hemorrhage." But is this operation a remedy for other hemorrhages than those caused by fibroids? The cases must be very rare that justify it.

Another indication is "certain malformations of the genital organs, deformities of the pelvis, and accidental obstructions of the vagina." The right to use the operation "is very limited in cases of ovarian dysmenorrhœa or neuralgia, and only when they have resisted all treatment, and life or reason is endangered."

He regards it as "inadmissible in nearly all cases of nervous excitement and madness;" he states that "it should never be done without the consent of a sane patient, to whom its consequences have been explained." He also says that "the excision of the morbid ovaries and appendages should be distinguished from oöphorectomy, and ought not to be done without the authority of consultation, as in most other cases of abdominal section," and that "in nymphomania and mental diseases it is, to say the least, unjustifiable."

It is probable that these conclusions, so conservative in character, will meet with the approval of the majority of gynecologists. There is a growing conviction in the professional mind that removal of the uterine appendages has been resorted to in many cases unnecessarily, and that some of the friends of these operations have been erecting too large a superstructure upon a limited foundation. These articles will help to a larger knowledge and a wiser practice.

HOSPITALS FOR THE INFECTED SICK.

A HOSPITAL for the infected sick is never looked upon with favor by the neighborhood, partly on account of the fear of the spread of the diseases treated in it to the inhabitants living in the vicinity, and partly on account of its depreciating effect upon the value of real estate and the impediment which it certainly offers to local improvements.

A proposition has been started in Philadelphia for the removal of its municipal hospital for contagious diseases, but no new location has been suggested, and it is not an easy matter to select a site against which some objection may not be raised. The site of the present hospital could not have been better selected, but the city is rapidly extending toward it with improvements of the best character, and, unless the hospital is removed, the growth of the district will be checked, or the improvements will be of an inferior character.

There is, however, another side to the question, which bears directly upon the purposes and uses of such an institution. A hospital of this character is an important and indispensable means of protecting the public health by the facilities it offers for isolating cases of infectious diseases which are liable to spread in the community with disastrous consequences. Such an institution is for the benefit of the entire community, and should not be distantly located from any part of it, otherwise the lives of the sufferers would be imperilled by the dangers incident to distant transportation. Under the circumstances great difficulty would be experienced in persuading the sick to submit to the increased discomfort and danger, even if it were justifiable, and fear would lead to the concealment of dangerous diseases.

In order to overcome these objections, the most

judicious course to be pursued by a city like Philadelphia, covering an immense area, would be to have a series of small hospitals of limited capacity, so that the spread of infection by the concentration of the sick may not occur, and have them distributed throughout the city so as to make access convenient.

Hospitals might be located in the midst of the community, so constructed and managed as to be perfectly safe from becoming sources of danger; and, moreover, as a means of securing personal coöperation, so necessary to success in restricting or preventing the spread of infectious diseases, the people, rich and poor, ought to be induced to take advantage of the superior facilities for treating the sick, near at hand, which such hospitals would afford, and thus protect their families and the community from unnecessary exposure.

This plan, if judiciously carried out, would tend to remove the motive for concealment, lead to early and efficient treatment, from the want of which the poor frequently suffer, secure better management of cases of infectious disease, check the spread of contagion, lessen the number of cases, and save life.

A VERY curious and interesting modification of the ordinary reaction of the pupil to normal retinal stimulation, and one in which the variations in response are conditioned by voluntarily induced changes in the subjective state of the person under observation, is thus described by HAAB in the *Correspondenzblatt für schweizer Aerzte*, 1886, No. 6.

The observer sits in a darkened room in which there is but one light, derived from a lamp or candle, before which he so places himself as to gaze steadily at a dark part of the room and a little to one side of the flame. If now, *without in anywise changing the direction of his gaze*, the experimenter directs his *mental* attention to the point of light, there is an immediate and vigorous contraction of both pupils, a condition which remains as long as the attention is continuously applied to the indirect vision. On the return of the attention to the point toward which the eyes have been constantly directed there is again dilatation of the pupils. This reaction is evidently conditioned by varying states of the cerebral cortex, and by it Haab seeks to explain some of the anomalies of pupillary action noted in dementia paralytica. His observation also shows that the pupillary reflex may be evoked not merely by stimulation of the macula lutea, but, under appropriate subjective conditions, by the action of light upon any portion of the retinal surface.

BY the death of M. PAUL BERT the profession in Europe loses a brilliant representative, and France mourns a devoted son. His was a restless genius which could not be confined within the narrow lines of one profession, but sought in science, in literature, and in political life, avenues for its exercise. He was essentially a physiologist, devoted to experimental work, and his researches upon the action of gases, and the effects of barometric pressure have a permanent value. Many of his earlier researches in comparative anatomy and physiology are characterized by great ingenuity, as in the experiments on animal grafting which first brought him into notice. As a politician, he achieved remarkable success, and, when Minister of Public Instruction, was instrumental in effecting many important changes in the educational system of France. He was an aggressive and uncompromising reformer, and possessed a boldness and skill which enabled him to carry out successfully measures of the most radical nature.

It is interesting to note that while in this country and in England the profession has not yet produced a politician of the first rank, there have been several on the continent of Europe. Of these Virchow is the veteran, though the conditions of life in imperial Germany have never enabled him to achieve the success which Paul Bert had in republican France. In Italy, Professor Bacelli has been a minister of the crown, and in France Dr. Clemenceau remains as one of the most trusted leaders of the people.

THE Michigan State Board of Health has requested the Regents of the University of Michigan to consider the advisability of establishing a laboratory of hygiene, in which original investigations—chemical, microscopical, and biological—shall be carried on, and attention shall be given to the subjects of the analysis of water, the adulteration of food, and the practical investigation of other questions in sanitary science. The importance to the public of the establishment of such a laboratory cannot be overestimated, and it is to be hoped that the request of the Board will be promptly acted upon by the Regents.

REYHER records, in the *Deutsches Archiv für klinische Med.*, Bd. 39, Hefte 1 und 2, thirteen cases in which pernicious anæmia was coincident with the presence of a bothriocephalus latus in the intestinal tract, and in which the expulsion of the parasite resulted in the cure of the disease. One of these patients manifested the symptoms of the disease three times within the space of five years, which symptoms were, in each instance, at once relieved upon the removal of the tapeworm. In several of the cases the host entertained at one time several of these parasites. The examination of the blood showed the presence of distorted "rouleaux," together with numerical diminution and alteration of form in the red corpuscles.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, October 25, 1886.

Dr. Lange presented a case of

ANEURISM OF THE OBTURATOR ARTERY,

giving the following history:

G. B., twenty-one years of age, had acute osteomyelitis of the left os ilei, about six years ago. During the acute stage spontaneous separation of the epiphysis of the femur occurred, and recovery took place after a sequestotomy of the ileum. The limb gradually became so much adducted, that, for its use in walking, a shortening of three or four inches took place, though bony ankylosis existed at the hip-joint. Subtrochanteric cuneiform osteotomy, about a year ago, done at the German Hospital, improved his condition so much that he was able to walk without adding anything to his heel, until lately, when moderate adduction again made itself manifest. At the seat of the hip-joint everything seemed to be one bony ankylotic mass, and still we must assume that within this mass gradual bending must have taken place, forcing the bone of the femur into adduction.

The day before yesterday the patient consulted him for a sciatic pain. He had contracted gonorrhœa two months ago, and in examining him I found a condition of things for which I take the liberty to solicit your attention and call forth your criticism.

You see here, immediately below the inner half of Poupart's ligament, a slight, but distinct, elevation extending a few inches down, and being situated somewhat nearer to the adductor side. One feels distinctly a swollen gland on top of this swelling, which, to the touch, seems to transfer a distinct and powerful pulsation isochronic to the radial and femoral pulse. One hears, also, a distinct bruit. The femoral artery can be traced right on the lateral edge of the swelling; but compression of this artery, also, above Poupart's ligament, seems not to have any effect on the pulsation. If, one, however, exerts a pressure on the tumor itself, deep toward the foramen obturatorium, the pulsation ceases. I have tried compression of the arteria obturatoria from the rectum, but I am not quite sure whether a large artery which I felt and compressed, was that vessel. Its isolated compression seemed not to have any decided effect on the pulsation in the tumor, but simultaneous compression of the external iliac seemed to stop it, or, at least, considerably to diminish it. I am inclined to assume, from the anatomical seat, its shape, consistency, and physical symptoms, that we have to deal with an aneurism, which seems to be furnished principally through the arteria obturia, but probably also communicates with the femoral or one of its main branches. I thought of the possibility, whether, perhaps, a small spiculum of bone, by gradual erosion of the arteria obturatoria, might have caused this aneurism.

Dr. Lange also presented a very interesting case of

PARTIAL RESECTION OF THE ELBOW-JOINT.

In this case an injury had taken place three months previously, and then soon ankylosed at an angle of 140°, with only a few degrees of motion. The capitum radis could be made out, and seemed to be in its proper position to the external condyle; a diagnosis of an oblique fracture of the humerus into the joint was made. There being a large protuberance on the inner side of the joint, which presented the outlines of the trachea, he thought that the outer half of the articular body of the humerus, together with the bones of the forearm, was dislocated outward, but on opening the joint a different condition was discovered. The condyles were almost normal, while, at the same time, an incomplete dislocation of the bones of the forearm was found to exist, so that the ulna articulated with the capitellum, the external condyle was dislocated outward and much thickened. After subperiosteal excision of the lower end of the humerus the wound was entirely healed at the end of three weeks, and the patient has motion of the joint now between the angles of 90° and 160°; at the same time he is steadily improving. The healing process took place under two dressings, and by first intention; there are both pronation and supination. The after-treatment consisted of passive motion and exercise, a light-jointed silicate splint with rubber muscles being worn, to assist him in using the muscles of his arm.

The splint, which had been exhibited by Dr. Lange on previous occasions, was then applied to the boy, and the method of exercising the muscles and securing further motion exhibited.

Dr. Wyeth remarked that if, as Dr. Lange suspected, aneurism of the obturator artery existed, the failure of pressure upon this artery (with the finger introduced into the rectum) to arrest pulsation in the tumor might be explained, by assuming that this was one of those instances in which this vessel had two origins, viz., one from the anterior branch of the internal iliac, and the other from the deep epigastric branch of the external iliac: a condition which he had seen in several subjects while making a series of dissections of the pelvis.

Dr. Gerster remarked that he thought there might be a possibility of the condition mentioned by Dr. Wyeth existing.

Dr. Lange said he had thought of that, but was compelled to exclude it, as at a certain point when pressure was made the pulsation stopped entirely.

Dr. McBurney thought the internal circumflex should not be excluded.

Dr. Lange asked what would be the best treatment for the case.

Dr. Stimson asked whether the tumor was increasing in size.

Dr. Lange replied that he had only detected it the day before, and the patient could give him no information on that point.

Dr. Sands remarked that it seemed clear that if this tumor is an aneurism it is not one of the usual kind—that is to say, not one of the femoral artery, but one which involves some branches of the internal and external iliac, and if that be the case and it is aneurismal in character, the treatment would be different from that commonly applied to aneurisms occupying this situation. He thought that under those conditions an operation involving the internal iliac might be necessary. At first, however, pressure in the rectum upon the internal or common iliac should be tried. He thought, however, that if operative procedures were decided upon, ligation

of the common iliac artery might prove necessary, and if he had such a case he would not postpone the operation very long. He would very much dislike to open such an aneurism, and he had no faith in treatment by medicine.

DR WEIR asked if he did not understand from Dr. Lange that external pressure controlled the pulsation.

Dr. Lange replied that it did, but the pressure had to be so intense that he thought the attempt should be made under chloroform. If this should prove a failure, he would prefer to tie the obturator artery first, fearing that the anastomosis might not be perfect enough to supply blood to the limb in case the common iliac was tied. It had seemed to him during an examination at his office that a large vessel inside of the pelvis, probably the enlarged obturator, was the principal feeder of the aneurism. He intended, however, to repeat the examination.

DR. WEIR called attention to the fact that pressure at one point arrested pulsation in the tumor. He would, therefore, before resorting to the methods proposed by Dr. Sands, first try external compression, having not long since shown a case of vertebral aneurism to the Society, which had been cured by compression under similar circumstances.

DR. SANDS said that in making his previous remarks he took it for granted the aneurism was fed from a double source; if from a single source, he might modify his expressions.

DR. STIMSON thought the youth of the patient would suggest that it was not an aneurism of the ordinary spontaneous kind, with fusiform dilatation of the artery, but more probably a pouched sac formed after wounding of the vessel. Such an aneurism would be suited to treatment by coagulation of its contents, induced by the introduction of coagulating substances; and, therefore, if compression failed, he would prefer such treatment to ligature of the common iliac.

DR. SANDS asked whether the insertion of a coagulating substance into the sac would not be a very serious matter.

DR. STIMSON replied that he did not think facts had proved it to be so. He meant solid bodies as well as fluids. Such substances had been introduced in intrathoracic and abdominal aneurisms without causing any serious reaction, although the patients had usually died from the progress of the disease.

DR. BRIDDON said in that case he would prefer the electrolytic action of the constant current to any other means except pressure.

DR. GERSTER remarked that in relation to the case of elbow-joint difficulty presented by Dr. Lange, he added his testimony as to the efficacy of the apparatus applied by him in the after-treatment of the patient; he had used it himself with the most satisfactory results, and it was so simple of application.

DR. POORE asked how long after the operation passive motion is commenced.

DR. LANGE replied, as soon as possible without exciting inflammation.

DR. LANGE then presented a case in which he had performed

RESECTION FOR ANKYLOSIS OF THE JAW,

giving the following history:

Girl, eight years of age, had scarlet fever and diphtheria in her third year, after that running ears and some deficiency in hearing. In her fifth year she suffered from measles, after which her mother noticed an increasing stiffness in her jaw. By and by the mouth became tightly closed, and remained so for the most of the time. Occasionally, however, the teeth could be more easily separated, when, also, hearing seemed to be improved.

At the time of admission to the German Hospital, slight mobility of the lower jaw could be made out, so that the blade of the knife could be put between the incisors, which, as a rule, overlapped each other, so that the lower ones were behind those of the upper jaw, and also to some distance backward. The lower jaw was abnormally small and slightly turned to the left, so that the middle line of the chin did not correspond to the middle line of the face. The left half of the bone seemed somewhat shorter than the right one. It was impossible to make out whether the ankylosis was seated principally in the left or right joint; the muscles seemed more active on the right. This, and the apparent shortening of the left jaw, led Dr. Lange to assume that the left jaw was the one affected.

The operation was done by an incision about one and a half inches in length, along the lower edge of the zygomatic arch (Koenig). In spite of that slight degree of motion, not a trace of the old joint could be found. Everything seemed to be changed into one bony mass, which, piece by piece, had to be dissected away. The operation was done strictly subperiosteally. After ten days, cicatrization was complete. At the end of the first week, exercises were made to increase the mobility of the jaw, which, immediately after the operation, did not allow of opening the mouth more than to about one centimetre distance between the incisors, so that Dr. Lange thought the other joint would have to be excised also. Very soon, however, the mobility increased; and now, about six weeks after the operation, the mouth can be opened to about one and a quarter inches.

It was very remarkable in this case, that, in spite of the complete bony ankylosis on one side, some slight mobility of the jaw existed before the operation. Dr. Lange had observed another case, where the ankylosis had been the result of an injury during birth. One blade of the forceps had caused, by pressure, gangrene of the soft parts above the left articulation, with complete ankylosis following. Dr. Lange operated upon the child at its sixth year of age. His jaw was less developed and abnormally small, as in the case presented. Both joints were excised, and also the coronoid process on the left, because its presence, through mechanical obstruction against the zygomatic bone, interfered with the attempts at motion. The result in this case was good and lasting until the child's death, which occurred about three years later, from tuberculosis.

DR. GERSTER then presented a patient on whom he had performed

CHISEL-EXSECTION OF MAXILLARY JOINTS FOR TRUE ANKYLOSIS.

Lina T., æt. fifteen, a semi-idiotic, rather anæmic girl, was admitted to the German Hospital, March 30, 1886, for a disability of opening the jaws. Her mother stated that, some years ago, the girl had a severe and

long-continued feverish illness, in the course of which a swelling of one cheek developed and pus was discharged from her mouth. Since then she was unable to open her jaws at all, and had to subsist on liquid food. On examination, a marked hemiatrophy of the left side of the face was noticed, together with a slight degree of microcephalism; no paresis of the cranial nerves. The upper and lower incisors were in close contact, and the greatest practicable force could not separate them or move them laterally, even in full anæsthesia. No cicatrices could be detected externally or in the oral cavity, nor was there anything noticeable in the outline of the osseous parts of the maxillary joints. Both masseters were found to form a sharply defined band of normal dimensions, but very great hardness. As the certain diagnosis by a true ankylosis was not possible, it was decided to cut the upper insertion of the left masseter, and eventually proceed to exsection of the left joint, where the origin of the disease was suspected to have been located, on account of the atrophy of the corresponding side of the face; atrophy, as a sequela of inflammations, being a plausible supposition. On April 3d, an incision along the lower edge of the zygoma enabled a division of the muscle, which was not followed by any improvement of the functional defect. Therefore, a vertical incision was added to the posterior end of the first incision, a triangular flap being thus raised, and the joint was exposed with some difficulty. This was due to the atrophy and smallness of the head of the inferior maxillary, which was found, together with the glenoid cavity, bare of cartilage. The head was removed with the chisel, without any trouble or mishap. But the immobility of the jaw remaining unchanged, it became evident that the principal trouble was located on the right side. On account of the duration of the operation, it was decided to postpone the exsection of the left temporo-maxillary joint to a later date. The wound, being sewed, healed promptly. On April 29th, ether was again administered, and a horizontal incision of two and a half inches was carried from the external meatus of the right ear forward along the zygomatic arch. The temporal vessels being doubly tied, were severed; and the region of the joint being exposed, it was found that a solid and rather massive bony union of the head and coronoid process with the temporal bone had formed, this mass exceeding the normal width of the head by about half an inch. A wedge of very hard ivory-like bone being removed by the chisel, the jaws could at once be separated freely, the distance between the incisors being four cm. On the 11th of May this wound was also healed, and the jaws could be separated by the patient herself to a distance of three cm. Chewing was practised without difficulty, and the function is excellent to this day. Regarding the causation, the presence of an inflammatory process is indubitable as an important element, probably in the course of a typhoid fever or acute inflammatory rheumatism. Whether the hemiatrophy was due to the presence of the ankylosis, is very doubtful; but it seems rational to assume that the atrophy of the temporo-maxillary joint of the left side was caused by the absence of the physiological stimulus of motion in the joint. The operation is rational and safe, and has yielded excellent results to other observers, abroad as well as at home. The horizontal incision, as devised by Bottom and König, has been found to be the better one, although deligation of the temporal artery cannot always be obviated.

The subject was discussed to some length at the Fourteenth Congress of German Surgeons.

Dr. Abbe thought the chance of retaining the benefit gained was great.

Dr. Lange asked Dr. Gerster whether bony ankylosis occurred on both sides with his patient.

Dr. Gerster replied it was only on the left.

Dr. Lange remarked there was one special point of interest connected with these cases, and that was how to decide upon which side of the face the ankylosis was situated. He did not know of any guide to this, as in the case he had introduced he was uncertain before operating; but was led to assume that the left joint was affected from the fact that the left side seemed shorter.

Dr. Weir asked if the history of the ear trouble did not help him.

Dr. Lange replied that that occurred on both sides.

Dr. Gerster remarked that it was the same in his case; but he was mistaken, as the disease was on that side of the face which was better developed.

Dr. Lange presented a specimen of

ANEURISM OF THE ABDOMINAL AORTA TREATED BY THE INSERTION OF WIRE INTO THE SAC,

occurring in a man at the German Hospital. The patient, about forty-five years of age, was originally treated for syphilis but with no effect. Finally Loretta's operation was decided upon, viz., the entrance of wires into the sac after laparotomy: the aneurism, however, enlarged very rapidly both in the epigastric and lumbar region about the right kidney. One morning it became apparent that the blood had effused behind the peritoneum and in front as far as Poupart's ligament. A modification of the above operation was afterward decided upon by passing a needle through the viscera and into the sac and introducing the wires; the aneurism had become very much enlarged and the patient very anæmic. The first operation was done fourteen days ago. A puncture was made in the epigastric and lumbar region, and three metres of thin wire were used; the patient did not need any anæsthetic and the operation caused no disturbance. The swelling in the epigastric region gradually diminished and in the lumbar region it became harder: a few days later a swelling appeared near the liver; the needle was again inserted at that point and just above Poupart's ligament: a solution of chloride of sodium was then infused into the cephalic vein, the patient bearing it well, but yet the aneurism gradually increased. A second transfusion five days later caused slight improvement, but all further attempts were desisted from; the patient dying of pneumonia twelve days after the first operation.

The post-mortem showed the viscera so much displaced that the right kidney was pushed forward and lay near the edge of the liver at the ascending transverse part of the colon, while the stomach was somewhat dislocated to the left side: there was no trace of puncture in the epigastric region or in any of the interlying organs: probably the puncture had been made through the left lobe of the liver and into the sac. On the left side between the layers of the meso-colon the abdomen was filled with blood, but the principal mass was on the right side, where there was about a gallon or

more. The aorta showed extensive atheromatous degeneration. The aneurism was located immediately below the diaphragm and communicated with the aorta by a lengthy opening through the posterior side of the vessel; there was also erosion of the twelfth dorsal and first and second lumbar vertebræ; the walls of the sac were quite firm from organized fibrin, the sac was as large as two fists and was ruptured on its right side, the silver wire being distinctly shown as it had been entered into the cavities; presenting in one case distinct coagulation which had taken place around the substance, but in the other sac in which the wires had been introduced the wires were quite clean; the punctures were made at three different points as before stated, but by all appearances two wires entered the same cavity. Dr. Lange did not think that coagulation was bound to occur, and he could not say whether the immense clot found in the original sac was produced by the wires or not; but where previously there had been a strong pulsation, two days before death that pulsation was hardly perceptible, and the bruit had disappeared. He thinks that if the case had been taken earlier rupture of the sac could have been prevented and a cure effected even in this severe case.

Dr. McBurney asked how much wire had been used.

Dr. Lange replied twelve metres, or about thirty feet.

Dr. Briddon remarked that the operation was performed many years ago by the late Dr. Gurdon Buck.

Dr. Gerster remarked that he was present at the operation by Dr. Lange and thought it much better than Loretta's method, which requires opening of the abdominal cavity; and at the post-mortem in this case it was proved there was no irritation caused by the introduction of the wire.

NEW YORK NEUROLOGICAL SOCIETY.

Stated Meeting November 2, 1886.

The President, C. L. Dana, M.D., in the Chair.

A CASE OF BITEMPORAL HEMIANOPSIA.

Dr. Edward Waitzfelder presented the patient, a lad, whose general history was negative until five months ago. He then noticed a "blur" over the right eye. He consulted Dr. P. A. Gallan, at the New York Eye and Ear Dispensary, who diagnosticated right temporal hemianopsia. The condition grew worse; the left optic nerve became involved, and left temporal hemianopsia developed. The nasal fields of both eyes were unaffected. Two months ago the patient had choked disk in the right eye. His condition November 1st was as follows: No other basal nerve affected; he has complete bitemporal hemianopsia, the whole of fixation point being included in the seeing field. Theoretically the fixation should be dissected, but practically it never is; there is atrophy of both optic nerves, most marked in the right. Vision, R. E. $\frac{8}{CC}$; L. E. $\frac{20}{XX}$. Diagnosis: tumor of the chiasm in the anterior portion; pressure upon the fascicula cusciata of both optic nerves, the fasciculi laterali being as yet unaffected. There is no tubercular or syphilitic history. The rapid growth of the lesion points strongly in the direction of sarcoma.

So far as Dr. Waitzfelder could ascertain, this was the first recorded case in the English language. The point of special interest in the case was that the fixation point was "dodged" by the line of the hemianopsia. Why this was so he could not say, but it would seem to indicate that there was a special set of nerves intended only for extreme central vision.

Remarks were made on the case by Drs. Pooley, Webster, Starr, Leszinsky, and Bullard.

COCAINE AND THE SO-CALLED COCAINE HABIT.

Dr. W. A. Hammond made some remarks upon his personal experience with some of the preparations of cocaine. He had used only the fluid extract, various wines, and hydrochlorate of cocaine. The fluid extract had been discarded by him two or three years ago, mainly because it had been badly borne by the stomach; it excited nausea and was disagreeable to the taste. He then began the use of the wines, but finding that they differed so much in their effects, he gave them up until he suggested to Thurber & Co. to try to make a wine of coca free from tannin and extractive matters, and they had, he believed, entirely succeeded in doing so. There were two grains of the hydrochlorate of cocaine to the pint of wine. With this preparation he had had an extensive experience, not only upon others, but upon himself. He has used it in spinal irritation with excellent results, results which could not be attributed alone to the wine, but in part to the cocaine. He had used it also as a general tonic and for fatigue. For some time past he had been in the habit of taking a wineglassful at the close of his day's duties, and with benefit; it certainly had a decidedly restorative effect, without being followed by a feeling of depression. He had also used it in some cases of dyspepsia with a very irritable state of the stomach. He supposed its action was by lessening the sensibility of the stomach, as it lessened sensibility when applied to other parts. It was remarkable to what an extent the irritability of the stomach was overcome by doses of two or three teaspoonfuls of the wine of coca repeated at intervals of fifteen or twenty minutes until half a dozen doses had been taken. If the first doses were vomited, the succeeding ones would be retained longer, until finally they were retained altogether. Cases of irritability of the stomach, due apparently to spinal irritation, had been relieved within a few hours by this treatment. Generally when he wished in any case to produce a powerful therapeutical effect he employed the salt.

Dr. Hammond here spoke briefly of the physiological effects of coca, and said that the first writer, Tschudi (?), who had described its effects upon the native Indians of South America, gave an exaggerated account of its baneful influence, and his ideas had been copied over and over again without the authority being given, until our minds had become thoroughly indoctrinated by them. That author said, among other things, that the coca rendered the teeth black, produced ulceration of the tongue, caused the breath to be fetid, the jaws to become ulcerated, the bones to soften, and rendered the patient an idiot. But subsequent observers said that such results must be entirely exceptional, as they had never seen them. If there was discoloration of the teeth, Dr. Hammond thought it might be accounted for by

the lime which the Indians mixed with the leaves, or by the presence of tannin.

There had recently been some very striking stories in the newspapers regarding the injurious effects of the drug upon persons who had become addicted to its use. In order to determine whether there was any truth in these statements, Dr. Hammond made some experiments upon himself. He first injected hypodermatically one grain of the hydrochlorate of cocaine, which caused an exhilaration of spirits and a happier state of mind than he had enjoyed during that day. He was unable to sleep that night until four or five o'clock in the morning, and when he got up he had a severe headache. He also had a large evacuation of urine. The effect of the drug was to produce an exhilaration such as would be produced by two or three glasses of champagne. The next night he injected two grains, which produced the same pleasant feeling, and, in addition, he felt an inordinate desire to write. He wrote eight or ten pages of foolscap, and thought it was the best that he had ever written, but the next morning he found that it was the most extreme nonsense. Each sentence was complete in itself, but no two sentences had any relation to each other. The first part was more incoherent than the latter. The next night he injected three grains, and although he again felt the disposition to write, he did not indulge it, but he talked a great deal and made speeches. He knew what he was about, and was able to restrain himself, but it was pleasant to speak. He went to sleep late and again awoke with a severe headache. It was a peculiar fact in his case that at the point of injection there always developed redness, and swelling stopping short only of an abscess.

He now had several hard spots on his arm, and waited four or five days, when he injected six grains of hydrochlorate of cocaine, three grains at two different places. He then felt decidedly "upset," yet he did not lose consciousness nor his relation to things. He gave instructions to his servants correctly, but he did not feel a strong disposition to write or to talk. He was unable to sleep at all that night. The injections were always followed by large evacuation of urine, and by headache next day, but without debility. Three nights later he injected eight grains with about the same effects. The next night he injected eighteen grains, making six different punctures, all inside of twenty minutes. He became intensely exhilarated, and was unable some hours afterward to recall what he did. He was in his office, but in some way got to bed, and the next day he found things in more or less disorder in his office. His headache remained for two days, and there was great action of the heart—palpitation; he could hear it beating on raising the arm to the head. Exaggerated action of the heart had also attended the smaller doses, but he experienced none of the horrible effects which are said to attend the use of the drug in large or continued doses; no disposition to murder, or commit acts of violence. He acquired no habit, he was able to quit its use at once. And regarding the cocaine habit, he would say that he had given the drug in doses of from one to five grains for three months to a lady suffering from exophthalmic goitre, and she was then able to discontinue its use without any difficulty. At no time did she manifest any loss of moral principle. She took two doses a day. From a theoretical standpoint perhaps cocaine should not be administered in this disease, but it proved beneficial in this case, for the heart's action, which had been increased, diminished, became steadier, and the patient felt much better. He also gave it for some months to a lady addicted to the opium habit, carrying the dose up to five grains injected once a day. It overcame the opium habit, and the patient failed to acquire the so-called cocaine habit. In this, and other patients to whom he had administered cocaine, it produced, as in his own case, extraordinary action of the heart, increased temperature and blood pressure, perspiration, and indisposition to sleep.

He had used a ten per cent. solution of cocaine, soaked in lint and applied to the vulva, for the relief of masturbation. But it had failed in one case, that of a girl four or five years of age. It had been ineffectual in boys, applied to the glans penis.

In three cases of melancholia in women who refused to speak, injections of hydrochlorate of cocaine had overcome the prolonged silence. The first was a marked case of melancholia with stupor, and the patient had not spoken for nine months. At the first sitting he injected one grain of hydrochlorate of cocaine. The patient then nodded or shook her head in reply to questions, but would not speak. At the next sitting three grains of the drug were injected, and within four minutes the patient replied to questions by yes or no, and within ten minutes she began to talk, and kept on talking, although incoherently. She did not sleep that night, and seemed to have pain in the head the next morning. The next injection of three grains caused the patient to talk, but less incoherently. This was a year ago, and the patient continued as melancholic as before, but she talked, if that was any advantage. Dr. Hammond had failed occasionally to induce patients to speak by injections of cocaine.

As to the cocaine habit, Dr. Hammond regarded it as similar to the tea or coffee habit, and unlike the opium habit. He did not believe there was a single instance of well-pronounced cocaine habit, the patient being unable to stop it at any time if he chose to do so. If a person were to continue its use for a long time he should be inclined to look for trouble with the heart rather than with other organs.

Dr. J. B. Mattison, of Brooklyn, could not agree with Dr. Hammond that there was not a cocaine habit. Within a few months he had had seven cases of the cocaine habit under his care, five in physicians, and two in druggists. He certainly believes there is such a thing as cocaine addiction. He regarded the drug as most dangerous and destructive of the tissues. In certain cases its action is more unfavorable even than morphine. The cases reported in newspapers he thought were founded on facts. In one instance he wrote to a physician asking whether the report was true that a certain doctor had been arrested in the street, under the influence of cocaine. The physician replied that it was true, that the doctor was a victim to cocaine. He could cite other similar cases.

In one instance a physician attempted to write a prescription for a patient, but instead wrote for the Sheriff to come and take him to jail. The effects of cocaine, so far as he had observed them, were similar to those described by Dr. Hammond, but besides the action of the heart, the great volubility, and the unrest, he had noticed

hallucinations and delusions, but no homicidal or suicidal tendency. In some cases there was marked emaciation. He thought the effects of the continued use of cocaine are more decided than those of the continued use of morphine. The patients whom he had treated had acquired the cocaine habit gradually, making comparatively small injections several times a day. Dr. Hammond seemed to think that no dose was toxic; but he regarded Dr. Hammond's case as exceptional, and he would not advise any physician to repeat the experiment.

Dr. J. Leonard Corning thought there was a morbid fear of cocaine spreading throughout the community, and he thought the remarks of Dr. Hammond were timely, as they would tend to allay the prejudice against a most useful remedy.

Dr. L. C. Gray remarked that between Dr. Hammond on the one side, and Dr. Mattison on the other, there was considerable distance, and he did not know how the question could be solved except by further experience. Dr. Hammond's statement, that no cases had been reported by medical men, was a mistake. Cases had been reported in Europe, but they were not numerous.

Dr. M. R. Richard said that about six years ago he had a case of despondency in a lady disappointed in love. This was in New Orleans, and a physician there told him that he was in the habit of using an infusion of coca leaves in such cases. He gave it to this woman with happy results. Three years ago he came to New York, and was unable to find any coca leaves. Taken in this manner the patient would not be likely to get a sufficient amount of the drug to acquire a habit.

The President read a communication from Dr. C. H. Hughes, of St. Louis, in which he said: Most of the cases of cocaine habit seen by me have been mixed cases of opium, cocaine, and alcohol or ether inebriety, combined, or alternating; though I think I know of cases in which cocaine is the chief, if not the exclusive, reliance. But these patients are not reliable in their statements. I have not seen a physician addicted to cocaine who stuck to cocaine exclusively. The finale has generally been cocaine and opium and whiskey, and ether, and all the other neurotic stimulants. Opium is a much more agreeable stimulant, and most patients evidently try to get back to the fatal bliss of opium. I have never relied on cocaine alone in breaking up the opium habit. I never use cocaine to intoxication, and never regularly. My rule with cocaine cases, as I usually see them, is to get them back to plain opium, and then to break them of that, if advisable. Dr. Hughes referred to the fact, that in some cases cocaine produced poisonous effects.

The President referred to thirteen cases of cocaine habit, reported by Dr. Erlenmeyer, and to a case reported by Bornemann. The subject, he said, had recently been discussed at the meeting of the German Congress of Physicians and Naturalists, when Dr. Smidt reported some cases of cocaine-morphine habit. The general opinion was that pure cocaine addiction was rare, but that the cocaine-morphine habit was not so, and was a very destructive and pernicious habit.

Dr. Hammond, in closing the discussion, said he did not deny the existence of a cocaine habit; he only claimed that it was unlike the opium habit, for the patient could break it off at will. He was aware that patients addicted to the use of opium sometimes added cocaine, greatly to their detriment. As to cocaine being a poison, twenty, and even thirty-two grains had been taken without serious results. He differed from Dr. Mattison, who thought it was more injurious employed hypodermatically. But the patient came under its influence more slowly when it was taken into the stomach.

The President reported, for Dr. Herman M. Biggs,

A CASE OF SUBACUTE SPINAL PARALYSIS,

and exhibited specimens of the cord and sciatic nerve. The case was characterized by gradual paralysis of the lower, and then of the upper extremities, with moderate atrophy. Later a slight anæsthesia of the lower extremities, no pain, loss of tendon reflexes, and no bladder troubles. The course was progressive. Death took place in five months. Autopsy. The patient was a male, aged sixty-two, not syphilitic. The interest in the case lay in the rarity of the affection, and especially of cases in which post-mortem observations had been made. Clinically it resembled mostly the subacute spinal paralysis of Duchenne, although that disease is very rarely fatal. It still more strongly resembles a chronic form of Landry's acute ascending paralysis, and gave support to Ross's classification of: 1, Landry's paralysis; 2, the subacute paralysis of Duchenne; 3, periependymal myelitis; and 4, progressive muscular atrophy, as inflammatory processes attacking the central gray matter of the cord, and distinguished by the greater or less acuteness of the process. The case was interesting, also, as showing that these paralyses are not always at least due to neuritis.

Dr. Dana showed sections of the lumbar and upper dorsal cord, which he thought presented evidences of a low grade of central myelitis. The anterior roots and the sciatic nerve were apparently normal.

BOSTON.

(From our Special Correspondent.)

Harvard's Two Hundred and Fiftieth Anniversary.—The celebration of the Two Hundred and Fiftieth Anniversary of the founding of Harvard University has been attended with much that is of interest to educated men, and especially to all of the professions, the medical profession no less than the others.

Of the four days over which the exercises extended, the last, which was designated as Alumni Day, was especially full of interest. The President of the United States, with several members of his Cabinet, and other invited guests from this country and abroad, and the officers of government and instruction of the University, and a long line of alumni formed in and near the library, and marched through the college yard to Sanders's Theatre, where were already assembled many ladies. The members of the various faculties, dressed in silk gowns and with Oxford caps, gave novelty to the procession.

In the theatre, and filling the ample balcony, were hundreds of ladies, including, Mrs. Cleveland, Mrs. Eliot, Mrs. Endicott, and Mrs. Robinson. On the stage, the two hundred seats were occupied by the guests, including the President of the United States, the

Secretaries of State, War, and of the Navy, Senator Hoar, Governor Robinson, the Mayor of Boston, the Sheriffs of Suffolk and Middlesex, delegates from universities and colleges, many distinguished invited guests, among them Prof. Leidy, Dr. John S. Billings, Dr. S. Weir Mitchell, and the members of the government and various faculties of the University. The body of the theatre was filled with the Alumni, the older classes entering first, beginning with the class of 1811. After all were seated, Chief Marshal Henry Lee called them to order, and Judge Devens, after a brief address of welcome, invited Professor Francis G. Peabody to begin the exercises with prayer. After the prayer, a chorus of one hundred and fifty men's voices in the gallery over the stage sang Gounod's "Domine Salvam Fac."

James Russell Lowell, who was greeted with great applause, then delivered a most finished oration, unsurpassed on such an occasion, and well worthy of careful reading by all intelligent and educated persons.

After more music by the Anniversary Chorus, Dr. Oliver Wendell Holmes read the poem. The chorus then sang "A Mighty Fortress is Our God," after which the honorary degrees were conferred upon many distinguished persons, among whom were three from the medical profession, Prof. Joseph Leidy, Dr. S. Weir Mitchell, and Dr. John S. Billings.

A benediction by Dr. A. P. Peabody brought to a close the morning ceremonies, which were in the highest degree dignified and impressive, and accompanied throughout by earnest and enthusiastic applause.

At two o'clock the procession reformed at Gore Hall and proceeded to Memorial Hall, the largest college hall in the world, where, surrounded by monuments of heroes and benefactors, the Association of the Harvard Alumni received their distinguished guests at dinner. During the banquet, Mrs. Cleveland, and the ladies accompanying her, entered the balcony; this was the signal for all to rise and greet her with great applause. On the dais sat many dignitaries, including the President of the United States, the foreign delegates and guests, the orator and poet of the day. The throng on the floor included men of all ages and of much distinction. The Alumni were fortunate in being presided over by Judge Devens, who most felicitously introduced the many noted speakers.

Of the speeches made, that by the President aroused unbounded enthusiasm, and the toast of "The Science of Medicine and Surgery" was ably responded to by Dr. Mitchell.

The Japanese and Quarantine.—The intelligent and independent judgment exhibited by the Japanese in their application of knowledge acquired in Europe and America is well exemplified by the port sanitary regulations, which the *Indian Medical Journal* states to have been enforced during the prevalence of cholera in 1885. All vessels from infected localities were subjected to medical inspection before any communication with the shore was allowed; if the crew and passengers were found healthy, the vessel was allowed to proceed. These reasonable regulations, founded upon a scientific knowledge of the disease and of the nature of infection, are in striking contrast with the panic-stricken haste with which many European nations impose their so-called "rigorous quarantine." The Japanese appear to possess the rare power of learning from the experience of others.

The Hygienic Museum of Berlin, presided over by Dr. Koch, was opened on October 11th. The collection is described as a very comprehensive one.

Electricity Utilized as a Means of Punishment.—An ingenious Swiss is said to have devised an electrical whipping apparatus which will inflict the requisite amount of pain without causing unsightly and inconvenient wheals.

The Disadvantages of using a Brook as a Sewer.—The presence of a small stream running through a village is very tempting to advocates of putting nuisances out of sight without regard to their ultimate disposal. When the stream becomes polluted by the drainage of the adjoining populated region some one is sure to suggest that it be arched over and made a sewer.

In general, it may be asserted positively that this is a bad plan. There may be exceptions occasionally to this broad assertion, but they are so rare as not to be worth taking into account in a general consideration of the question.

A small natural stream is liable to excessive fluctuations. In dry seasons its flow will be very slight, and after heavy showers it will be a turbid torrent. Any channel to carry its waters must be of a capacity many times greater than is needed for certainly nine-tenths of the time. The occasional flushes which it receives from storm-waters are not sufficient to keep it clean and sweet during the intervals of small flow and slight fluctuations.

A channel for conveying sewage-water ought to be adapted to keep itself clean by its natural flow as nearly as practicable, and to effect this object it must have a limited capacity and be capable of frequent flushing with a quantity of water only slightly in excess of the greatest flow likely to occur during the hourly fluctuations of the household use of water.

This fluctuation is theoretically, according to German experiments, between 38 and 190 per cent. of the average hourly flow during the day. According to some American experiments the variation lies between 55 and 130 per cent. of the average hourly flow. This flow is quite constant during the year, and it may safely be assumed that a sewer to act efficiently need not, and indeed ought not, to be larger than is essential to carry when full double the average daily quantity of sewage likely to reach it.

It is easy to see that the size and cost of such a sewer will be much less than that of arching over a natural water-course and making it large enough to convey flood-waters.

A small marginal sewer along each side of a water-course properly constructed, with its sides and grade determined by a competent expert engineer — not guessed at by a committee or a local surveyor unskilled in the subject—will cost less and be more effec-

tive, nine times out of ten, than will the water-course itself when arched over and sewage turned into it.

The Alcoholic Red Nose.—*The Church of England Temperance Chronicle* states that the following appeared among the miscellaneous advertisements in a recent issue of the *Irish Times*: "How to Change the Color of an Alcoholic Red Nose.—Recipe, which is effectual in nine cases out of ten, may be had by sending postal order for 10*s.* to 'K.,' 738, this office." There is a very watchful worker in Dublin in the person of Mr. T. Wilson Fair, the energetic Hon. Secretary of the Dublin Total Abstinence Society, so it is not a matter for surprise that the quaint advertisement above quoted was immediately followed by this: "How to Change the Color of an Alcoholic Red Nose.—Don't waste 10*s.* Call over to the Coffee Palace, 6 Townsend Street, and in 99 cases out of 100, if you sign the pledge and keep it, your nose will assume its natural shape and color.—Alcoholic Red Nose Curing, 6 Townsend Street, Dublin."

The Disposal of Refuse.—The Whitechapel Board of Guardians are successfully adopting a plan for the effectual disposal of dust and refuse without danger to the health of the inhabitants, which is pursued by some other bodies. Under the supervision of Mr. W. La Rivière, the architect and surveyor to the Board, works on an extensive scale have been erected in Wentworth Street, where the contents of the East End dust-bins are simply cremated, the smoke being, by an ingenious process, purified of any noxious gases it may possess, and then carried away through an upcast shaft 180 feet in height. Taking the foundations into account, the whole structure is 213 feet in length. The refuse is brought up on an inclined plane in the dust-carts of the Board, and emptied out on a platform, whence it is immediately discharged into the "destructor," which consists of eight cells, placed back to back in pairs. These cells are very strong draught furnaces, which in a short space of time reduce the unsavory mass to a heap of clinker, which is taken out and carted away. The smoke makes its way to the shaft by an underground flue seven feet high and four feet wide. It is stated that a considerable saving will thus be effected. Up to the present, the Board have been obliged to cart the "dust" away to Bow, and sometimes to Temple Mills, a couple of miles, or perhaps more, beyond Stratford, at a cost of from 1*s.* 6*d.* to 3*s.* 6*d.* a load. By means of the "destructor," the refuse can be destroyed for 2½*d.* to 3½*d.* a load, and thus the cost of the freehold site and construction, amounting to about £13,000, will be speedily recouped. This favorable experience will, no doubt, influence the authorities of other districts.

Method of Removing Nitrate of Silver Stains.—Dip the fingers into a strong solution of cupric chloride. In about a minute the silver will be converted into chloride, and may then be washed off with sodium hyposulphite solution.

Diluting Skimmed Milk.—A novel defence, raising the question of the liabilities of milk-sellers, was made in a case which came before the Brighton magistrates on October 9th, when Mr. William Edwards, one of the members of the town council, was prosecuted by the corporation officials for selling skimmed milk adulterated with forty per cent. of added water. The offence was not denied, but the defendant's solicitor relied for the defence on the fact that, after a previous prosecution on a similar charge, Mr. Edwards had given formal notice to the chief constable, the borough officials, and all whom it might concern, that he had never intended, and did not intend to sell pure milk, but only skimmed milk and water, or milk adulterated with water. The stipendiary magistrate ruled that such a notice could not be held to absolve the defendent, inasmuch as, however widely circulated, it could not be considered to make it patent to the mind of every purchaser, that milk was sold to them adulterated with water. Still he thought the notice lessened the offence, as it showed there was no intention to deceive or be dishonest, and he consequently imposed a smaller fine than he would otherwise have done. Defendant was fined twenty shillings and costs, or seven days' imprisonment.

Restrictions on Veterinary Practice in France.—The French Minister of Agriculture has drafted the following resolution, which has since become a law: "No one who is not in possession of a diploma in veterinary medicine, granted to him by a French veterinary school, shall practise this branch of science in France." Any breach or evasion of this law is punished by a fine of from sixteen to four hundred francs for the first offence, and if the offence be repeated, a double fine, with from six to thirty days' imprisonment.

An Unusual Case of Poisoning.—The papers have recently related a fatal case of poisoning from an overdose of podophyllum. A physician in Maine ordered, in a prescription, "Podophyllum, gr. ss." The last two letters were mistaken by the druggist for figures, and read "88." He thereupon dispensed the latter quantity, which was taken at one dose (as was presumably ordered for the correct quantity), death occurring soon after. The clinical history of the case is not given, but the toxic symptoms were probably those of an acute irritant poison. However much the physician may be blamed for his illegible writing, it is hardly conceivable any druggist could have given such a quantity of a powerful drug without at least verbal instructions to the customer as to its potency.

Medical Education of Women in Edinburgh.—The reopening of the Extra-mural Medical School on Wednesday, October 20th, was marked by the readmission of women to medical education in Edinburgh, after an interval of more than twelve years. The first year's course comprises, as usual, anatomy and practical anatomy, chemistry and practical chemistry. The ladies' class consists at present of six students, most of whom have just passed the preliminary examination in arts held by the Educational Institute of Scotland on behalf of the Colleges of Physicians and Surgeons. The classes are conducted by Dr. Macdonald Brown and Dr. Stevenson Macadam respectively, and Dr. Sophia Jex-Blake is acting as organizing Secretary.—*British Medical Journal*, Oct. 30, 1886.

Is Cock-crowing a Legal Nuisance?—People vary very much in their susceptibility to noise, but to most

persons of a nervous temperament, an intermittent noise during the night-watches is distressing in the extreme. It is all very well to read how chanticleer proclaims the morn in the country, but it is quite another thing when he lives in a shed at the bottom of the next garden in London. As Carlyle said, it is not merely the distressing noise of his crow, but the agonizing suspense while the sleepless watcher waits for him to crow again. A householder bolder than his fellows has brought an action against the owner of a loud-crowing cock, and the grand jury has found a true bill, so that the case will shortly be tried at the Middlesex sessions. The proverbial uncertainty of the law forbids any confident anticipation that the decision will lead to any considerable transference of crowing cocks from central London to their proper home in the country; so much will depend on the disposition of the jurymen.

DEATH OF DR. JOSEPH G. RICHARDSON.—Dr. Joseph G. Richardson, Professor of Hygiene in the University of Pennsylvania, and a member of the Board of Health, died very suddenly of apoplexy, at his home, No. 3238 Chestnut Street, Saturday, November 13th.

Dr. Richardson was born in Philadelphia, January 10, 1836, and was graduated from the Medical Department of the University of Pennsylvania about twenty-five years ago.

After serving as Resident Physician in the Pennsylvania Hospital and Wills Hospital, he practised medicine in Western New York. He afterward returned to Philadelphia and resumed practice here.

He was a voluminous writer on hygienic subjects, being the author of several well-known works in the department of science and also of a *Handbook of Medical Microscopy* which is used as a text-book. He was an untiring student of hygiene and microscopy.

Dr. Richardson was a member of the County Medical Society, the College of Physicians, and various other medical organizations, as well as a corresponding member of La Société Française d'Hygiène.

He spent the past summer in Europe. While there he was duly accredited by the Board of Health, and at its request investigated various matters connected with the sanitation of cities, and especially their water supplies.

DEATH OF M. PAUL BERT.—A Paris dispatch announces the death, on November 11th, of M. Paul Bert, the French scientist and statesman. He was a native of Auxerre, where he was born October 19, 1833. He studied law and medicine in Paris, and in 1868 was appointed Professor of Physiology in the Faculty of Science of Paris. He devoted himself to physiological research, and made many valuable experiments by means of balloons to ascertain the conditions of existence at various altitudes. In August, 1875, he was awarded the biennial prize in the Institute in recognition of his scientific work. M. Bert was elected to the National Assembly by the Department of Yonne in 1872, and was reëlected in 1876 and 1877. He acted with the extreme Radicals, and advocated various educational schemes, especially an act to exclude the clergy and members of religious orders from the schools of France. When Gambetta came into power in 1881 M. Bert was made Minister of Public Instruction, and in April of the following year he was elected a member of the Academy of Sciences. Last January he was appointed Minister of France at Hué, the capital of Anam, and he was holding this position when he died. He published a number of scientific works and many political articles.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 9 TO NOVEMBER 15, 1886.

SMART, CHAS., *Major and Surgeon.*—Granted leave of absence for one month.—*S. O. 265, A. G. O.*, November 13, 1886.

LORING, L. Y., *Captain and Assistant Surgeon.*—Sick leave of absence further extended three months on surgeon's certificate of disability. To be relieved from duty in the Department of California, and, on the expiration of his present sick leave of absence, will report by letter to the Surgeon-General of the Army.—*S. O. 262, A. G. O.*, November 10, 1886.

MOSELEY, E. B., *Captain and Assistant Surgeon.*—Assigned to duty as attending surgeon in San Francisco, California.—*S. O. 94, Division of the Pacific*, November 1, 1886.

BARROWS, CHAS. C., *First Lieutenant and Assistant Surgeon.*—Ordered to report to the commanding officer at St. Francis Barracks, St. Augustine, Florida, for duty at Fort Marion.—*S. O. 180, Division of the Atlantic*, November 10, 1886.

MACAULEY, C. N. B., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for twenty days.—*S. O. 118, Department of Dakota*, November 8, 1886.

PHILLIPS, JOHN L., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply at Headquarters of the Division of the Missouri for an extension of one month.—*S. O. 116, Department of Dakota*, November 2, 1886.

CROSBY, W. D., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort McDowell, Arizona Territory, to Fort Bowie, Arizona Territory.—*S. O. 110, Department of Arizona*, October 29, 1886.

MORRIS, E. R., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Bayard, New Mexico, to Fort Thomas, Arizona Territory.—*S. O. 110, Department of Arizona*, October 29, 1886.

EWING, CHAS. B., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Supply, Indian Territory, to Fort Leavenworth, Kansas, for duty.—*S. O. 126, Department of the Missouri*, November 6, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING NOVEMBER 13, 1886.

AMES, R. P. M., *Passed Assistant Surgeon.*—To proceed to duty at Vineyard Haven, Massachusetts, as inspector, November 10, 1886.

URQUHART, F. M., *Passed Assistant Surgeon.*—Granted leave of absence for seven days, November 8, 1886.

WASDIN, EUGENE, *Passed Assistant Surgeon.*—Granted leave of absence for seven days, November 11, 1886.

MAGRUDER, G. M., *Assistant Surgeon.*—Relieved from duty at Norfolk, Virginia. Assigned to duty at Marine Hospital, Chicago, Ill., November 10, 1886.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL ARTICLES.

SOME OF THE CAUSES OF PULMONARY CONSUMPTION VIEWED FROM A DARWINIAN STANDPOINT.[1]

BY THOMAS J. MAYS, M.D.,
OF PHILADELPHIA.

THE most competent authority of the present day, Mr. Herbert Spencer, defines life as "a continuous adjustment of internal to external relations," and qualifying this he says that "the degree of life varies as the degree of correspondence between it and its environment." It is not necessary to illustrate the truthfulness of this definition to any great extent, for the development of muscle in the athlete's arm, the thickening of the epidermis on the laborer's hands, the callosity of the gums resulting from the loss of teeth, cardiac hypertrophy due to obstruction in the circulation, eyeless fishes inhabiting subterranean waters, the long-sighted countryman as compared with the near-sighted townsman: all attest the correctness of these observations.

While it is true that life as a whole depends on an adjustment of internal to external relations, it is also true that the same adjustment takes place between any part of life and its immediate surroundings. For if from any cause, either external or internal, the normal or ordinary course of an organ or of its function is enhanced, collateral changes supervene in neighboring organs. In the undue development of the athlete's arm it is not alone the muscular tissue which is implicated in the process, but the bones of the arm, especially the points of insertion for muscles, and every subjacent organ become enlarged. The hypertrophied textures demand a larger amount of nutritive material, and this in turn demands greater facilities for supplying the same, which implies not only more blood and larger bloodvessels in the part, but also a greater capacity of the heart and of the whole circulatory system.

The same delicate adjustment which exists between the eye and light, between the ear and sound, also exists between the lungs and the atmosphere; indeed, the evolution hypothesis demonstrates that the many varied organs of the animal body are but the creatures of a differentiated environment. The respiratory organs pass through a certain well-defined process of evolution, and while it is true that in man the respiratory function is carried on with highly specialized organs, this is not the case throughout the animal world; for in very lowly developed organisms respiration is performed by the cutaneous surface of the body, while in those of a somewhat higher type there appear special vascular spots in the skin which facilitate the exchange of gases. Then as complexity of structure increases, the respiratory function of the skin is supplemented by a special respiratory apparatus which differentiates from the wall of the alimentary canal in the shape of an air bladder, and which in the higher vertebrates evolves into the highly complex respiratory organs. It must not be forgotten that even in the highest animals the lungs do not monopolize the function of respiration exclusively, for the human skin is capable of absorbing $\frac{1}{150}$th as much oxygen, and of eliminating $\frac{1}{220}$th as much carbonic acid as the lungs.

The lungs, therefore, are organs of absorption and of excretion, are intimately connected with the atmosphere on the one hand and the blood on the other, and are subject to the same law of development through exercise as are other organs. This is not only abundantly illustrated in those who expand their lungs through systematic training, but also in those who inhabit elevated regions. The Quichua Indians, who dwell on the lofty plateaus of Peru, are a good example of this. By constantly living in and respiring the rarefied atmosphere of this region their chests acquire enormous dimensions, and the air cells of their lungs become more numerous and capacious.

While physiological exercise strengthens an organ, disuse favors its impairment. This is supported by many clinical and physiological facts. Destruction of a nerve or of a bloodvessel leads to atrophy of all the dependent textures. "Reugger attributes the thin legs and thick arms of the Payaguas Indians to successive generations having passed nearly their whole lives in canoes with their lower extremities motionless. Other writers have come to a similar conclusion in analogous cases" (Darwin, *Descent of Man*, p. 32). In the high table lands of Peru there lives a tribe of Indians, which is closely allied to the Quichua tribe, the bodies of many of whom have been carefully measured by Dr. Forbes, with the result of showing that, as in the case of the Quichua Indians, their chests are developed out of all proportion to the rest of their bodies; and he, moreover, states that the people are so thoroughly acclimated to their cold and elevated abodes "that when formerly carried down by the Spaniards to the low eastern plains, and when now tempted down by high wages to the gold-washings, they suffer a frightful rate of mortality" (Darwin's *Descent of Man*, p. 35). Nevertheless, Dr. Forbes found a few families on the low lands who had survived for several generations, but the increased size of the thorax so characteristic of their progenitors on the high elevations had materially decreased, although they still showed some enlargement.

What is the probable condition of a lung or a part of a lung suffering from the effects of disuse? This can only be conjectured, for we have no exact data on which to base a reliable opinion. We have com-

[1] Read before the Philadelphia County Medical Society, November 10, 1886.

plete knowledge, however, of acquired atelectasy—a condition of complete collapse of a portion of lung owing to occlusion of the bronchus leading to it, and this gives us a picture, at least, of what is possible under such circumstances. In the acquired form of atelectasy the pulmonary capillaries, differing from the congenital form, are profusely developed already, and when the atmosphere is cut off the alveolar structure of the lung collapses, the elastic fibres of the framework contract and so form a mechanical barrier to the pulmonary circulation. The blood-flow, therefore, becomes sluggish, the blood accumulates, and the part becomes hyperæmic and gives to that portion of the pleural surface a dark, flesh-colored tint.

We have no evidence for believing that mere disuse of any portion of lung structure is followed by such decided pathological changes as those outlined in the last paragraph, yet there can be no doubt that something akin to it must necessarily develop where the expansion of a portion of lung is habitually at fault. Such a lung is practically partially deprived of air, and, therefore, in a state of semi-collapse and hyperæmia, and more vulnerable to disease than its more active neighboring parts. This observation is very applicable here when we reflect that on account of a peculiar downward direction of the bronchial tubes there is an unequal rate of expansion of the lungs. The base and middle portions always expand before the apices, and the latter only expand fully toward the end of a deep inspiration. We see, therefore, that, owing to their inactivity, the apices offer the strongest inducements for the lodgement of disease there, and it is precisely these territories which are notoriously liable to pulmonary consumption.

Now, whatever belief we may entertain concerning the origin of the human species, there can be no doubt that the progenitors of the present civilized race were at one time in a state of savagery, and that the gulf which separates the civilized man from the savage of to-day is no smaller than that which exists between the latter and the anthropoid ape. During the period of man's development the process of adjustment between internal and external relations has wrought such a complete revolution in his existence that his habits and customs, his civil and his social and intellectual interests are diametrically opposed to those of his savage ancestry. When we come to inquire into the causes which have brought about this difference between the savage and the civilized man, we find that, so far as his physical well-being is concerned, they consist principally in a change of occupation, of shelter, and of clothing. The occupation of the savage consists of hunting and fishing, while that of his civilized neighbor comprises the complicated industries and the varied agencies which have been evolved and accumulated during thirty centuries of intellectual development; the shelter of the savage is a rude hut, or the canopy of heaven, while that of the modern man is that of magnificent dwellings and palaces; and the clothing of the former is reduced to a minimum, while the body of the latter is covered and embellished with the most elaborate dress.

The question around which centres the greatest interest for us at present is whether the higher development of civilized man has in all respects resulted advantageously; or rather, whether the adjustment of his internal to his external relations is beneficial to his respiratory organs. This can unhesitatingly be answered in the negative. There is no reason for believing that civilized man requires less air for breathing purposes than his savage brother, yet by spending more than half of his lifetime in poorly ventilated dwellings, there can be no doubt that the former receives much less than the necessaries of his life demand. Especially does this observation become pregnant with meaning when it is linked with the facts that the lungs in improved breeds of cattle, which naturally take little exercise and are domiciled much of their time, "are found to be considerably reduced in size when compared with those possessed by animals having perfect liberty" (Darwin, *Animals and Plants*, vol. ii. p. 361), and that the vital lung capacity is smallest in persons who lead sedentary lives, such as professional men, students, clerks, etc., and the greatest in those who follow an outdoor occupation, such as sailors, recruits, etc. It is also true that the vital lung capacity of non-singers is less than that of singers (Waldenburg).

Then again, when we reflect that civilization consigns the great majority of its members to occupations which are carried on indoors, and which in many instances are of a sedentary character, where, besides breathing a vitiated atmosphere, the free expansion of the chest is hampered by a bent and cramped position of the body, it does not require a very vivid imagination to realize that the respiratory organs soon begin to suffer from the consequences of disuse and fall a prey to that pathological condition which was pictured in the early part of this paper.

These deductions are amply confirmed by the statistics which have been obtained concerning the influence of occupation as a causative factor in pulmonary consumption. In the report of the Brompton Hospital for Consumption, in London, for the year 1849, a number of tabular views are given, one of which is here presented (copied from Ancell' *Treatise on Tuberculosis*, pp. 497, 498):

Dr. Ancell (*loc. cit.*, p. 501) states that from other statistics we are enabled to draw the following conclusions: That in Paris, Geneva, Vienna, and Hamburg there are a greater number of persons leading a sedentary life afflicted with consumption than of those leading an active life, in the proportion of 141 to 89; and that a bent posture appears to augment the frequency of the development of phthisis.

An exchange of outdoor life for one of confinement frequently leads to pulmonary consumption, as is attested by the following facts: Animals transported from both warm and cold climates to the menageries and zoölogical gardens of our great cities persistently die of pulmonary consumption. The natives of the East show but little liability to the disease in their own climate, but when serving as soldiers in Ceylon and China, where they are confined in barracks, they become exceedingly susceptible to it. The negroes are comparatively free from it in

TABLE XXIII.—SHOWING THE TRADES AND OCCUPATIONS OF 4358 PATIENTS LABORING UNDER PHTHISIS TREATED AS IN- AND OUT-PATIENTS, FROM SEPTEMBER, 1842, TO DECEMBER 31, 1848.

MALES—Total, 2682.

Indoor.		Outdoor.		Mixed.	
Clerks, warehousemen, and shopmen	314	Laborers of various kinds	490	Carpenters	120

their native climate, but when transported to foreign countries, especially as slaves or prisoners of war, the mortality from consumption is frightful among them.

The natives of Van Dieman's Land furnish an appropriate illustration of the effects of a sudden change of environment on the human constitution. These savages in their native state had the reputation of being free from pulmonary consumption before the advent of the white race. But Ancell (*loc. cit.*), to whom we are indebted for many interesting facts, says that, according to Dr. Power, on account of their frequent depredations the white settlers confined them on an island in Bass's Straits and furnished them with

"provisions, clothing, dwelling places, and proper superintendents. But to a wandering race accustomed to rove at will through a large and extensive country, to procure their food, as they pleased, by hunting and fishing, and, regardless of dress, to live where and how they liked, this confinement to a narrow little island, and immediate change of their own free and unfettered habits to the more constrained and artificial ones of civilized life, proved speedily fatal. They died in great numbers, and the majority from pulmonary consumption."

"It is probable," quoting from the same authority (p. 542), "that one-fourth of the Europeans who migrate to the East Indies are hereditarily affected with the tuberculous predisposition, and yet a very small proportion indeed fall into active tuberculosis, or die of any form of the disease. The disease being also comparatively infrequent among the inhabitants, it becomes a great question whether the qualities of the climate, or the modified habits of the inhabitants and of emigrants, have most to do with this exemption. The circumstances of air, etc., of Europeans in London, and in Calcutta or Bombay, contrast greatly. The comparatively small and close rooms, the mode of heating apartments in England, the imperfection of ventilation in towns, streets, and houses, the great number of hours spent within doors, in close sleeping rooms, and in close carriages, present all the elements for the production of the disease here; while the more spacious apartments, and the outdoor habits, the habits of complete ventilation, and of almost constant exposure to the open air, are totally opposed to its production in the East; and where we find that the result of the withdrawal of these sanitary influences, even in the East, is the production of the disease, as in the case of half-caste and natives, and in the interior of jails, it becomes probable even here that the climate may have but a secondary importance in reference to etiology. . . . In fact, the statistics lead to one general conclusion, viz., that as respects the etiology, the habits and customs of mankind ride over all climatic influences; that if the European inhabitants of Calcutta or Alexandria were to adopt the modes of life pursued in the metropolis of the British Empire (London), tuberculosis would, after a period, be as frequent in those localities as it is here; and conversely, if the inhabitants of the densely populated countries of Europe were to improve their habits and customs as to labor and rest, indoor and outdoor occupation, the size, construction, modes of ventilation and sites of their houses, streets, and towns, with other circumstances of hygiene, after a sufficient period had elapsed for hereditary influence to wear itself out, that they would probably be more free from this disease than the inhabitants of Lapland, Canada, Greenland, India, Egypt, or Ceylon."

We have thus far briefly considered the influence of occupation and shelter in their relation to man's pulmonary organs, and hope we have given proof to show that the baneful effects of a sedentary and cramped position of the body, of breathing a vitiated atmosphere, and of an impediment to free respiratory activity, incidental to the transition period from savage to civilized life, have so far modified these organs that in many instances man has been unfitted and unable to maintain a prolonged struggle in the battle for existence. It is evident, however, that in this process of elimination to which the human family is subjected, the weak will fall a prey to it first, and that the bad effects of adjustment may be sufficiently counterbalanced in the strong as well as in the weak to enable them to survive the operation; hence, in order to be able to counteract them by artificial means, it is of the greatest importance to inquire into the causes which create a tendency to weakness in this direction. Of all the causes there is probably none which is more potent to produce a predisposition of this kind than that of reproduction, and the remainder of this paper will be devoted to a discussion of a few of the more salient points of this process.

There can be no doubt that there is a direct an-

tagonism between nutrition and reproduction, for "reproduction is a form of nutrition and a growth of the organism to a size beyond that belonging to it as an individual, so that a part is thus elevated into a new whole" (Haeckel, *Generelle Morphologie*, vol. ii. p. 16). Herbert Spencer, in writing of the antagonism existing between growth and sexual genesis, says: "Whether a deduction is made from one parent or from two, whether it is made from any part of the body indifferently, or from a specialized part, or whether it is made directly or indirectly, it remains in any case a deduction, and in proportion as it is great or frequent or both, it must restrain the increase of the individual (*Principles of Biology*, vol. ii. p. 428). From these principles it follows that reproduction is most perfect when growth is completed and before bodily decay sets in; that the higher the rate of nutrition during the reproductive period the higher the rate of reproduction; and that if the bodily expenditure is greater for other purposes than for reproduction there is a corresponding deduction from the resources which would otherwise be devoted to the maintenance of the latter process. In other words, offspring will be, if other things are equal, most vigorous when the growth of both parents is complete and the state of nutrition good; and least vigorous and most prone to decadence when the state of nutrition of the parents is low, when their expenditure for other purposes is great, or when reproduction takes place rapidly or follows at short intervals, or takes place before the body is fully developed, or during the period of bodily decline. All other things being equal then, the last or the youngest children, as well as those who are born before the bodies of the parents are fully developed, should be the weakest, and those born during the remainder of the reproductive period should be the strongest.

We have before us a most interesting work[1] (to which we are very much indebted for many of the ideas suggested in this paper on the relation between reproduction and pulmonary consumption) on the etiology of pulmonary consumption, in which are related the histories of five hundred cases of pulmonary phthisis—giving the age of the patient, the number of children in patient's parents' family, order of patient's birth, number of children in grandfather's family, father's side; also, in that on the mother's side, and, in many instances, the order of birth of both father and mother. We have taken the liberty of analyzing four hundred of these cases, in order that their conspicuous bearings will be more readily perceived, and, also, for the purpose of showing to what extent they verify the above deductions on the relation between reproduction and pulmonary consumption. The results of this analysis are as follows:

The first one hundred cases are patients who come from numerous families, average size of each, 9.87, and whose fathers and mothers came from rather small-sized families, averaging 4.96 and 4.69 respectively, and who were free from every trace of phthisis. About seventy-five per cent. of the patients are the youngest, or belong to the youngest members of their families, none of the older ones being affected.

The second one hundred cases are patients who come from rather small families, the average size of which was 5.52. Their fathers and mothers were healthy, and without a taint of phthisis, but all came from large families, averaging 7.72 and 7.18, respectively, and about seventy five per cent. of them were the youngest members, while very few belonged to the oldest or even the older members of their respective families. Thus, in fifty-four instances, so far as the statistics show, was the father the youngest, and in twenty-four instances the second youngest; thus seventy-eight per cent. were the youngest and second youngest, while there were no oldest, third or fourth oldest, and only one second and one fifth oldest among them. On the mother's side, in fifty-seven instances she was the youngest, and in eleven instances the second youngest, while there was no mother among the second, third, fourth or fifth oldest, but four were the oldest members of their families. In three of the last four instances, however, she was the only child. The patients themselves are principally the products of the beginning and of the termination of the reproductive period, especially of the former, while those of the middle period are comparatively exempt. Thus, of the whole number, twenty-nine are the oldest, and twenty are the youngest of their families.

The third one hundred cases can be considered most conveniently in two sections of fifty cases each. These are cases which occurred in families the parents and grandparents of which were healthy, and in most instances became aged; but the children, who are the patients, manifested a scrofulous tendency in youth. The first fifty cases occurred in families, the children of which were rather numerous, averaging 9.48 per family, whose fathers and mothers came from medium sized familes, averaging 6.54 and 6.86 per family respectively. More than two-thirds of these patients belong to the youngest or younger members of their families, while the older remain almost entirely unaffected. These cases are analogous to the first one hundred cases just related. The second fifty cases occurred among families, the children of which were less numerous than those of the first fifty cases, averaging only 6.70 per family. The fathers came from families of rather larger size than were the families of the first fifty, averaging 7.76 per family; while the mothers came from families of the same average size as those of the first fifty cases (6.86 per family). The patients, like those of the second one hundred cases, came principally from the oldest and the youngest members of their families, especially from those of the former, while those coming from the middle of the reproductive period remained comparatively free.

The fourth one hundred cases are patients, either of whose parents or some of their near relatives suffered from pulmonary phthisis. They are children of small families the average size of which was 5.96; but both their fathers and mothers belonged to large families, these averaging 8.78 and 6.04 respectively.

[1] Die Aetiologie der Chronischen Lungenschwindsucht, von Dr. Hermann Brehmer, sen. Berlin, 1885.

Here again the victims belong chiefly to the two extremes of the reproductive period, and the products of the intermediate period are comparatively free, although less free than in any of the previous sets of cases.

The analysis of these four hundred cases, among other things, shows very clearly—

1. That not all the members of large families are equally vigorous and alike resistant to pulmonary consumption, and that, as a whole, they are less vigorous than those of smaller families.

2. That the youngest members of numerous families, provided their parents are healthy and come from small families, are most liable to pulmonary consumption. This is illustrated in the first one hundred, and in the first fifty of the third one hundred cases.

3. That both the youngest and the oldest members of small families are liable to pulmonary consumption, while the intermediate members are less susceptible to it, even though the parents and grandparents were healthy and became aged; provided, that either or both parents come from the youngest members of numerous families. This is well demonstrated by the second one hundred, and the second fifty of the third one hundred cases.

4. That children born of parents having phthisical antecedents are subject to the same law of liability as those children whose parents are healthy but come from the youngest of numerous families, with the exception that it is not necessary for one or both parents to come from the youngest of their families. This is clearly shown by the fourth one hundred cases.

5. That those children who are born within a year after the birth of the preceding members are more liable to pulmonary consumption than those who are born two or three years apart.

6. That children born of phthisical parents are liable to pulmonary consumption three years earlier on the average than those born of healthy parents. This is shown by contrasting the average age of the patients of the first one hundred cases with that of the fourth one hundred cases.

7. That parents with a family history of consumption are less prolific by nearly one-half than those who are healthy. This is shown by comparing the average number of children in the patient's families of the first one hundred cases with those of the fourth one hundred cases.

8. That, given a patient coming from a numerous family, of which the parents came from medium-sized or small but healthy families, we can predict that the patient is the, or one of the, youngest of the family; or, given a patient coming from a small family, of which the parents came from numerous families, and were among the youngest but healthy, we can predict that the patient either belongs to the youngest or the oldest, and not to the intermediate ones of his family; or again, given a patient coming from a small family, of which the parents came from a numerous family, but who have a phthisical history, we can predict that the patient belongs to either the older or the younger members, provided the patient's parents are not the youngest of their families; if they are the youngest, then the intermediate members are not exempt, although even then more so than those of either extreme.

In concluding this interesting subject, I hope that sufficient evidence has been brought forward to show that the environment of the modern man, so far as his shelter and occupation are concerned, is directly opposed to that of his savage progenitor; and hence through the operation of the law of adjustment of internal to external relations, his respiratory organs have been so changed as to predispose them to pulmonary consumption. I have also endeavored to show that, under certain conditions, the process of reproduction has the power of decreasing the vital resistance of the individual organism, and thus prepares it for the evolution of the same disease. Converging, therefore, both the external and the internal evidence as here given, we can, from this source alone, predict, with a great degree of certainty, which, from a certain number of individuals, are most prone to become a prey to the greatest scourge of modern civilization.

Note.—Since finishing this paper, I have collected a number of cases of phthisis coming under my own observation, accompanied by the necessary data, and all of them confirm the close relationship between reproduction and the liability to pulmonary consumption which seems to be so firmly established by the history of these four hundred cases. As soon as I have collected a sufficient number of such cases, I shall tabulate them for publication.

1716 Chestnut St., Philadelphia.

AN ANALYSIS OF FORTY-FIVE CASES OF DIPHTHERIA.

By E. C. CARTER, M.D.,
Assistant Surgeon U. S. Army.

As some medical magazines have recently contained articles asserting that sundry drugs or methods of treatment were certainly, or almost certainly, curative in diphtheria, I shall not apologize for laying before the numerous readers of The Medical News, the result of an experience derived from observing forty-five cases of that grave disorder. I had at first no favorite drug or method of treatment, and while the results strongly indicate to my mind the advisability of the use of bichloride of mercury, I prefer that each physician, who chooses to read this paper, should draw his own conclusions from the data I shall furnish.

In February, 1884, an epidemic of diphtheria appeared near Fort Thomas, Arizona. It was reported on what seemed trustworthy authority that ninety or more persons had died of the epidemic within fifteen days, at a mining town not very far from Fort Thomas.

The disease gradually spread down the Valley of the Gila, and made its appearance at every settlement near that stream. The weather was warm, 70° to 90° F. at noon, and in the earlier part of the time during which the epidemic prevailed the sky was cloudless. The water supply wherever the disease appeared, was drawn from the Gila River or from shallow wells. The houses were of sun-dried

brick—adobes—small, poorly ventilated, and were usually roughly furnished within. The walls were porous, and the floors commonly of earth. The disease always progressed much more favorably when the patient's friends could be induced to allow the sick-room to be thoroughly ventilated. But among the Mexicans and most frontier people of a certain class there exists the greatest imaginable fear of air-draughts, and of taking cold. Commonly the authority of some old woman overbalanced the most stringent orders and pathetic appeals of the physician. The friends of the patient usually remained in his chamber. And as there were often as many as fifteen persons, including children, in a low-pitched room twelve by fourteen feet, with one small door and a microscopic window, there was no theoretical difficulty in accounting for the spread of the disease.

The first case which came under my observation was that of a Mexican boy, ten years of age. He was moribund when I saw him, and before my assistant could run two hundred yards to get the instruments necessary to perform tracheotomy, the boy died—thereby, no doubt, saving me from the opprobrium of performing a fatal operation. The patient's neck was swollen, the cervical and submaxillary glands hard and prominent. The diphtheritic membrane covered the fauces and lined the nasal cavity, extending over the upper lip where it had been excoriated by the discharge from the nostrils. The cause of death appeared to be asphyxia, and the operation of tracheotomy was in consequence believed to be indicated. No post-mortem examination was permitted in this or in any case.

Cases 2, 3, and 4 were children of a Mexican mother and an American father. The symptoms were the usual symptoms of diphtheria. The prostration in cases of half-breeds was always very considerable. These cases were treated by a local antiseptic application—wash and spray—a wash of lime water, and by the internal administration of this mixture.

R.—Potass. chlorate	ʒj.
Muriated tinct. of iron	ʒij.
Quinia sulph.	gr. xv.
Sodium hyposulphite	ʒj.
Alcohol	ʒj.
Water	q. s. ʒvj.—M.

One or two teaspoonfuls were given three times a day.

I found this prescription in an article by Dr. F. Peyre Porcher, and it did me yeoman's service. Dr. Porcher said he believed this mixture possessed the virtues of a prophylactic against diphtheria, but requested that those who used it for this purpose should report their success or failure. I regret to be compelled to state that in no case was any individual saved from an attack of diphtheria by taking this mixture, provided he remained in the room or house in which there was a case. The remedy was thoroughly tried in at least twenty cases, but proved of no value as a prophylactic. After the development of the disease the remedy seemed to me to be of very great value.

Of these three cases, 2, 3, and 4, 2 and 4 recovered while 3, who seemed least ill of all, died suddenly. A Mexican girl, aged ten, also died suddenly. These two fatal cases appeared to die from failure of the heart's action due to paralysis.

Case 10 was that of a frail girl, eight years of age. Her throat was much swollen, and the fauces were choked with membrane, which exhaled a horrible stench. She died within twenty-four hours after the disease declared itself. Lime water, applications of various antiseptics, full doses of Porcher's mixture and of stimulants were used in vain in this case.

Case 11 was that of a robust girl of six years. She received the same treatment which Case 10 received, and likewise died. Case 12 was the younger brother of the girl mentioned as Case 10, and when seen was equally as ill as she. He received one-sixty-second of a grain of corrosive sublimate, and began to improve after taking the first dose. He made a good recovery. Cases 14, 15 16, 17, 18, 19, and 20 occurred in the same family. Here the prophylactic effect of Dr. Porcher's prescription was *nil*. Bichloride of mercury was used internally and locally from the beginning of the disease in all of these cases. All made good recoveries. Cases 21, 22, 23, and 24 occurred in one family in spite of the persistent use of Dr. Porcher's prescription. Bichloride of mercury was used internally in these cases, and all recovered. One suffered from paralysis of accommodation for some months. Cases 25 to 31 inclusive recovered under the internal administration of the bichloride of mercury, but two of these cases suffered from paralysis of accommodation. Case 32 was a robust soldier. As the case was a mild one, Porcher's prescription alone was used. The patient recovered, but twelve months later was suffering from paralysis of the soft palate, which appeared a few days after he began to suffer from diphtheria. His voice had a muffled nasal sound, and when he attempted to swallow liquids, they would regurgitate through the nose.

Case 33 recovered under the bichloride treatment with temporary paralysis of the lower limb. Case 34, under the same treatment, recovered with paralysis of accommodation. Cases 35 to 45 inclusive, were treated with bichloride of mercury internally, and all made good recoveries, with three cases of temporary accommodation-paralysis (one accompanied by paralysis of the soft palate), and one of temporary partial paralysis of the lower limb accompanied by formication. In one of these cases, acute gastritis was set up by the bichloride of mercury.

The following table exhibits the results of the treatments.

Thirty-three cases treated by bichloride of mercury gave no deaths, but 12 paralyses, not one of which was permanent. All of these cases of paralysis were among children. The 11 cases treated by other remedies gave 4 deaths and 1 permanent paralysis. The case of permanent paralysis was the case of a man aged twenty-six years.

In considering the number of cases successfully treated by the bichloride of mercury, it is well to bear in mind that these cases occurred later in the epidemic than those treated by other methods.

No. of case.	Sex.	Age.	Condition when seen.	Treatment.	Result.	Sequelæ.

34	Female.	13 "	Very ill.	" " "	"	Paralysis of accommodation.
35	Male.	1 "	Not very ill.	" " "	"	
36	Female.	8 "	Very ill.	" " "	"	Paralysis of lower limbs, nervousness, and formication.
37	Male.	6 "	Not very ill.	" " "	"	Paralysis of accommodation and of soft palate; and
38	Female.	4 "	Very ill.	" " "	"	Acute gastritis due to poisoning by bichloride of mercury.
39	"	18 "	Not very ill.	" " "	"	
40	"	15 "	Very ill.	" " "	"	Paralysis of accommodation.
41	"	12 "	Not very ill.	" " "	"	
42	Male.	8 "	" " "	" " "	"	Paralysis of accommodation.
43	"	6 "	" " "	" " "	"	
44	"	28 "	" " "	" " "	"	
45	"	32 "	" " "	" " "	"	

Some of these, however, were as severe when first seen as any from Cases 2 to 11 inclusive. Case 38 was as ill as any patient I have seen recover.

The success attending the use of bichloride of mercury would have led me to believe that many of the cases treated with this drug were cases of pharyngitis, if paralysis had not frequently occurred.

The diphtheritic membrane usually began to come away in from two to four hours after the administration of the bichloride of mercury. The dose varied from one-twenty-fourth to one-sixty-second of a grain, according to age and effect.

COLUMBUS BARRACKS, OHIO, September 16, 1886.

BELLADONNA POISONING.

BY J. H. BRADSHAW, M.D.,
OF ORANGE, N. J.

WE not infrequently hear of very large doses of medicine being taken by mistake, and a toxic effect, naturally expected, failing to ensue. It is quite common to ascribe this fortunate failure of symptoms of poisoning to put in their appearance to the diminished strength of the drug taken. I have heard of a teaspoonful of tincture of aconite being taken by a small child, without giving any alarm to the family. The case I am about to report can hardly be classed as one in which dangerous symptoms failed to appear because of a poor preparation of drug used, as the one taken was the normal liquid of belladonna leaf (Parke, Davis & Co.).

A patient, a young lady to whom I had given a mixture containing belladonna for asthma with good results, came to my office, stating that her medicine had been lost, and that she desired a new prescription. This I gave her, and, as she was unable to have it filled at the drug-store that night, and was suffering from her complaint, I handed her about two drachms of the normal liquid of belladonna, telling her to take five drops in water before going to bed. As she had been accustomed to take her other medicine in teaspoonful doses, she disregarded

the new directions, and, upon retiring, took an overflowing teaspoonful of the drug. The dose was taken at ten o'clock. Soon after eleven, the mother of the patient was awakened by the labored breathing of her daughter, and becoming instantly alarmed at her pallid appearance, summoned her physician. I arrived about two hours after the drug had been taken. There had been no vomiting, and when I reached the room the patient was standing in the middle of the bed, highly delirious, swaying from side to side, respiration difficult, and sobbing, heart beating about 120 to the minute, and the radial pulse extremely feeble. A small rim of iris surrounding an extremely dilated pupil instantly gave the diagnosis. Although a sufficient period of time had elapsed since the dosage for most of its absorption, still my first efforts were made in causing emesis. Unfortunately, I had no access to apomorphine, and had to resort to such agents as mustard and yellow sulphate of mercury, by the mouth. After struggling with the patient for a long time in vain attempts to make her swallow, efforts of this kind were abandoned, and a half grain of morphine was given hypodermatically.

I have struggled with the delirium of fevers, and with the delirium of tremorous drunkards, but I never before met a patient so violent as was this poor girl. I remained with her the remainder of the night, and repeated the morphine in quarter grain hypodermatic doses; I do not now recall exactly how many, probably *half a dozen*. The morphine acted beneficially almost from the first, and the patient, toward morning, went into a slumber, respirations falling to ten per minute about five o'clock.

The next day the patient dressed herself, and spent the greater portion of it upon a sofa, and in a few days was as well as ever. It is interesting to add that for about six months the patient had no attack from her asthma.

MEDICAL PROGRESS.

ACUTE PNEUMONIA IN UTERO.—DR. HENRY STRACHAN writes to the *British Medical Journal* of November 6, 1886:

I am not aware whether the following case is the first recorded. I have been unable to find any account of a similar one, but whether that be so or not, it seems to me of great interest, and worthy of being placed on record,

A patient, Nancy M., was admitted into the hospital under my care in December last, suffering from acute pneumonia (whole of left lung), and a history of illness covering the four days previous to admission. She was eight months pregnant. On the evening of the day of admission, her temperature was 103.6° Fahr., and she was delivered of a female infant. The infant died in less than twenty-four hours after birth, with symptoms of acute pneumonia. A post-mortem examination showed acute pneumonic consolidation of the whole of the left lung. The mother made a rapid and good recovery.

Whilst there is ample evidence that the other acute specific diseases (so-called "fevers") are capable of being transmitted by the pregnant woman to her offspring yet *in utero*, this is the first time I have had any evidence that the "acute pneumonic fever" could also be so transmitted.

GALVANOPUNCTURE IN GYNECOLOGY.—APOSTOLI has formulated the following practical rules in regard to the employment of galvanopuncture in gynecological practice:

1. In the treatment of either the uterine parenchyma or of the periuterine cellular tissue, great care should be exercised that the peritoneum be not implicated in the puncture.

2. Facilities for the elimination of the products of suppuration should be maintained, in order to avoid injection, and to permit of local antiseptic treatment.

3. Short punctures, of one to two centimetres (five to ten lines), are always preferable to those of greater depth.

4. The bladder should always be carefully sounded in all directions, in order to avoid its implication.

5. In all cases of lateral or posterior puncture, the localities of arterial pulsation should be determined by digital examination, and the perforation of the larger vessels carefully avoided.

6. Enforced rest in bed, of from one to several days, is demanded of all patients thus treated.

7. Before and after each puncture, an antiseptic vaginal injection is given, and a tampon of iodoform gauze is to be retained in the vagina until the complete cicatrization of the orifice of the puncture is effected.

8. All sexual approach is prohibited until the cure is complete.—*L'Union Médicale*, Oct. 19, 1886.

CANTHARIDES IN THE BITES OF RABID ANIMALS.—DR. KARCHEVSKI mentions in the *Russkaya Meditsina* that he has successfully treated some patients who had been bitten by a rabid wolf with cantharides. The wolf attacked three men, inflicting on the first a large and deep wound in the left groin, a piece of skin several square inches in area being torn off. The other men were wounded in the face, legs, and arms, but more superficially. Still the bites of a rabid wolf are well known to be peculiarly dangerous. Dr. Karchevski remembered a conversation he had had with Professor Lashkevich, in which the latter had suggested cantharides as a remedy in hydrophobia, and he therefore made up his mind to give it a trial. Cantharides plasters were applied to all the wounds, and powdered cantharides was administered to each of the three patients in doses of a grain a day. The internal administration was continued for a week, until the patients complained of some heat in the urethra. Seven months having passed, and all the patients being still perfectly healthy, the author thinks the case worth recording, though he is quite aware that *post hoc* is not necessarily in this instance *propter hoc*.—*Brit. Med. Journ.*, Nov. 6, 1886.

ANTI-DIARRHŒIC PILLS.—TROUSSEAU recommends the following formula in rebellious cases of diarrhœa which have resisted treatment by salines:

R.—Powdered ipecac.	. . .	gr. viij.
Extract of opium,		
Calomel		āā gr. iss.

To make twenty pills.

The dose, one to three pills daily, is continued for a week or longer.—*L'Union Médicale*, Oct. 24, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SATURDAY, NOVEMBER 27, 1886.

THE INOCULATION OF TUBERCULOSIS BY OPERATIONS FOR ITS RELIEF.

UNTIL very recently it seemed as if the indications for operation upon tuberculous foci in the bones and joints had been clearly laid down, and the propriety and usefulness of such operations had been fully established. But in the Thirteenth Congress of German Surgeons, KÖNIG called attention to the possibility of surgical interference hastening the death of a patient by becoming the means of inoculation of the specific virus, or specific germ, of tuberculosis, thus leading to the rapid development of acute miliary tuberculosis.

At the last Congress VOLKMANN also recognized and admitted this possibility, but no systematic and complete presentation of the relative frequency of such an unfortunate issue to operations intended to be strictly conservative had as yet been presented. The first attempt in this direction has been recently made by WARTMANN, of St. Gallen, who, at the suggestion of Feurer, has used the material of the latter's service in the hospital at St. Gallen, as a basis for an elaborate study of the relation of operations upon tuberculous joints to subsequent outbreaks of general tuberculosis. To this material Wartmann has added an analysis of all the reliable reports bearing upon the matter which were accessible to him, and has embodied the results of his work in an admirable paper published in the *Deutsche Zeitschrift für Chirurgie*, Bd. xxiv. Hefte 5 und 6, 1886.

In this paper Wartmann restricts himself to a study of the relation of resections to the outbreak of acute miliary tuberculosis. He gives a detailed account of the history of 74 cases in which Feurer performed such operations for tuberculous disease of the joints. Of these, 1 was done at the shoulder-joint, 10 at the elbow-joint, 3 at the wrist-joint, 18 at the hip-joint, 38 at the knee-joint, and 4 at the ankle-joint. In the whole series there were eleven deaths while the patients were under observation, and one followed five months after a resection of the elbow-joint, the patient having pronounced lung disease at the time of the operation. Two followed resection of the wrist-joint; one occurred three months after the operation in a miserable patient with lung disease at the time of the operation; and one occurred ten months after the operation in a patient who had a number of tuberculous foci so old that they could not be attributed to inoculation by the operation. Four deaths followed resection of the hip-joint; one from acute carbolic acid poisoning; three from chronic tuberculosis at periods of two years, one year, and nine months, respectively, after the operation; and one died in seven days after the operation with fresh miliary tubercles in the lungs and small caseous foci in the pericardium, besides tubercles elsewhere. This case, Wartmann thinks, may have been one of inoculation at the time of operation. We cannot admit as much without question, since the patient had before the operation a large abscess above Poupart's ligament, and after the operation vomiting on the second day, with evidence in the urine of carbolic acid poisoning. There can be little doubt that the operation hastened the patient's death; but we think it very questionable if the fresh tubercles in the lungs, or the recent pleurisy with bloody effusion ought to be attributed to inoculation at the seat of the wound. May not the inoculation have arisen from the caseous foci in the pericardium under the influence of the vomiting and the depression of carbolic acid poisoning?

Hartmann records, further, two deaths after resection of the knee-joint. One of these occurred five months later from erysipelas attacking a fistula, which remained after the operation. The other death occurred three and a half months after the operation, in a thin and feeble girl, who had no other evidence of general tuberculosis at the time of the operation. At the time of death the patient had cavities in both lungs and tuberculous ulcers in the bowels. This case Wartmann properly excludes from his list of acute tuberculosis due to inoculation, although he thinks that some bacilli may have found their way to the lungs and bowels in this way. After resection of the ankle-joint, one death is here recorded. The patient was a well-nourished boy, four years old, with slight enlargement of the glands of the neck and of the groin of the affected side. About three weeks after the operation the patient had an attack of pleuro-pneumonia, from which he

recovered. Three and a half months after the operation symptoms of basal meningitis appeared, and the lad died two weeks later, having tubercles in the pia mater and in one lung. Wartmann classes this case with the one of death after resection of the hip-joint, mentioned above, as being possibly instances of inoculation from the wound. But we may say of this case what we have said of the other, that we cannot admit as much as Wartmann does in regard to it. Both cases are open to the same objection which we urged in THE MEDICAL NEWS of April 3, 1886, in regard to two cases of so-called inoculation of wounds with tuberculosis, reported by Kraske in November, 1885.

Wartmann adds to the statistics of the hospital at St. Gallen 763 cases of resection of joints for tuberculous disease, collected from other sources, with 214 deaths, and of these 24 were due to acute miliary tuberculosis. This makes a total of 837 cases, with 225 deaths, of which 26 may be attributed to infection from the operation wound. Wartmann does not venture to generalize much upon these figures, but he very sensibly suggests the collection of the statistics of a large number of cases treated without operation, with which to institute a comparison.

We may go a little further than does the author, and point out the relative infrequency of even a presumable inoculation by operation. Only about one-tenth of all the deaths are attributed to this cause, and only a little more than three per cent. of the whole number of patients can be supposed to have lost their lives by this accident. When to this we add the fact that König, in his *Die Tuberculose der Knochen und Gelenke*, 1884, reports only about sixteen cases in which infection followed operation, among the many thousand cases treated in the hospital at Göttingen, and that Volkmann and Ollier, with their very large experience, have observed it so rarely that it has not until recently attracted their special attention, we cannot but conclude that while the subject is eminently worthy of serious and careful study, the danger of setting up general tuberculosis is not a formidable objection to operation for the relief of tuberculous disease of the bones and joints.

In conclusion, we would call attention to one of the most interesting points in connection with Wartmann's paper, namely, the evidence it furnishes that the limitations of a comparatively small hospital offer no insuperable obstacle to valuable work. Careful study of a few cases under personal observation, joined with an examination of what has been published by others in regard to similar ones, will enable even the most modest worker to add—as Wartmann has added—a worthy contribution to the common fund of surgical knowledge.

BRIGHT'S DISEASE AND APOPLEXY.

THE condition of the arteries is an index of a man's age. He is old or young, the prospects of life are bad or good as these vessels are hard or soft, stiff or elastic. The circulatory apparatus is nothing more than an elaborate system of supply tubes with the heart as a central pumping station, and the kidneys as waste pipes of elaborate and peculiar construction. So close in health is the functional relation of these three parts—heart, arteries, and kidneys—that we almost naturally expect to find them associated together in disease.

Although the broad clinical and anatomical fact of the close connection of certain chronic forms of renal disease with cardio-vascular changes is universally recognized, yet the precise mode of relationship is still under discussion. Unquestionably in a majority of cases the renal trouble is primary, while the changes in the heart and vessels are secondary to it. But there are instances in which the chronic nephritis seems a sequence of the arterial disease. It has been for years a matter of common observation that a large proportion of all cases of hemorrhage into the brain were in persons with arterial degeneration and kidney disease of the form known as interstitial nephritis. This is essentially a slow, progressive malady, insidious to a degree, creeping on from year to year, producing, perhaps, but few symptoms, and in too many instances the patient, without warning, is seized with serious illness which may prove quickly fatal.

The cardio-vascular changes which this form of Bright's disease brings with it are of the utmost importance with reference to apoplexy, one of the most common events in this condition. The tension of the blood in the arteries is increased, and the pulse is felt to be hard and incompressible. The existence of this so-called renal pulse may give a cautious physician the first clew to the nature of the trouble. The vessel walls also become harder and less elastic, the condition described by Gull and Sutton as arterio-capillary fibrosis. The arteries of the brain are very prone to participate in this change. Lastly, the heart hypertrophies and supplies a force capable of maintaining sufficient pressure in the diminished capillaries of the kidneys to furnish the full quota of urine; with variations in the frequency with which certain symptoms, such as œdema, occur, these are the essential features in the history of most cases of chronic interstitial nephritis.

The recent death from apoplexy of an eminent citizen, who had for some time been the subject of this form of renal disease, illustrates forcibly one of its most formidable dangers. We have gradually come to regard the disease as a very chronic malady, lasting for years, and with which the individual, if careful, may enjoy a fair measure of health, and

even do active work, but if once fully established, there are risks of accidents, of which cerebral hemorrhage is the most serious.

On the occasion of the death of Vice-President Hendricks we called attention to the intense wear and tear of political and business life in this generation as tending to induce arterial disease, and the same is an important factor in the increasing prevalence of chronic Bright's disease. That this increase is in the business and professional classes of the community rather than among the workingmen, is an opinion held by men of wide experience.

SPERMATORRHŒA IN GONORRHŒA.

The occurrence of a genuine spermatorrhœa, that is to say, an involuntary discharge of semen without erection or orgasm, is rare. Still, it is known to take place often enough to merit attention; and there can be no doubt that it sometimes occurs without producing any subjective effects sufficient to attract the attention of the patient, so that only accident or rare detective ability on the part of the physician leads to its discovery. Whether or not it is to the advantage of the patient that such unfelt losses of seminal fluid should be known to him or to his physician, cannot as yet be positively asserted. There are those who feel sure that such losses are injurious, others are not so clear on this point. Among the former is Fürbringer, of Berlin, who has for some years made a special study of the conditions in which spermatorrhœa may take place, and who has published a paper on this subject in the *Deutsche medicinische Wochenschrift*, No. 42, 1886.

In studying the causation of spermatorrhœa Fürbringer finds that a previous attack of gonorrhœa is the cause of spermatorrhœa in the majority of cases, as compared with true neurasthenic spermatorrhœa. He has been able to determine this fact for himself by a careful examination, during four and a half years past, of the urine of patients under treatment for chronic gonorrhœa. In making his examinations he has been careful to exclude cases in which the presence of a small quantity of semen could be attributed to natural coitus, or nocturnal emissions, or the practice of onanism in the correct sense of the word, or of masturbation, as well as those cases in which straining at stool, or in any other way has forced out a little semen from the vesicles. Excluding all such cases, Fürbringer has found in one hundred and forty cases of chronic gonorrhœa, no less than twenty-five patients with what he calls "latent spermatorrhœa"—that is, with the presence of a few spermatozoa in the urine, totally unsuspected by themselves. Fürbringer's investigations seem to indicate that in the spermatorrhœa of gonorrhœal origin the discharge is not mixed with the secretion of the prostate, is devoid of the characteristic odor of the seminal fluid, and contains no Böttscher's crystals, while all of these are present in cases of neurasthenic spermatorrhœa.

Fürbringer explains the pathological process and mechanism of this form of spermatorrhœa as follows: By the effect of a chronic inflammation of the deep urethra, the ejaculatory duct becomes insufficient, and thereafter the intraäbdominal pressure caused by straining at stool, or in passing water, or in any other way, causes expression of the contents of the seminal vesicles without the participation of the prostate in this act. Fortunately, according to the observations of Fürbringer, this form of spermatorrhœa is not prejudicial to the power of coitus, or of begetting children.

These observations and opinions of Fürbringer are of decided interest, and it is quite possible that the systematic examination of the urine of patients who have chronic gonorrhœa may throw a light upon the processes of spermatorrhœa which will be of the greatest value in understanding this disorder.

The President on November 18, appointed Lieutenant-Colonel John Moore, Assistant Medical Purveyor, to be Surgeon-General of the Army. Dr. Moore is a native of Indiana, and entered the service as Assistant Surgeon in June, 1863, and after doing duty in Florida and in the Utah Expedition of 1857, he was ordered in 1861 to the Marine Hospital at Cincinnati. In June, 1862, he was promoted to be Surgeon, and was assigned to duty as Medical Director of the Central Grand Division of the Army of the Potomac. In May, 1863, he was transferred to the West, and was appointed Medical Director of the Department and served with the Army of the Tennessee at the close of the siege of Vicksburg. He served through the campaign ending in the capture of Atlanta. He accompanied General Sherman's grand army on the famous march to the sea and through the Carolinas.

Subsequent to the war he served as Medical Director of the Department of Mississippi; was on duty in New York as member of the Army Medical Examining Board. He was Medical Director of the department of Texas and of the Columbia. He was promoted Assistant Medical Purveyor, with the rank of Lieutenant-Colonel, October 8, 1883, which rank he now holds, and is stationed in San Francisco, Cal. He was brevetted Lieutenant-Colonel for gallant and meritorious services in the Atlanta campaign, and Colonel for faithful and meritorious services during the war.

It has been stated that Dr. Moore was not an applicant for the Surgeon-Generalship, but that his excellent record and proved executive ability have probably commended him to the favorable notice of the President. He can hold the office for four years

before he will be eligible for retirement on age. He has been ordered to report at Washington at once.

Dr. Bernays, of St. Louis, last week, successfully performed a gastrotomy upon a tailor aged forty, for the extraction of an ordinary silver-plated dinner knife 9½ inches long, which he had swallowed in imitation of the juggler's feat.

There came, accidentally, into our possession, a short time ago, a memorandum, signed by the late Joseph Pancoast, relating to a remarkable injury received by the late James P. White, the well-known gynecologist of Buffalo. The note was as follows: "A front segment of the atlas vertebra, a little more than an inch on the superior margin, a little less below, with the facette which received the odontoid process. It was in the possession of Professor Granville S. Pattison, to whom it was loaned by Dr. White, to show Professors Joseph Pancoast and McClellan. It is probable that the transverse ligament retained its hold on the two extremities of the remaining fragment of the atlas, thus protecting the spinal marrow from injury. This bone in possession of Professor Pattison I repeatedly saw, and carefully examined; he exhibited it to his class, and it was mislaid or lost. At the request of Professor White, I make this statement of facts. This bone was in our possession in 1838–39–40, or thereabout. I then understood and believed (since confirmed by conversation with Professor White), that it came from his throat, coming out through the mouth as a consequence of ulceration; the result of an accident while riding in a stage-coach on the morning of December 17, 1837. The bone was discharged at the expiration of forty-five days after receipt of the injury."

This statement, signed "Joseph Pancoast," records an interesting and remarkable accident which, so far as we know, has not been made public, and of which there are only one or two instances mentioned in literature.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 10, 1886.

I. Minis Hays, M.D., in the Chair.

Dr. Thomas J. Mays read a paper on

SOME OF THE CAUSES OF PULMONARY CONSUMPTION VIEWED FROM A DARWINIAN STANDPOINT.

(See page 589.)

Dr. J. C. Wilson thought that we must hesitate to accept fully the conclusions which the author draws from his studies. He has used, in speaking of this subject, the three terms, pulmonary tuberculosis, pulmonary consumption, and phthisis, interchangeably. He has called attention very carefully to the well accepted views that indoor occupations, bad ventilation, etc., are predisposing causes of this group of affections, but he certainly fails to establish the fact that they are exciting causes.

With reference to the second part of the paper, it is also true that influences which unfavorably affect the offspring, are rather predisposing than exciting causes of the disease. The time has scarcely come when we can satisfactorily discuss this subject. We are now passing through a transition period with reference to the etiology of pulmonary phthisis. He was one among those who regard pulmonary consumption in its ordinary form as a chronic infectious disease. With this view of the subject, the conditions spoken of by the author could only be regarded as predisposing influences.

Dr. J. H. Musser said that there is no doubt that a want of correspondence of the body to its environment leads to such a condition of the system as predisposes to phthisis. He is a profound believer, however, in the specific origin, and in the infectious nature of tuberculosis. He cannot explain the occurrence of cases of phthisis simply by the surroundings of the individual. There are on record instances of locations which, for a long period of time, have been free from tuberculosis; in fact, it never occurred there until, from source of infection, one or two cases have arisen, and from these the disease has spread, so as to become almost epidemic. Under such circumstances, there must have been some distinct specific agent. Again, a person whose family history is good, one who has lived largely an outdoor life, a person of fine physique, surrounded by the most favorable environment, may develop a severe form of tuberculosis. In such a case, the cause is direct contagion. There is another line of thought which is brought out by this paper, and that is with reference, plainly speaking, to breeding. The intermarriage of races, of kinship, of individuals of various diathetic vices, undoubtedly produces individuals that are predisposed to phthisis. When we are as careful as the stock-breeder about the purity of strain, then we will get fine men, and that anatomical condition which predisposes to phthisis will be effaced. He has seen the statement made that pulmonary consumption is rare in the pure negro and in the pure Indian, even when their surroundings have been changed, as compared with the negro or Indian with mixed blood. With regard to tuberculosis in animals in a state of confinement, the question of possible contagion must be considered. Who can tell but that the cages or places in which they are confined are reeking with bacilli. Unless contagion is completely excluded, he thinks that we are not warranted in stating that these animals develop tuberculosis as a result of the change in their environment.

Dr. Harrison Allen said that a Darwinian study must rest upon a morphological basis. Darwin gave great attention to the subject of variations. It is not necessary that variations should be found in a normal state of the body; they may be of the abnormal state as well. It is a matter in dispute as to the significance of variations. Darwin inclined to look upon the majority of them as signs of progressive change. There is no doubt that many of them are retrogressive. Virchow claims that all variations are pathological. The speaker expressed a wish that Dr. Mays had developed his theme

more into the direction indicated. Clinical medicine should rest firmly upon anatomy. In pursuing a research to ascertain the etiology of disease, the student can take no step (if he follow the methods of Darwin) which is not guided by the tenets of morphology. Dr. Formad has admirably defined the morphological basis of tuberculosis. He did not mention the fact that the cause of the left side of the thorax being slighter than the right is due to the circumstance that the left lung is smaller and weaker than is the right. Its lobes are fewer in number, and it lacks a bronchus in advance of the pulmonary artery. Here is found the essential reason why the left lung is so commonly involved. But to secure this fact, the entire mammalian series had to be investigated. This has been done by Aeby. May it not be surmised that gross variations of the arteries, as well as of other structures of the body might be found if they were sought for? Beneke determined the essential condition in rickets to be a preternatural increase of diameter of all the arteries. Virchow obtained an opposite result in chlorosis. It may be said, in an axiomatic way, that a well-defined clinical condition will be always found to rest upon an equally well-defined group of structural peculiarities.

Dr. S. S. Cohen said that the mobile chemistry of the organism favors decay as well as repair, and it is only under favorable circumstances that development can proceed to its greatest perfection. The most trying period in the life history of cell, individual or species, is that in which it is adjusting itself to its changed surroundings. He was not sufficiently expert in mycology to determine the true relation between the bacteria and the disease to which they are supposed to give rise, but he can certainly conceive, as held by Dr. Mays, that in the transition from savagery to civilization, and in the readjustment of organism to environment, such conditions could arise as would lead to the development of phthisis without the presence of any infectious or specific principle whatever. We know that organs atrophy from disuse, and there is no reason why the cellular elements of the lungs should be subjected to any other laws than those which govern living cells in general. He might add to illustrations cited by the lecturer, the fact that the majority of retired pugilists die of pulmonary consumption.

Dr. E. T. Bruen said that one of the interesting points suggested by this paper, is the important bearing which a study of the predisposing influences has upon the proper management of cases of phthisis. We undoubtedly have the anatomical conditions which have been mentioned, and which, of course, cannot be removed, but by appropriate gymnastics the chest may be brought to resemble more closely the ideal chest. Again, the study of the relation of crowd poisoning to conditions interfering with respiration is a very practical point. As long ago as the time of MacCormac, the danger of pre-breathed air was recognized. Purity of the atmosphere is one of the prime conditions of a climate favorable to cases of phthisis. It has been shown that in elevated altitudes, when factories have been established, and the condition of the inhabitants is similar to that of those living in cities, phthisis is rife. Under such circumstances the disease is more frequent than it is in the plains, where crowding does not exist. If the process of nutrition can be brought to such a point that the waste will be more than counter-balanced, much will be accomplished in the way of bringing about the arrest of the disease, and causing a so-called cure. The reason that we cannot do more, is that we have so many anatomical conditions against us.

Dr. T. Mays said that he purposely abstained from giving a definition of the terms to which reference had been made, but had included under the head of pulmonary consumption all the different forms, both tubercular and non-tubercular. Since confessions were in order, he too had one to make, for he experienced a change of view in regard to this question; for when the discovery of the bacillus tuberculosis was announced by Koch, he hoped that it would be a lever by which we could combat the disease. After a thorough study of this subject, both from a theoretical and practical standpoint, he was convinced that the bacillus is not the causative agent, and hence of no therapeutic importance. In regard to the anatomical peculiarities which have been mentioned, he had considered this matter, and concluded that they might possibly be considered as results. There are no investigations of which he is aware that show the shape and size of the respiratory and circulatory organs in persons before they became the subjects of this affection, and until this is done, comparative speculation is useless.

He did not recall having heard of an instance similar to that related by Dr. Musser, where the disease has become epidemic in a locality where it had not before existed. If this were proven, it would be important testimony against the origin of the disease in the manner which he had described. Dr. Musser also stated that the pure Indian is less liable to consumption than the Indian with mixed blood. Yesterday he received from Dr. Given, of the Carlisle Indian School, a letter in regard to this point. He stated that the Indian with mixed blood is less liable to phthisis than the full-blooded Indian, and this fact substantiates the theory of the development of consumption which he had advocated in his paper this evening.

NEW YORK STATE MEDICAL ASSOCIATION.

Third Annual Meeting, held in New York on November 16, 17, and 18, 1886.

The third annual meeting of this Association was opened in Lyric Hall by the President, Dr. E. M. Moore, of Rochester. The scientific interest of the meeting centred around the special discussion which had been arranged on the subjects of gunshot wounds of the intestines and on eclampsia,

Dr. Wm. S. Tremaine, of Erie County, opened

THE DISCUSSION ON GUNSHOT WOUNDS OF THE INTESTINES.

He said that the chief thought that occurred in connection with them is their marked fatality. The universal opinion being that a perforating gunshot wound of the intestines permitting extravasation into the peritoneum is hopelessly fatal, consequently, until quite recently the attention of surgeons was chiefly directed, in their treatment, to some form of euthanasia—and were surgery a non-progressive art, if its recent magnificent triumphs offered no hope for the future, he might well end here and be without excuse to pro-

pound certain questions for consideration. Happily there is hope. The impunity with which in these latter times the abdominal cavity has been opened and extensive surgical manipulations carried on therein gives reasonable ground for hope, that the "do-nothing system" will generally be abandoned and that laparotomy, where there is reason to suspect that the intestines have been wounded, will become a legitimate and successful surgical procedure. And this, without further preamble, opens to our consideration the first question—What are the reasons which lead us to suspect or believe that the intestines have been wounded? Or, in other words, does a group of symptoms exist which would lead to an accurate diagnosis of perforation of the intestines by penetrating gunshot wounds of the abdomen?

In seeking for the answer to this question recourse must be had to the literature of the subject, and of this, by far the most comprehensive is contained in the *Surgical History of the War of the Rebellion*, in which are tabulated 653 wounds of the intestines with a mortality of 80.3 per cent.

But here the meagreness of details of symptoms of reported cases is very marked. In a very few recorded cases such symptoms as "vomiting, small pulse, extreme restlessness" are given. The wound of the intestine was either inferred from the direction of the wound or demonstrated by the autopsy.

Without quoting extracts, it is sufficient for the present purpose to say that faint light is thrown upon the subject in most of the standard text-books, and that so far as books go, but little positive information can be gained as regards accurate diagnosis.

A somewhat extensive experience of the speaker, in wounds of this class, in both military and civil practice, leads to the following conclusions: that the calibre of the ball, the proximity of the weapon, and the position of the wounds of entrance and exit have an important bearing. That as regards general symptoms, the existence of prolonged shock, a lowered temperature, a feeble pulse, great restlessness, marked anxiety of countenance, accompanied by tympanites and great pain, taken in connection with the anatomical location of the wound, afford very strong evidence of a perforating wound of the intestines. That the escape of blood from the anus rarely happens soon after the injury, and is consequently of little value as a diagnostic sign.

Given a case of penetrating wound of the abdomen by a rifle or pistol bullet of from 32 to 45 calibre, fired at ordinary range, accompanied by the above mentioned general symptoms, the probability in at least nine cases out of ten would be death. Does the surgical art offer any plan of treatment by which this fearful rate of mortality may be lowered? In searching amidst the recorded thoughts of master minds in surgery, one finds this question often propounded, and occasionally the answer hinted at with more or less positiveness.

It is a subject for congratulation to us, that the most practical contributions to the answer are largely of American origin. Our own Gross, in 1843, wrote an *Experimental and Critical Inquiry into the Nature and Treatment of Wounds of the Intestines*, in which he makes the following statement: "It will not do for the surgeon to fold his arms and look upon the scene as an idle and disinterested spectator. Far otherwise; he has a duty to perform, and that duty consists in dilating the external wound, if it be not already sufficiently large, in hooking up the injured bowel, and inclosing the solution of continuity with the requisite number of stitches, at the same time that the effused matter is carefully removed with tepid water and a soft sponge. All wiping must, of course, be carefully avoided, as this would add much to the risk of peritonitis."

The question was debated by some of the older surgeons, and in 1836 Baudens advocated the enlargement of the wound and the application of the suture, and reports two cases of enterorrhaphy. Guthrie, after speaking of the frightful mortality, says: "The 'do-nothing system' is commonly followed by death. A well-regulated interference is likely to be more successful." In the Danish war, Lohmeyer advocated "a search for the opening, sew up the wounded knuckle, and to return the latter after removing effused fecal matter." In the Crimean war, similar views were advocated by Legouest. In our own war, these doctrines were carried out by Drs. Bentley, Judson, Gill, and Kinloch.

But in all this the question seems to be restricted to enlarging the wound, and in cases where the diagnosis of perforation was not doubtful, the method of making an incision in the linea alba seems not to have been considered. The propriety of closing by suture a perforation of the intestines is no longer debateable. The question before us is the propriety of incising the abdomen in the middle line: First, for diagnosis; second, to arrest hemorrhage; third, to sew up the wounds in the intestines, should any exist; and, fourth, to remove extravasated blood and fecal matter.

The knowledge gained by laparotomy for other troubles, such as abdominal tumors and the like, undoubtedly gave a great impetus in this direction; consequently, we find a great master in abdominal surgery, the late Dr. Marion Sims, uttering, in 1882, the following words: "I have the deepest conviction that there is not more danger of a man's dying of a gunshot or other wound of the peritoneal cavity properly treated, than there is of a woman's dying of an ovariotomy properly performed. Ovarian tumors were invariably fatal till McDowell demonstrated the manner of cure, which has now reached such perfection that we cure from ninety to ninety-seven per cent. of all cases, and by the application of the same rules that guard us in ovariotomy to the treatment of shot wounds penetrating the abdominal cavity, that there is every certainty of attaining the same success in these that we now boast of in ovariotomy." (*British Medical Journal*, March 4, 1882.) Let us hope that these bold words may prove, in a measure at least, truly prophetic.

I have stated laparotomy first, for purposes of diagnosticating; this is perhaps a debatable ground, for I take it that no surgeon would now question the propriety of exposing the abdominal cavity and suturing the wounds in the intestines, were such were known positively to exist, to do so, would be to abandon the case to inevitable death. Let us suppose a penetrating gunshot wound of the abdomen, where the indications are not clear that the intestines have been perforated (a point, by the way, almost always more or less in doubt).

Is it proper to incise in the middle line and explore? To this I answer, yes: First, because the intestines may be wounded; second, in any event, it is in nine times

out of ten required for the removal of effused blood. We have often in abdominal sections realized the difficulty of arresting hemorrhage from an exceedingly small vessel or oozing point. We are all familiar with the danger from effused blood allowed to remain in the cavity of the abdomen; third, the abdominal section adds but little, if any danger, when done under proper precautions, to which may be added, fourth, the assurance given to the patient that his intestines have not sustained a fatal wound, which cannot but have a marked tonic effect, conducive to recovery.

When the intestines are perforated there can be no longer any doubt as to the propriety of abdominal section, for just so certain as there is perforation, there will be fecal extravasation, and with this extravasation will follow peritonitis and death, providing the patient survive the immediate shock of the injury. Happily, the question of the advisability of the operation has been set at rest by at least three successful cases in America. It is doubtful if there is any well-authenticated case of recovery after a perforated gunshot wound of the small intestines with fecal extravasation, so no amount of negative evidence can weigh against the positive evidence of these successful cases of laparotomy with enterorrhaphy for perforating gunshot wounds of the small intestine. The first case, that of Bull, with perforations; the second, that of Hamilton, with eleven wounds; the third, that of Bull, with perforations.

But little remains for us to consider beyond the "when" and the "how," the "time," when laparotomy should be done, and the manner of doing it. I think there can be no question that the operation, having been determined on, should be done as soon as practicable after the receipt of the injury, for the following reasons: It is believed that the first effect of the injury is to paralyze temporarily the peristaltic action of the bowels, thus for a short time preventing fecal extravasation. It is obvious that moving the patient, if it does not overcome this, will tend to displace mechanically some of the contents of the intestines. Again, if intra-abdominal hemorrhage is going on, it will not be likely to stop spontaneously; moving the patient will not, it is certain, conduce to the arrest of hemorrhage, if it exists; delay increases the chances of peritonitis, thus bringing secondary troubles to add to the primary one, already grave enough.

The disadvantages of delay are well shown in a case reported by Dr. C. T. Parkes to the Chicago Medical Society, October 5, 1884, *Journal of the American Medical Association*, October 31, 1885, where the patient was removed to his home in a farmer's spring wagon a distance of seven miles, and the next day removed to the hospital. It may be also remarked that in this case section was not made in the median line, but the wound was enlarged. At the autopsy, commencing peritonitis and a quantity of extravasated blood were found; one wound had been overlooked. On the other hand, the advantages of immediate operation at the place where the shooting has occurred, and as soon as possible after the injury, are to a certain extent offset by the fact that the surroundings are liable to be unfavorable to abdominal section and that the average general practitioner is not sufficiently skilled in the surgical manipulations considered necessary to attain succes. It has been demonstrated that success in abdominal surgery, other things being equal, increases with favorable surroundings and personal experience in the technique. If laparotomy in gunshot wounds is to become an established operation, it can scarcely be expected that an experienced surgeon can always be obtained, or that the appliances and trained assistance so earnestly insisted on as essential, in other departments of abdominal surgery will always be immediately available, this difficulty can of course be overcome. I would suggest that medical men may train themselves by practice on some of the lower animals. A few experiments will thoroughly convince anyone unfamiliar with this work of the necessity of just such training.

Wherever practicable, I believe the dangers of removal will be counterbalanced by placing the patient where the sanitary surroundings are good and where skilled assistance and necessary appliances can be had. So far, the successful cases have occurred in the hands of men exceptionally well trained for their work—men of superior surgical skill—and assisted by all the apparatus and advantages of well-appointed hospitals. The wounds were inflicted by pistol shots, bullets of medium calibre, viz., 32.

But what of the battlefield? Here it is obvious that by far the greater number of gunshot wounds occur. The modern rifle bullet, weighing 500 grains or more, at ordinary range must inflict a much more serious wound than the comparatively small pistol bullet of 22 and 32 calibre. Although the difficulties of immediate laparotomy under such circumstances may not in the future prove insurmountable, yet it must be confessed that, so far, they have not been met; the proceeding, if not positively detrimental, amid the smoke, dust, haste, confusion, and pressing demands upon the time of the military surgeon on the actual battlefield, will, at any rate, not be found easy of execution. So far as our present experience goes, it would seem the better practice to wait until the wounded man can be carefully removed to a division hospital, in the meantime occluding the external wound or wounds by some convenient form of antiseptic pad. The value and praticability of laparotomy with enterorrhaphy, in military practice, can only be satisfactorily determined by experience in future wars. There are many points to be considered that do not greatly concern the civil surgeon.

In regard to the method of operating, the general plan will follow that of ovariotomy, with the same rigid precautions to prevent sepsis. The method of dealing with the wounded intestine occupied the attention of the older surgeons from the time of the "four masters" who flourished in Paris in the latter part of the thirteenth century, and who used a section of the trachea of an animal. Others used metallic rings, or the ferrule plan as it was called. These were of course applied to incised wounds, or where exsection of portions of injured intestines had been made. The suture of Jobert, 1822, Lembert, 1826, Gely, 1827, each have their advocates, but the present accepted one seems to be that of Lembert or the Czerny-Lembert suture. It may be said of the latter that it is difficult of execution, and as expedition, without undue haste, is of great importance, that form of suture which is most easily applied and at the same time is effective in preventing escape of intestinal contents is best—experience and experiment have shown

that this is the suture of Lembert, the chief point being to bring together the peritoneal coat of the bowel.

It must be remembered that gunshot wounds are lacerated and contused, and before being sutured they must be converted into incised wounds, by carefully paring away the contused portions. Where the injury to the bowel is extensive, or several perforations are close together, this is not always practicable, without resection of the intestine. In this case certain precautions are necessary, the lumen of the intestines above and below the portion to be removed must be occluded with some form of clamp. Treves and Bishop have devised instruments for this purpose. I have found the ordinary spring clothespin, slightly altered, as it may be in a few minutes, to answer this purpose. I also suggest, as a precaution against the escape of blood and the contents of the intestines into the peritoneal cavity, that the portions of the intestines to be operated on should be drawn through an opening in a piece of thin India-rubber used by dentists, and known as rubber-dam.

As the bowel derives its blood supply from the mesentery, it is important, in order to prevent gangrene, that the mesenteric attachment should be as far as possible preserved. When necessary a V-shaped portion of the adjacent mesentery can be removed and this wound closed by the continuous catgut suture.

A question may here arise, "How much of the intestine can be removed with safety?" Baum removed 137 centimetres of the small intestine; the patient recovered from the operation, but six months afterward progressive emaciation resulted in death. This case would seem to indicate that there is a limit to the amount that can be removed without impairing the health.

Sir Spencer Wells suggests that hollow cylinders of cocoanut butter and gelatine be used to afford a support to the intestine and facilitate the passing of the sutures, when enterorrhaphy is necessary. The sutures may be of catgut or fine pure silk, and should be not less than one-tenth of inch apart. I prefer the needle known as Schnetter's, as there is no cutting edge—but ordinary round sewing needles will answer the purpose well. Very small wounds can be closed with the continued suture. All bleeding points must be carefully sought, and ligatured or cauterized. Careful attention must be given to the toilet of the peritoneum; a clean cavity is essential.

After-treatment. Rest, opium, a small quantity of phosphorized milk.

The following case occurring under my own care, while perhaps not strictly germane to the subject, is sufficiently so to warrant relation here. John B., aged eighteen, was admitted about 10 A.M., September 6, 1885, to the Emergency Hospital. At 12.30 A.M. of the same day, or about nine hours prior to admission, he had been stabbed in the abdomen. The wound was three and a half inches in length from the median line toward the right, and three inches below the umbilicus. It penetrated the abdominal cavity, and divided the rectus muscle together with the right deep epigastric artery. He was seen immediately after the injury by a physician, who placed three silver wire sutures through the skin only, and ordered one grain of opium to be given every hour, which was probably faithfully carried out, as on admission he was markedly under the influence of opium, with contracted pupils, slow sighing respiration, cold surface, pulse 132. One of the stitches had given way; there was a bunch of intestine the size of a man's fist protruding through the wound in the muscular wall of the abdomen and distending the skin. After consultation with my colleagues of the staff of the Hospital, I made an incision in the median line, and removed about a pint and a half of clotted blood from the abdominal cavity, which was washed out with warm solution of bichloride of mercury 1 part to 3000 of water. The toilet of peritoneum was practised carefully as in ovariotomy, and with antiseptic precautions. As there was no bleeding, the peritoneum was sutured with fine catgut separately, and silver sutures passed through the skin and abdominal muscles, closing the original wound, and also the wound of operation, a rubber drainage tube left in the dependent angle of the incision, and over all an antiseptic dressing of wood flour prepared with bichloride of mercury and naphthalin (the usual dressing in use in the hospital), and the patient put to bed. He never rallied. At 5.30 P.M. he asked for a drink; at 10.30 P.M. pulse scarcely perceptible: at 11 P.M. he died. Before admission to the hospital he had probably taken (at least so it was stated) eight grains of opium. Had he been admitted to the hospital soon after the injury the result might have been different. It is difficult to say whether he died from the wound or from opium narcosis, or both combined.

The experiments of Dr. C. T. Parkes, of Chicago, as detailed in his valuable paper read before the American Medical Association, at its meeting in Washington, May, 1884 (see The Medical News, May 17, 1884), are, in my opinion, of very great value in teaching many points in regard to the technique. I think they should be carefully studied by every practitioner of medicine.

Dr. Joseph D. Bryant, of New York, in reply to the question, *What are the diagnostic signs of involvement of the intestines in shot wounds of the abdomen?* said: It is presumed that the expression "diagnostic signs" is intended to be accepted as synonymous with "diagnostic symptoms," and also, that diagnostic signs or symptoms are considered to be those signs or symptoms which are characteristic of the abdominal state under consideration. The signs of intestinal involvement will be divided into two classes, viz.: 1. Those referable to the abdomen itself, or the local signs. 2. Those referable to the constitutional effects of the injury as the constitutional or general signs.

The *local signs* will be considered first, and will be arranged somewhat in the order in which they will naturally present themselves to the attention of the professional observer.

The wound of the abdominal wall is the leading local sign of primary interest, and the one most eagerly sought for by the medical attendant. The direction of the wound, the character of the discharge from the wound, and emphysema of its borders or of the neighboring connective tissues, are all of great importance in a diagnostic sense. If the course the missile has taken be such that it must have entered the peritoneal cavity, if undeviated, the presumption is strong that the contents of the cavity have been injured. Yet missiles of large size have passed through the peritoneal cavity, without being followed by symptoms of intestinal in-

volvement, and post-mortem examination of similar cases has failed even to show any evidence of the existence of an intestinal wound. However, instances like these are more illustrative of a freak of physical force, than of its inconstancy, and are, therefore, more curious than convincing. If blood flows from the wound of the abdominal wall and the wound be not in the course of the important bloodvessels of the structure, the hemorrhage is strongly suggestive of intra-abdominal bleeding and consequently of visceral involvement. If the bleeding points that are found in the wall of the abdomen do not account for the entire loss of blood, the evidence of intra-abdominal hemorrhage, dependent on intra-abdominal involvement, is conclusive. The passage of bloody stools, or bloody urine, at a near period to that of the receipt of the injury, will serve to confirm the belief that may exist of intra-abdominal visceral involvement. The escape of intestinal contents from the abdominal wound is positive proof of involvement of the intestine itself. This evidence is seen, however, very infrequently as an immediate sign, since the extravasated fluids are quite easily retained in the peritoneal cavity, owing to the change of the relations of the wound of the abdominal wall to those of the intestinal wound, caused by the intestinal vermicular motions, the natural movements of the patient, as well as those movements incident to the occurrence of the injury. The ragged borders of the abdominal wall interfere also as a notable obstacle to the escape of these fluids into the external world. Still, if the missile have caused large and gaping wounds of the soft parts, the intestinal contents will escape often at the time of the receipt of the injury especially if the intestine be plethoric with its characteristic matters, in spite of these circumstances. This sign appears somewhat late in the history of a case as a rule, and after the formation of inflammatory adhesions that guide the fluids along the adventitious channel formed by them, often from a considerable depth within the abdominal cavity. With this condition of things the intestinal contents escape readily through the abdominal wound, and alimentary substances may escape even quite as soon as swallowed.

Emphysema. This sign is not associated very frequently with penetrating wounds of the abdomen, but, when present, is almost invariably due to the escape of intestinal gases into the connective tissue situated between the intestine and the abdominal wall; hence it is associated especially with injuries of those portions of the intestinal tract that are not surrounded entirely by peritoneum. Emphysema may be limited to the immediate neighborhood of the external wound or become general by spreading gradually from the seat of an intestinal wound into the surrounding connective tissue of the abdominal wall. It may be due also in part or entirely to a complicating wound of the pulmonary tissues. Early emphysema of the abdominal wall has been considered by some writers as a certain sign of intestinal perforation, when associated with a suspected penetrating abdominal wound. This statement, while commonly true, must be accepted as yet with a certain degree of caution, since it has happened that a circumscribed subcutaneous emphysema has taken place around non-penetrating stab wounds of the abdominal wall, in two distinct cases within the observation of the writer. This emphysema was caused apparently by the suction influence exerted on the external air by the retraction of the divided fibres of the abdominal muscle, its escape being prevented by the valvular arrangement of the structure at the opening through the integument and subcutaneous tissues. Air in the peritoneal cavity may give rise to emphysema if it be forced between the structures bordering upon an abdominal wound into the connective tissues beyond this point. If decomposition occur in the course of a penetrating wound of the abdomen, emphysema of the contiguous connective tissue may ensue, even though the intestines themselves have not been injured. In such a case as this, the emphysema takes place at a later period than in the former case and is attended by the symptoms peculiar to decomposition and usually without the acute signs of intestinal penetration. Pain, tenderness, tympanites, bloody stools, and retention of urine are signs of common occurrence with intestinal involvement. The pain is located primarily about the seat of the wound, it is dull or lancinating at first and is increased by all muscular movements of the patient; later it becomes more intense and of a burning character, accompanied by exquisite abdominal tenderness, retraction of the thighs, and obstinate constipation. Not infrequently griping pains are present attended with frequent desire to stool. Retention of urine; frequent calls to micturition which may or may not be successful, are of common occurrence in both the early and late history of intestinal involvement.

Tympanites. Tympanites may depend either on gaseous distention of the intestine, or the pressure of intestinal gases in the peritoneal cavity; on extensive emphysema of the abdominal wall or on a combination of these factors. If tympanites develop soon after pain and tenderness appear, and increase in proportion with them, being at the outset best marked at and around the site of the wound, it is certain to be due chiefly to intestinal distention. If tympanites follow quickly, antedating the symptoms of inflammation, or be out of proportion to them, or if much distention of the abdomen with a drum-like sound attended by little or limited pain and tenderness be present, the tympanites depends without doubt on the presence of air in the peritoneal cavity. The substitution of tympanitic resonance for normal hepatic dulness may be considered a strongly diagnostic sign of even a small amount of air in the peritoneal cavity: but it may be caused by the adhesions of the intestine to the anterior abdominal wall in this situation, by a distended colon pressing firmly against the under surface of the liver, and by distention of the colon accompanied by a diminished area of hepatic dulness due to a contracted liver. In the former of the last two conditions, however, the area of hepatic dulness will be increased posteriorly by the pressing upward of the liver, providing the lung of that side be not emphysematous. In the later of these two conditions the posterior area of hepatic dulness will be lessened in proportion to the diminution of the size of the liver. Prof. E. G. Janeway has noted that the transverse colon may pass between the liver and the abdominal wall, causing tympanitic resonance in this situation. This condition has since been observed post-mortem by Dr. H. M. Biggs. If the serous surface of the liver be adherent to the anterior abdominal wall, hepatic dulness will be present even though air be in the peri-

toneal cavity. The foregoing marked conditions are so infrequent, however, that tympanitic resonance in the hepatic region, existing in a case of suspected intestinal involvement, may be considered almost pathognomonic of the existence of that condition. *Percussion of the abdominal wall* may elicit an abnormal line of dulness due to fluids in the peritoneal cavity. This line will be parallel with the long axis of the body and be influenced by its position. However, the amount of blood or of other fluid necessary to cause this sign must be considerable, especially if the pelvic pouches of the peritoneum have first become filled with it.

Palpation may detect a doughy feeling of the wall of the abdomen, which is imparted to it by the large amount of extravasated blood in the peritoneal cavity.

The constitutional or *general symptoms* that have a recognized bearing on the diagnosis of intestinal involvement are shock, nausea, vomiting, and hiccough. Shock is the first of the series of constitutional symptoms. It may be mild or severe, and while its gravity may depend either on the degree or on the idiosyncrasy of the patient, yet severe shock at the outset may be considered as almost diagnostic of a profuse hemorrhage or an extensive visceral involvement. Intense thirst, constant wakefulness, excessive restlessness, and great anxiety are manifestations of intestinal involvement, all of which are associated more or less intimately with shock, and the first of these with the initial processes of a consequent peritoneal inflammation.

Nausea commonly appears immediately after the intestinal involvement has taken place, vomiting also occurs at intervals and usually both nausea and vomiting are present subsequently during the entire course of a fatal case. Hiccough usually follows both nausea and vomiting, but is often controlled by the anodyne treatment addressed to the patient. There are many other signs of a primary and secondary character that are to be found in connection with the earlier or later history of a penetrating abdominal wound complicated with intestinal involvement. They are too well known already to require a recapitulation at this time, and moreover they are of a secondary importance, since they are of little practical use for the diagnosis of intestinal involvement, when considered independently of the sequelæ that so constantly follow it. It is now to be seen that there are very few positive early indications of intestinal involvement associated with an abdominal penetrating wound. The escape of the intestinal contents from the abdominal wound is a positive one; the presence of extravasated air in the peritoneal cavity, as indicated by modification of the area of hepatic dulness, is a positive sign of the involvement of the intestines or stomach, provided the area of hepatic dulness has not been modified already by abnormalities of position or morbid processes. It should not be forgotten, however, that intestinal involvement may exist without the presence of any or at least of a sufficient amount of extravasated intestinal gases in the peritoneal cavity, to modify appreciably the area of hepatic dulness.

The escape of blood from the peritoneal cavity through the abdominal wound is positive proof of intra-abdominal involvement, but which of the structures is involved must be largely a matter of speculation. Hemorrhage from the bowel or from the bladder, other things being equal, should be accepted as conclusive proof of intra-abdominal involvement.

Percussion, as an aid in the diagnosis of ascitic fluid in the abdominal cavity, is of the utmost importance, especially if the line of dulness may be varied by changing the position of the patient. But when this sign is sought for in connection with the diagnosis of extravasated blood in the peritoneal cavity, which blood may be mixed, possibly with intestinal matters, or urine, its importance as a diagnostic sign is greatly overshadowed by the dangers arising from the dissemination of the irritating agents through the peritoneal cavity. Surely, the surgeon who would change the osition of the patient, and await the slow gravitation of the fluid contents of the peritoneal cavity to its most dependent part, that he might define a line of dulness by percussion, will expose the peritoneum to the danger of irreparable injury. This sign can be of but little practical use when properly sought, because when it is found without a change of the patient's position, the loss of blood will have been so great that other signs will have betrayed its occurrence already.

Palpation, when cautiously employed, can develop no facts in connection with extravasation that will possess a decisive influence in determining the question of intestinal involvement in an ordinarily obscure case.

Indeed, it would be far better for patients and for surgery, if the diagnostic importance of both percussion and palpation, in this instance, be not recognized at all in these injuries, than that the evidence to be gained by them be incautiously sought for by the surgeon. The severe constitutional symptoms already mentioned can be looked upon with that foreboding which is almost akin to certainty. The minor secondary symptoms also are not to be ignored; but are to be employed as connecting fibres in the diagnostic fabric.

DR. WILLIAM T. BULL considered *under what circumstances, and how soon after the injury, should laparotomy be resorted to in shot wounds of intestine; and when is the operation indicated?*

It is admitted by surgeons generally, that shot wounds of the intestine are almost uniformly fatal injuries. Even balls of the smallest calibre used in civil life, a "22" for instance, which have made only one or two wounds of the intestine, have brought about fatal peritonitis, and the instances of recovery have been very exceptional, and at he expense of dangerous peritonitis. It has furthermore been demonstrated that operative interference can deal with these injuries successfully. Three recoveries after laparotomy have been reported; one by Dr. Hamilton (*New York Medical Journal*, Nov. 14, 1885), and two by myself (THE MEDICAL NEWS, Nov. 6, 1886). And the unsuccessful operations have revealed the existence of injuries which would certainly have proved fatal without surgical assistance. It may, therefore, be considered settled that laparotomy is the best treatment for shot wounds of the intestine, and that it is generally indicated.

In applying this general indication to the individual case, we are beset with difficulties. It is often impossible to ascertain by the usual exploration with probes, whether a wound of the parietes be penetrating or not; and even when the intestine has been perforated, positive symptoms of that injury are often wanting at the

outset. Again, if laparotomy be delayed till the symptoms have made the diagnosis, it will be undertaken with very much diminished chances of success.

It is not my province to discuss the value of symptoms which indicate wound of the intestine; that has been undertaken by others. In cases which present these symptoms the indication is clear and imperative, and no surgeon should hesitate to give his patient the chance of operation if the general condition be such as to permit it.

But what I wish to emphasize, as bearing on the application of laparotomy, is the fact that many cases present few or none of these symptoms; that the sudden onset of peritonitis is the first indication of intestinal wound; and, again, that a bullet which has entered the abdominal cavity in the region occupied by intestine is much more likely to have injured the gut than to have missed it. Experiment has shown the possibility of avoiding the gut in the cadaver, but clinical evidence is lacking to support it. If we can be sure that a bullet has entered the peritoneal cavity, we may safely assume that it has injured the intestine or other viscera, and any doubt will be dispelled by the presence of feces, fecal swelling, gas, much blood, or serous exudation. There is but one way to ascertain these conditions at the outset, and that is by exploration of the bullet wound. And this should be done at the earliest possible moment, when the immediate shock of injury or transportation has subsided, and proper arrangements for operation have been made. I need not dwell long on the necessity of an early operation. Delay gives an opportunity for renewed bleeding and fecal extravasation, and invites septicæmia from the absorption of peritoneal exudations. If peritonitis be actually developed with tympanites, firm adhesions, and purulent foci, the difficulties of operation are almost insuperable, and the chances of success extremely doubtful. This plan of procedure which I have advocated and already put into practice, will, in my opinion, prove safer in the aggregate of cases than the policy of waiting for symptoms, inasmuch as exploration, conducted with antiseptic precautions, must be regarded as of trifling risk to the patient. It is not without advantage in a non-penetrating wound. It will enable the surgeon to remove the bullet, explore the wound in the most favorable condition for rapid healing, and reassure the patient.

A penetrating wound enlarged to two or three inches in length, will permit the inspection of the viscera in the neighborhood, and the examination of other parts with a sponge or the finger. In the further exploration of the viscera, section in the middle line is preferable. As a general rule, I believe it will be safer in the aggregate of cases to perform laparotomy when the wound is found to be penetrating, even if the cavity be tolerably clean. But it is worthy of note, that in none of the cases hitherto reported has there been any lack of blood or bloody serum in the cavity. In two instances when the abdomen was opened, only two hours after the injury, there was an abundant exudation of serum of blood clots.

Let me present, in support of this treatment, the result in eight cases observed at the Chambers Street Hospital since 1877. These are all the cases in which the nature and extent of the wounds were determined by autopsy or operation and in which, with but one exception, the intestine alone was involved.

1. The whole number of wounds in 10 years is 20. 5 were of the parietes only; 7 were of the intestines alone; 1 was of the intestine and bladder; 1 was of the stomach, and 1 was of the stomach and liver; 2 were of the liver alone; 3 were not examined after death. They were presumably 1 of the intestines alone, 1 of the intestines and kidney, 1 of the liver and intestines. The five wounds of the parietes recovered. All the others died except the two intestinal cases, which were subjected to operation.

The number is small but the contrast is striking. Five cases of shot wound treated on the expectant plan have all proved fatal. Three cases in which laparotomy was performed after exploration of the bullet wound have yielded two recoveries and one death. The two successful cases have already been reported. *Case 1.* (Med. News of Feb. 14, 1885): William McE. was operated on November 2, 1884, seventeen hours after the bullet of 32-calibre had entered the abdomen an inch and a half to the left and an equal distance below the umbilicus. Seven wounds of the intestines (from one of which the bullet was removed) were sutured and the cavity cleared of clots and bloody serum. The intestines were not adherent, though "coated here and there with clots and flakes of fibrin," so that in order to inspect their surface it was necessary to rub the peritoneum lightly with a sponge. The operation lasted two hours. The wound healed by granulation. I have seen the man within a few weeks; he remains in good health, working as a truckster.

Case 2. (Med. News of Nov. 6, 1886): Daniel M., aged twenty-five, was operated on August 12, 1886, only two hours after he had been shot with a 38-calibre pistol-ball two inches below the umbilicus and two inches to the left of the median line. There were no symptoms of shock and no evidence of intra-abdominal injury. The incision into the bullet wound showed that it entered the cavity and bloody serum escaped freely. Three wounds of the intestine were sutured, and two wounds of the sigmoid mesocolon left gaping after being dusted with iodoform. From one of these wounds there was free hemorrhage which was controlled by ligature; and a large blood extravasation in its vicinity made it probable that the bullet was looped there. It was not interfered with. This moved normally on the fifth day, but complete recovery was delayed till eight weeks, owing to suppuration in the line of abdominal incision and the protrusion of a knuckle of intestine which was reduced by gradual pressure while its wound cicatrized over it.

Case 3, which proved fatal, I will mention more in detail, since it is reported for the first time.

On November 6, 1886, a muscular mechanic, of intemperate habits, twenty-four years of age, was shot in the back ten minutes before admission to hospital. The bullet, of 44-calibre, entered one and a half inches to the right of the spine on a level with the last rib and could be felt anteriorly beneath the skin one and a half inches to the right and two inches above the umbilicus. Pulse 62; resp. 22; temp. 98°. Severe abdominal pain. Surface pale and extremities cool. An hour later he vomited contents of stomach. Five hours later he was still pale but warm; had severe pain. Pulse 92; resp. 35; temp. 98°. Hepatic dulness diminished but not absent, abdomen not swollen, tender about bullet; left

lumbar region resonant, right dull—dullness differs on turning to the left side (bloody fluid in cavity). After consultation with Drs. Peters, Weir, and T. B. Hunter, the bullet was removed by a three inch incision and the finger passed into the cavity. Considerable bloody serum and gas followed its withdrawal, the latter thought by some to be of fecal odor. No feces. The abdomen was then opened in the middle line from three inches below the sternum to two inches above the pubes —eleven inches. One or two pints of bloody serum and clots were opened out. Four perforations, two of the jejunum, two of the transverse colon, were sutured with Lembert's suture; the stomach, liver, and spleen inspected, and the intestines and cavity thoroughly washed with carbolic acid (1 to 100). The posterior wound was covered with iodoform compress. In holding the small intestine out of the wound a vein in the gastro-ophemic omentum was torn, but vainly secured with ligature. The point of entrance of the bullet was not detected. The tissues of the ascending mesocolon were stained black with extravasated fluid. The operation lasted one and three-quarter hours. At its close the pulse was 125 (small), resp. 42. Reaction was imperfect and death ensued at the end of eight hours. The autopsy made by the deputy coroner did not disclose the point of entrance into the abdominal cavity. In the retro-peritoneal tissues about the kidney and ascending colon was extensive extravasation of blood. Kidney uninjured, stone, bloody serum in the cavity. The wounds were tightly closed and no others were found.

Comment on these cases is unnecessary, but it is worth noting that none of them presented positive symptoms of injury of the intestine, and that all were submitted to operation on the strength of the preliminary exploration of the bullet wound. The unsuccessful cases undoubtedly died from the shock of operation, but the lesions found demonstrated clearly the necessity of interference.

The following are the fatal cases in which no operation was done:

Case 4. An Italian woman, twenty-three years of age, was shot with a "22" pistol, September 23, 1884, the bullet entering the abdominal wall in the middle line half way between umbilicus and pubes. No shock and no abdominal pain. A local peritonitis developed gradually; an abscess burst through the wound, which discharged feces on the twenty-second day. On the twenty-third day a hemorrhage of a few ounces from the wound brought about her death in collapse. The autopsy showed general peritonitis and an abscess encapsulated by adherent intestines and communicating with the wound. In the wall of this abscess was the epigastric artery (ulcerated), and connecting with the cavity were two ulcerated openings in the sigmoid flexure —the original bullet wounds. The bullet was embedded in the muscles near the crest of the ilium. There were no other intestinal wounds.

This woman died three weeks before McElroy (the first patient operated) was brought to the hospital. I had looked on this case as one likely to recover. The autopsy showed so little damage to the gut that I was led to look carefully into the histories of the other cases. The result of this investigation, together with a knowledge of the success obtained in pathological cases, led me to decide to give the next case that presented, the chance of operation. But another fatal case presents intestinal lesions quite as trifling as the last.

Case 5. On November 2, 1886, a French cook was brought to the hospital four hours after being shot with a 32 pistol. There was a superficial wound of the chest, and another entering the body in the eleventh intercostal space three inches to the left of the spine, and passing forward. Anteriorly the bullet could be felt beneath the skin in the left mammary line close to the cartilages. Abdominal pain; trifling shock. Abdomen normal except for tenderness about bullet. Pulse 100; resp. 36; temp. 99⅗°. Two hours later the bullet was removed, the wound sutured over a rubber drain. Twenty-four hours later there were vomiting, tympanites, and general prostration. In the next forty-eight hours the symptoms were aggravated. At the end of the third day the wound was enlarged so as to admit the finger, on withdrawing which fluid feces escaped. The general condition did not admit of further interference than free incision of the parietes in the track of the wound; but this was sufficient to let out a quantity of fecal matter, and to reveal an opening in the posterior wall of the descending colon. Death ensued on the fourth day. The autopsy disclosed a general purulent peritonitis, feces being found in the exudation, and the intestines matted together. The omentum was firmly adherent to the transverse and descending colon. The bullet had passed through the wall of the descending colon both posteriorly, where it was uncovered by peritoneum, and again anteriorly close to the point of reflexion of the peritoneum to the lateral abdominal wall. The two wounds were about an inch apart. There were no other intestinal wounds, and the other organs were healthy.

In this instance enlargement of the wound from which the bullet was extracted would have been sufficient to examine the colon, and to detect and suture the wounds.

The three following cases I cannot present with as full details as is desirable. But they will serve to strengthen your convictions, as they gave rise to mine, of the necessity for operation:

Case 6. A machinist, forty-nine years of age, shot himself accidentally June 24, 1878. On admission to the hospital, a few minutes later, he was in a state of profound shock. The wound was situated two inches to the left and one inch below the umbilicus. Reaction was slow and imperfect. Two hours later he vomited contents of stomach and bile. The vomiting was repeated, collapse occurred, and he died at the end of twenty-four hours. The autopsy revealed several ounces of coffee-colored fluid in the peritoneal cavity (feces not referred to). The bullet had passed through the small intestine and psoas muscle, and lodged in the abdominal wall near the crest of the ilium.

Case 7. A laborer, aged twenty-five, was shot in the abdomen. On reaching hospital he was drunk, and in good condition, but bloody urine was drawn. Within twelve hours vomiting occurred, peritonitis developed, and he died in three days. Autopsy showed "several perforations of the small intestine, and the bullet lodged in the ascending colon."

Case 8. May 4, 1879, a mechanic, thirty-seven years old, shot himself with a pistol. The bullet entered two inches to the right and one and three-fourth inches below the umbilicus, and was felt under the skin on inner side

of left thigh, and removed. Pulse 108; resp. 25; temp. 99½°. Bloody urine, moderate abdominal pain. In a few hours vomiting and collapse. Retention of urine persisted. It was found in autopsy that the ball had made wounds of the small intestine, and passed through the bladder to the thigh.

In the light of our present knowledge, the record of these cases is a melancholy one. None of them, with possibly the exception of the last, presented lesions so serious as those of the cases which have been operated on. All of the patients were victims to that policy of non-interference which was born of the dread of wounds of the peritoneum. The achievements of antiseptic surgery have dispelled that fear; and we are in duty bound to give to abdominal injuries the chances offered by an early and thorough exploration. And, as our experience extends, there is every reason to believe that our successes will multiply.

In considering the contra-indications to laparotomy, we must remember that many wounds involve the solid viscera as well as the intestine. This is true of those which enter the abdomen in the epigastric, or within the hypochondriac region, and pass through the stomach spleen, and liver, or, entering from behind, around the kidney. These are very complicated injuries, and for the case of liver or spleen, and kidney to a less degree, are accompanied generally by profuse hemorrhage and consequent profound shock and depression. I am doubtful of our ability to cope with such serious lesions in addition to those of the intestine. Dr. Dennis has reported one case of a bullet entering the epigastrium opening through the liver, in which laparotomy was of no avail, and two similar cases in my service have been subjected to operation by Dr. Wiekin and myself. One patient died during the operation (reported in The Medical News, of November 6, 1886), the other survived but an hour. The stomach might offer insufferable difficulties if the posterior wall were perforated, but the spleen and kidney could be dealt with more satisfactorily by extirpation. But those manifestations make success extremely doubtful; and operation would certainly not be justifiable in a patient suffering from a serious degree of shock. Uncomplicated intestinal wounds are not attended with profound shock, and the subsequent depression is apt to be followed by reaction.

When the solid viscera are involved, the shock will be profound, its phenomena prolonged, and reaction incomplete. Hence I regard a prolonged condition of shock as a decided contra-indication to laparotomy. The phenomena of this condition must be interpreted by the individual surgeon according to his own experience and judgment. A partial or complete reaction may change his view as to the gravity of the case, and justify a disregard of this contra-indication. But it must be remembered that the exposure and handling of the viscera are of themselves procedures compromising to the life of the patient and should not be undertaken unless there are reasonable chances of success.

A well-developed peritonitis might be regarded as a contra-indication in view of the diminished chances of successful operation from the reasons mentioned at the beginning of this paper. I do not think we are in a position to decide upon this yet; but in view of the fact that it is no longer considered an obstacle to operations for the removal of tumors, or for intestinal obstruction, and that it has been cured by laparotomy with irrigation and drainage, we are justified in disregarding it, unless the patient be too much depressed to warrant any operation.

In conclusion, let me make one exception to the rule of treatment I have advocated, viz., to explore the bullet wounds first. It is in cases where the wound is situated in the posterior wall of the abdomen, or in the lateral wall covered by the lower ribs, and there is no evidence of any wound anteriorly. Here enlargement of the wound would not permit a satisfactory inspection of the cavity, and there are many chances of the missile being looped in the thick layer of muscles, or deflected by the ribs, and I believe it would be manifestly proper to wait for symptoms before resorting to laparotomy. But with this exception, and the contra-indication I have mentioned, I am convinced that the surest, safest, and quickest way of dealing with shot wounds of the intestine, is first to assure one's self by exploration of the wound of entrance, that the cavity has been entered, or the gut injured, and then to repair that injury by laparotomy.

Dr. Theodore R. Varick, of Jersey City, said that:

Assuming that a diagnosis has been made that perforation of the intestines has occurred, we are brought face to face with one of the most formidable conditions a surgeon is called upon to treat.

The indications for treatment are based upon the recognition of the various factors leading to death; which are, primarily, shock and hemorrhage; and, secondarily, peritonitis, resulting from the wounds and the extravasation of intestinal contents into the peritoneal cavity, which, if life be sufficiently prolonged, terminates in sepsis. The gravity of wounds of the kind is modified by location and size, as to whether affecting the large or small intestine, or inflicted from behind, opening the gut where it is uncovered by peritoneum, and whether it is a simple perforation, multiple, or complicated by the opening of an artery or vein.

The symptoms indicating the predominance of either one of the factors alluded to, might be construed as a guide as to the immediate or later resort to operative procedure. In some instances the eversion of the mucous membrane, it is alleged, in cases of small wounds, may possibly for a time prevent extravasation, but later on the occurrence of sloughing at the periphery of the wound allows extravasation to occur and peritonitis to ensue. Sloughing may occur at an early period, as in a fatal case reported by Dr. Charles A. Jersey, in which death took place on the fourth day. The autopsy showed "the edges of the two perforating wounds in the mesentery had separated, and their surfaces were covered by a blackened, softened slough, discharging pus into the peritoneal cavity." This eversion of the mucous membrane observed in wounds of the intestines acting as a temporary barrier, seems to me to exist more in theory than clinical observation would warrant, and should be disregarded altogether in the question of treatment, especially when we consider the difference between a clean-cut or punctured wound made with a sharp instrument, and one inflicted by a bullet. In the one there is no loss of substance, but a simple solution of continuity; in the other there is not only a solution of continuity, a frequent actual loss of substance, but the tissues are torn, frayed out, and the vitality of the sur-

rounding tissue destroyed, the part being apparently punched out; while the contraction of the muscular fibres tends more and more to keep open and enlarge the wound, offering increasing facilities for the extravasation of the intestinal contents.

No matter how small the perforation may be, there is almost always a corresponding amount of extravasation. It is barely possible that peritonitis, provided the opening be small, and the extravasation be limited and gradual, may, as in non-traumatic cases, cause a sufficient amount of adhesions to circumscribe the effused matter, and terminate in abscess. This is so very improbable as to merit little consideration.

The exceedingly small percentage of recoveries after gunshot wounds of the intestines, raises the question, not so much as to the necessity of an operation, as it does regarding the time when laparotomy should be performed.

The contraindications are only such as would foreshadow the rapid approach of dissolution, when the operation would be absolutely useless. Shock, to a greater or less extent, always accompanies shot-wounds of the intestines, and it is a factor which is often a source of embarrassment, governed oftentimes as much by the nervous susceptibility of the patient, as it is by the gravity of the wound. Viewed in the abstract, it is exceedingly fallacious, but taken in connection with gradually increasing evidence of exhaustion, such as rigidity and feebleness of the pulse, jactitation, sighing, respiration, and sinking of the temperature, indicating intra-abdominal hemorrhage, and in cases in which, in addition, is found dulness at the more depending portions of the abdomen, with tympanitic distention of the anterior portion, immediate laparotomy is clearly indicated, that the bleeding vessels may be tied, and the extravasations removed.

In this connection I desire to call attention to the significance of tympanitic resonance over the liver, and also to the persistence of hepatic dulness, first brought to the notice of the profession by one whose memory is dear to every one of us, the lamented and illustrious Flint: "Tympanitic resonance over the liver, however, cannot be considered a proof of the presence of gas in the peritoneal cavity, inasmuch as the resonance is found not infrequently when the transverse colon is much distended with gas, or when this portion of the intestine is pushed upward above the lower margin of the liver; but persistent hepatic flatness is proof almost absolute against perforation."

The first condition, taken in connection with other corroborative symptoms, would, as before remarked, call for prompt action, while the latter, although not an absolutely certain contra-indication, might justify delay. It should be borne in mind that the condition of fulness or emptiness of the stomach and bowels, or, in other words, whether the injury is received shortly after a meal or fasting, are important factors governing the amount of extravasation from the wound.

The character of the vulnerating body enters into the estimation of the gravity of the wound; thus a charge of shot produces a more ragged and extensive injury than one inflicted by a single bullet; and the frequent lodgement of pieces of clothing and other foreign substances withinthe abdomen, adds to dangers of irritation and sepis, and demand immediate removal. The longer these substances are allowed to remain, the less chance there is of ultimate recovery.

To the genius of Ephraim McDowell are we indebted for the demonstration of the practicability of intra-abdominal operations, and this demonstration has given rise to the brilliant results obtained by a host of surgeons eminent in the domain of gynecology, until laparotomy has become firmly established as a justifiable, and, in many instances, an operation imperatively demanded. If it is demanded in the various phases of ovarian and uterine disease in which a fatal result may seem far distant in the future, how much the more necessary is it in cases which, if active measures are not at once resorted to, a fatal result ensues, not in days or weeks, but in hours, or, perchance, in minutes?

If the operation is considered a desperate one, we should bear in mind that we have a desperate case to treat. The day of expectancy is past, and the time for bold and decisive action has arrived. Would not a surgeon be worse than criminal, to allow a patient whose life-blood is oozing away, whose peritoneal cavity is subjected to the contact of feculent matter, or, perchance, foreign substances from without, lighting up peritonitis and sepsis, leading to inevitable death, to die, when, in the light of surgical science of the present day, means are offered to stem the outflow of life, to remove by thorough cleansing of the peritoneal cavity all foreign substances, and, by the various methods of continuous suture, close the door to further extravasation, and allow a conservative plastic exudation to complete what art commenced.

Who would not at once remove a foreign body from an extremity the effect of which would be simply the production of a limited amount of inflammation and suppuration? And how much more is it the duty of the surgeon to remove from the abdominal cavity more deadly material, whose presence, moment by moment, tends more and more to shorten life? If time enough has already elapsed to note a gradual descent of temperature, it indicates a continuous hemorrhage.

Operate at once and arrest the hemorrhage. If the temperature has ceased to fall and has begun to rise above the normal, inflammatory consequences are already initiated, but, possibly, it may not yet be too late to operate. At all events, give your patient the benefit of a chance, no matter how small, as against an almost absolute certainty of death.

DR. CHARLES B. NANCREDE, of Philadelphia, remarked that out of a number of cases to which he had referred, and to those cases with which he had been brought in contact, he had found that about eight per cent. recovered, which he thought taught us the necessity for laparotomy.

What is the danger of laparotomy and what are the advantages derived from it? First, the tendency is toward death. One surgeon reports that he has met with four cases in his own practice, where the gut was unwounded, by the showing of the post-mortem. The passage of the ball, whether obliquely or straight, and the shape of the ball and its calibre have all to be considered in these cases. In one case the point of entrance was so tightly closed that it would hardly open on manipulation, and yet frequently the abdominal wound allows fluid to pass out to the external surface.'

What are the causes of death? In nearly every case,

septic peritonitis caused by feces or pieces of cloth. About ninety per cent. die within forty-eight hours where there is extravasation of feces; hemorrhage in itself is rarely the cause of death where an operation can be contemplated. Septic intoxication is also a cause of death. Dr. Nancrede here called attention to the question whether this was not more frequently the cause of death than sepsis.

When recovery ensues, what conservative process takes place? This occurs in eight per cent., but this is not exact, for probably adhesions form more often. Again, a small primary fecal extravasation may occur, giving rise to an abscess, which, if it bursts internally, results in death. In gunshot wounds of the intestines, shock is all we need dread; we can almost certainly prevent septic infection; should peritonitis set in we can secure drainage. We can restore continuity of the gut, we avoid the risk of fecal fistula, and we secure the arrest of hemorrhage.

Always operate in shot wounds of the intestines, except when certain contraindications exist; but still there is always room for mistakes, and no wound of the bowel may exist. In a penetrating wound of the abdomen and probable wound of the intestines, laparotomy is the proper procedure; tympanites in such cases demands an operation; exit of blood, feces, etc., from the wound demands operative interference, and should be resorted to as soon as the patient is in a condition to operate upon.

Dr. Nancrede considered that the surroundings of the patient should not contraindicate an operation, but still every surgeon should not operate, and during the operation only one pair of hands should enter the abdominal cavity. Inexperience of the surgeon is a contraindication, and most cases will do better if left alone than if operated upon by a poor surgeon. He could not advocate laparotomy in those cases in which peritonitis exists; injury of other organs may also contraindicate it; one must remember that the opening of a tense abdominal wall, and removing portions of intestine, is a different matter from that of removing an abdominal tumor where no peritonitis or previous shock exists.

Dr. John B. Hamilton, of Washington, discussed the following question, *What are the essential features of the technique of laparotomy, including the management of the wounded intestine?*

He remarked that his experience in relation to this subject had not been large, and he was unable to mention more than one successful case occurring in his own practice, which had been previously reported in the medical journals. He did not think there were any positive diagnostic signs of intestinal injury in gunshot wounds, in the very early stages. In support of this he quoted a case of a woman twenty-two years of age who was admitted to the hospital just after she had been shot in the abdomen. The surgeon there at the time could find no shock or pain, but simply a small abdominal wound where the ball entered; he allowed her to remain over until the next day. Dr. Hamilton then coming on duty, took charge of the case. Tympanites was then developing and there were signs of intestinal involvement, but he was unwilling to perform laparotomy so long after the injury, and under the condition the patient was in. She had no pain, but tympanites was increasing. Death occurred on the third day after the injury. At the autopsy four perforations of the intestine were found. The abdominal wound was very small a little below and to the left of the umbilicus, at the edge of the rectus muscle. He thought the case sufficient to prove that the intestines may receive serious injury and yet give no signs of it, as up to the time of her death there had been no shock or pain at any time.

What shall be the method of treatment?

In Dr. Hamilton's opinion the first question is to consider whether the intestines are injured. At the rate of percentage death nearly always followed, especially when the wound was inflicted at short range. We first wish to know whether the abdominal cavity has been entered, and for this purpose he advised the use of the probe, although he knew it was against some of the most ancient customs of surgery; but no one has yet pointed out the evil of using the probe, and the objection to it rests only upon tradition. In advocating the use of the probe as a means of diagnosis, he wished to be understood that its use should be restricted to cases of small pistol-shot wounds, using a soft flexible probe which could do no harm. The only danger in the use of the probe, he thinks, was in passing too small a one.

The indications for laparotomy are clear and distinct in these conditions; if there is shock an exploratory laparotomy would be indicated.

Under what circumstances, and how soon after injury should laparotomy be resorted to, and when is it contraindicated?

He thinks it should be resorted to whenever the surgeon believes the intestine has been perforated. He also drew attention to the advisability of an early operation, as illustrated by the following case. A patient was brought to him three hours after a shot wound of the intestines; laparotomy was performed. At the point of injury there was considerable hyperæmic redness, but the rest of the intestines retained their pearly color and were not congested throughout until the close of the operation. This is an important guide in searching for the injured parts, for had a few more hours elapsed the intestines would have been inflamed all over and the difficulty of finding the wounds much greater.

He thought the operation was contraindicated after the lapse of forty-eight hours after the injury, where the patient is in a state of collapse, and peritonitis present.

As to the essential features of the technique of the laparotomy, Dr. Hamilton does not think they differ from any other laparotomy, except as to the management of the intestines; of course, the usual antiseptic precautions are to be taken, and hot towels placed over the chest, stomach, and intestines. On opening the abdominal cavity, first look for bleeding vessels, carefully examining the omentum, and tying all bleeding points, attending to the slightest abrasion of the mesentery with great care. The intestines should be drawn out, loop by loop, with the finger; the use of instruments for this purpose is not as good as the finger. As the intestines are drawn out, he lays them on a hot towel, covered with another one wrung out in hot water. When the wounds are found, stitch them up as fast as possible, but be careful not to wound the mucous membrane; he prefers to use Lembert's sutures for this purpose, using catgut of small size, cut short; the closure of the abdominal incision being effected as in other cases of laparotomy, the peritoneal

cavity, of course, having been previously thoroughly cleansed.

DR. CHARLES B. NANCREDE, of Philadelphia, then discussed the question—*What are the best methods of after-treatment in cases of gunshot wounds of the intestines upon which laparotomy has been performed?* He said the subject should be considered under three different heads: 1. When peritonitis does not exist at the time of operation; in other words, when a primary operation has been performed. 2. When incipient peritonitis does not exist at the time of operation. 3. When, despite all our efforts, or due to some neglect in technique, peritonitis develops after operation.

Of course, in all cases, antiseptic methods of dressing should be continued. Under the first conditions a recumbent position, with knees flexed, seldom changed, and then not by the patient's efforts, should be insisted upon. Alimentation should be carried on by the rectum entirely, when possible, for at least twenty-four hours, and in some cases even longer, when the stomach is irritable; at the most, cracked ice and small quantities of beef peptonoids should be given when the rectum rejects enemata, or when feeding by the mouth is begun. The higher up the canal the wounds are, the more imperative the rectal feeding becomes. At the end of a few days, full quantities of food may be given. Should tympany occur to any extent, the rectal tube and enemata should be tried; if masses of feces are suspected to be lodged in the colon, about thirty grains of inspissated ox-gall, dissolved in some mucilaginous vehicle, should form the enema, and will sometimes relieve severe tympanites when an ordinary injection will fail, owing to the occlusion of the intestinal tube by fecal plugging.

When incipient peritonitis exists at the time of operation, with the probable formation of large quantities of acrid septicæmic or sapræmic serum, precisely as in similar conditions after ovariotomy, drainage should be instituted; when possible, the tube should be of glass, and have its end kept well down between the rectum and bladder in the male, or in Douglas's cul-de-sac in the female. Presupposing that a previous careful toilet of the peritoneum has been made, the tube should be periodically emptied by a syringe with a soft rubber tube attached, the syringe aseptic, and tube corked with some iodoform cotton. Should the discharge have been or become large or purulent, careful irrigation with a weak bichloride solution, or, if this is feared, boracic acid solution should be resorted to. To favor drainage, a semi-prone position with flexed limbs, changed by the nurse from time to time, is to be advised.

The rules governing the exhibition of opium, stimulants, and the use of cold will be presently mentioned in detail, but it must be steadily borne in mind that neither much food nor alcoholic stimulants will be needed, since the patient will either die or recover before exhaustion demanding large quantities of aliment or alcohol comes on. As will presently be explained, atropia is better than alcohol for the exhaustion—*i. e.*, the shock of commencing peritonitis, or of the late stages, the depression of the nerve centres, especially those of circulation and respiration.

When peritonitis develops after the operation, our initial treatment must depend on whether it comes on gradually or suddenly. When the latter occurs, if there be any evidence of shock, as does occur at times from vasomotor paresis, shown by an apathetic, conscious condition, with extended limbs, pinched features, and a weak pulse, opium in large doses will prove fatal. Here small doses of morphia with atropia will stimulate the heart. The heart itself should be examined by auscultation, since this may demonstrate that it is really feeble while the pulse is hard and wiry. Now, under such circumstances, the pain is often severe, but large doses of opium, unless combined with atropia or digitalis, are very dangerous. I say large doses—I mean those ordinarily recommended for peritonitis in the text-books.

Later, owing to asthenia, the recumbent position, and compression of the lungs by tympanites, hypostatic pneumonia is apt to develop, and then the improperly aërated blood partially paralyzes the respiratory centres. In this condition morphia must be very carefully given, or, better, withdrawn, and always should be used in combination with atropia, ammonia, or digitalis. Stimulating hypodermatic injections and revulsives, such as dry cups to the lungs, are indicated. In case of peritonitis, which develops more gradually, as Burchard points out, the ideal condition to be obtained by opium is freedom from pain, irrespective of the quantity of opium exhibited; and when this is secured, the patient falls asleep, but can be readily aroused. It had better always be given as morphia, and hypodermatically, since opium by the mouth is not always absorbed, and may remain unchanged for days, to be suddenly taken up in fatal quantities.

In the latter stages of peritonitis, especially when the heart and lungs fail, and when gastric regurgitations and hiccough are rapidly exhausting the patient's vitality, one or more hypodermatics of atropia, either alone or in combination with morphine, digitalis, ammonia, or alcohol (Burchard), according to indication, will, at times, save an otherwise hopeless case.

Are there any means which will directly affect the vascular processes involved in a peritonitis? We undoubtedly possess two powerful ones. Free leeching done at the commencement of the attack, or when it has not progressed far, supposing the patient has not lost much blood from the accident, is of signal benefit. This I have witnessed at the bedside of patients, and also experimentally proved, as may be gathered from my *Observations on Bloodletting*, published some years since.

Cold, by means of the ice-coil to the abdomen, is a second means of controlling peritonitis. Cold applied to a peripheral sensory nerve has been shown by physiological experiment to control the afflux of blood to those parts supplied by the vasomotor nerves which inosculate with such sensory branches. In the present resistance the nerve circuit consists of the lumbar nerves supplying sensory filaments to the abdominal parietes, and the branches of the solar plexus which supply the intestines and peritoneum. Cold applied to the former nerves—*i. e.*, to the abdominal walls—will, therefore, cause contraction of the bloodvessels and intestines—it will do more, for it lowers temperature, relieves tympany, and calms the nervous system. If, by any chance, the sutures have failed and gas be in the cavity of the

peritoneum, aspiration may be tried, as suggested by Burchard, to whose admirable paper I am much indebted for useful facts and for confirmation of my own observations.

In such a case, however, I should be more inclined to reopen a portion of the laparotomy wound, introduce a drainage-tube, and freely irrigate the peritoneal cavity with an antiseptic solution. Should persistent and rising temperature, despite the ice-coil, etc., be present without the local signs of peritonitis, I should suspect the presence of some fluids, which generating ptomaines, were being absorbed and producing sapræmia—*i. e.*, septic intoxication as contra-distinguished from septicæmia. In such an event, the reopening of one angle of the wound, free irrigation of the abdominal cavity with mercuric bichloride, and the insertion of a drainage-tube, as already indicated, would perhaps save some otherwise condemned patients. In the same way should septic peritonitis arise with probable effusion of considerable quantities of fluid, such as are often found after death. I should strongly advocate a similar plan of treatment.

Owing to the anatomical position of the kidneys they are liable to become involved when the peritoneum is inflamed, hence the use of turpentine stupes for tympanites is to be deprecated, and Burchard states that "more than one has a timely application of cups, and a digitalis poultice over the kidney saved for him the life of a patient who was insidiously developing a nephritis." Daily examination of the urine should, therefore, be made, since retention of the urinary excreta in Bright's disease is a well-known cause of peritonitis. Digitalis in some form, and perhaps other diuretics are also peculiarly indicated in the sapræmic condition, to aid in the evacuation of the poisonous ptomaines, for if none of these products are allowed to remain in the peritoneal cavity, and if those already absorbed can be eliminated, recovery will often ensue.

I can hardly conceive, as I have already said, of a case of traumatic peritonitis living sufficiently long to develop enough true exhaustion to demand large quantities of food and stimulants; but, should this occur, of course the experiment must be tried, but the stomach will probably rebel. I am sure what would be a deficient amount of aliment for one in health had better be the rule in cases of traumatic peritonitis, all the more as they generally occur in those in robust health.

I am opposed to operating when advanced peritonitis is present. If it were possible to determine beforehand that only one perforation existed, a laparotomy might be done, and providing the injured loop of bowel could be found and secured to the abdominal wonnd, and free drainage instituted, good might accrue; but my experience of laparotomy for diffused peritonitis following rupture of the bowel, and for ball wounds, teaches me that it is extremely improbable that we should be able to find the wounded bowel without excessively prolonged manipulation, that if more than one perforation existed, the gut would be in no condition to suture, that multiple perforations would be so situated that all the loops of wounded intestine could not be secured in the abdominal wound; and if not all, what good can the operation do? and finally, that neither free drainage nor an effectual toilet of the peritoneum could be secured.

Dr. Charles T. Parkes, of Chicago, thought that sufficient data had not yet been offered upon which to form a correct diagnosis.

First, the size of the firearm must be taken into consideration, distance, shape of the bullet and calibre: bullets of large calibre are less likely to glance; though a small bullet may often prove as serious in its result. (Dr. Parkes then showed a drawing in which the intestine had been wounded in two places; the first wound was of an oblong shape, while the last, in which the bullet was found, had shattered the gut, causing an immense opening; the calibre of the bullet being only 22.) Then, again, the result of the injury may be affected by the obliquity with which the missile enters the body. Dr. Parkes then gave the history of a thief who was shot when running away from his pursuers. The bullet was of 44 calibre, and struck him in the back; he fell down, but jumped up and managed to escape. The next morning he went to the hospital, where it was found the ball had entered the back about four inches from the spinal column, and came out near the umbilicus. He never developed any serious symptoms, and left the hospital on the second day.

He thinks that close body shots require abdominal section; also, that round bullets, at ordinary range, do but slight damage, but that the firearms at the present day have immense penetrating force. He considers that every surgeon, on being called to a case of gunshot wound of the abdomen, should go prepared to operate at once. If the patient be suffering from deep-seated pain; the abdomen tender on pressure, with other pathognomonic symptoms, the diagnosis may be safely made. Vomiting of blood may be considered as a positive sign of perforation of the stomach, but still there are exceptions even to this rule; bloody stools, also, would be diagnostic, but these are seldom present in the early stages; ordinary tympanites is of slow development. In two cases he had seen, deep-seated emphysematous crackling occurred; severe injuries to the deep-seated vessels are more liable to bring about shock. He considered that laparotomy adds but little to the danger to life when perforation be present.

As to treatment of intestinal wounds, Dr. Parkes remarked that he would say practically the same as had Dr. Bull. First, diagnosticate positively the presence or absence of perforation; if not satisfied, enlarge the wound and follow it up. It does not necessarily follow that fecal matter should cause peritonitis, or that fecal gas alone will produce it, but fecal extravasation is sure to have this result Always operate on the spot, if possible, and enjoin absolute rest. Should your patient have to be moved, be careful about avoiding shock.

How soon after the perforation of the intestine should laparotomy be performed?

Just as soon as the patient will allow it and the surgeon can prepare himself for the operation. But there are some cases in which it is contra-indicated. As a last resort it should be performed in all cases. An obviously fatal result is a contra-indication, but who is able to assert positively the presence of such conditions; therefore, it may be said that there are no contra-indications to the performance of laparotomy, and any one who has had experience in abdominal surgery meets with great and pleasant surprises in these cases.

What are essential features as to the management?

No surgeon can fail to be convinced that a line through

the linea alba is the only line of incision; this is the same in operations upon the cadaver. The speaker had seen two cases in which the abdominal incision was lateral: the post-mortem of the first one showed fecal matter and blood, which had not been discovered by the operator. In the second case the man was sinking from hemorrhage, the bleeding vessel could not be found, but was traced to the other side of the body, but could not be uncovered, and the patient died.

After the primary incision secure all bleeding vessels, and if necessary, draw out the intestines, passing the whole carefully through the fingers while searching for the wound, keeping them covered with hot cloths. In closing the wound turn the edges in and use Lembert's intestinal stitch, taking up as much tissue as you possibly can. He considered a double row of sutures unnecessary, as being liable to increase shock; the best needle to use being a small round one, putting in the stitches about an inch apart; take up more than the peritoneum, but do not go through into the mucous coat.

Swift bullets make a clean cut; those of diminished velocity do more damage. The large majority of wounds can be treated successfully in the first class of cases. In the latter, resection may be required, the fingers of an assistant being the best clamps in such cases. In some cases the continuous suture may be used, but if there is much oozing, provide drainage; close the wound in the ordinary way, but look out for hernia. Great care should be used in fastening all the wounds, do not make them too tight or sloughing will result; if the peritoneal surfaces are held together for a few hours they will firmly adhere together. It is a fact to be remembered, that the circulation of the tube is not sufficient if the mesentery be destroyed; therefore, care should be taken always to restore the mesentery.

The after-treatment is to be carried out on general principles; the use of opiates, etc.; if the temperature rise, the application of cold externally, but if it does not go over 101°, the patient should be let alone.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, November 5, 1886.

The President, James C. Cameron, M.D., in the Chair.

MASTOID DISEASE RESULTING IN ABSCESS OF THE BRAIN.

Dr. Proudfoot reported a case of abscess of the brain, dependent on mastoid disease. The patient, a girl, aged twenty, was admitted into the Western Hospital under his care, suffering from a discharge of pus from the left ear. She had for years suffered at times from a purulent discharge from the ear, which had followed an attack of measles. Of late the discharge has been more profuse, and a few days before her entrance into the hospital she had had vomiting. On admission her temperature was 100° F., and pulse 65. There was no swelling or tenderness about the mastoid, but she had a purulent discharge from the ear, severe pain in the head, and occasional attacks of vomiting. On examination a polypus was discovered in the meatus and removed, after this the vomiting ceased. The pain, however, continued, and the discharge remained profuse. On consultation it was decided to trephine the mastoid, but when he came a few hours afterward to perform the operation, he found that the girl had died suddenly a half hour previously. A post-mortem examination revealed a large abscess in the middle lobe of the brain, which had burst through the base and compressed the medulla.

REMOVAL OF UTERINE APPENDAGES.

Dr. Kennedy showed the uterine appendages which he had removed from a young married woman, who has the following history: After her first pregnancy she contracted an attack of gonorrhœa from her husband, and this was followed by pelvic troubles, she had incessant pelvic and abdominal pain, which increased exceedingly during each menstrual period, and during intercourse; her life became a burden to her, and she requested that something might be done, and Dr. Kennedy resolved to perform Tait's operation. The operation presented no peculiar features, and the patient made a good recovery. On examining the removed structures the tubes were found to be distended with a serous fluid, and there was complete occlusion of the fimbriated extremity. No pus was found.

Dr. T. Johnson-Alloway asked if anything could be made out by vaginal examination previous to operation. From the appearance of the removed structures he thought the pathological changes were not such as demanded operation, and that the condition could not have been determined by vaginal examination.

Dr. Gardner remarked that he thought the operation of removal of the appendages a perfectly justifiable one; he had performed it with success. The good effects following the operation were not always immediate. In some cases he had found that the pernicious neurotic habit previously acquired was often not got rid of for many months after the performance of the operation; indeed, it might almost be said to be the rule that improvement does not appear for some time, often a year or more. The operation was more suitable in women who had to earn their living, and could not be nursed for months at a time.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting, November 15, 1886.

The President, Charles A. Leale, M.D., in the Chair.

Dr. T. Gaillard Thomas read a paper on

LAPAROTOMY AS A DIAGNOSTIC RESOURCE,

which will appear in full in an early issue of The Medical News.

Dr. Joseph D. Bryant said that the question of exploratory laparotomy was, to his mind, the most important one at the present time connected with the subject of abdominal surgery. The distinction should invariably be borne in mind between exploratory laparotomy and what he termed laparotomy in its entirety. He believed that exploratory laparotomy is justifiable in all cases where the diagnosis is doubtful, but with this reservation: that the means should always be at hand for performing the operation in a proper manner as regards antiseptic precautions, hygienic sur-

roundings, etc. Unless the operation is surrounded with proper safeguards, there is danger that discredit will be thrown upon it, and that it will be relegated to the obscure position which it occupied a few years ago.

During the late war gunshot wounds of the abdomen, under the expectant plan of treatment, showed, notwithstanding the many discouraging circumstances which attended them, a percentage of from five to seven recoveries. To-day in laparotomy performed in its entirety (which includes a thorough examination of the abdominal cavity and its contents, the suturing of the wounded intestines, the thorough cleansing of the cavity, and the closure of the wound), there was found to be a percentage of recoveries of no less than sixteen, a gain of more than half. These figures include not only the reported cases, but a considerable number which have come to his personal knowledge, but which have never been regularly recorded. In the cases actually reported, there were nearly twenty-five per cent. of recoveries.

Dr. Janeway said that the part of the paper which particularly interested him was that which referred to certain diseases of the abdominal cavity. The question of laparotomy in medical cases was all the time coming more and more prominently before the profession. In peritonitis, however, the conditions are usually so unfavorable that it was improbable that the exploratory operation would be attended with very brilliant results. He said he became so impressed with the unfortunate results attending purely medical treatment in many cases of peritonitis, that in a case last spring he resolved to give the patient the benefit of the best surgical advice, and called Drs. Bryant and W. T. Bull in consultation. It was one in which there was no hope of recovery whatever unless from operative procedure; and as this offered a possible chance (though the prospect was not by any means encouraging), it was resolved to perform laparotomy. This was accordingly done, but the patient unfortunately lived only twelve hours afterward, the autopsy showing a perforation of the vermiform appendix. Still, he believed that the operation was justifiable, and he should recommend the same again in any case in which the diagnosis could be made sufficiently early.

There is always more or less uncertainty, however, about the diagnosis in such cases, as was well illustrated in the case of a physician which had come to his notice. This gentleman had already had two attacks of what was apparently well-marked perityphlitis, when there were great pain and tenderness in the right iliac fossa, accompanied by a temperature of 104° lasting for a week or ten days. Last week he had another such attack, while in Boston, and laparotomy was then performed there by Dr. Marcy. Curiously enough, however, the exploration of the abdominal cavity revealed the fact that there was no assignable cause to be found for the trouble, though all the special symptoms regarded as typical of perityphlitis were present. Fortunately the case terminated favorably, and now, at the end of five days after the operation, the patient was doing well.

In many cases of perforation of the intestines in typhoid fever he said he would be inclined to recommend the trial of laparotomy, if the condition were recognized, especially by the presence of liver resonance, sufficiently early; and one case of this kind with a favorable result has already been reported in Germany.

Dr. Ira B. Read presented specimens from a case of

RUPTURE OF AN ANEURISM OF THE THORACIC AORTA,

as a sequel to a paper read before the Association several months ago. The case then reported was one of double popliteal aneurism where both femoral arteries were successfully ligated, the one in June, 1882, and the other in February, 1883. It was consequently more than three and a half years since the last operation, and more than four years since the first. The patient, while pursuing his usual avocations, died suddenly on the afternoon of October 29th, and at the autopsy made on the morning of the 30th, the pericardium was found filled with blood. On opening it the heart was found to be completely embedded in a large clot of blood, and further search showed that there was a rupture of the ascending portion of the aorta, the orifice in the sac easily admitting the finger. There was, however, but little dilatation observed, and other parts of the aorta showed marked atheromatous degeneration, so that rupture would soon have occurred in some of these had not the point of rupture described proved the earliest.

Dr. Read also exhibited a section of the femoral artery above and below the point of ligation. Below, the artery was occluded by what seemed to be an organized fibrous growth, while above there was the ordinary appearance of the normal artery. Unfortunately, he said, he was never able to examine the patient for abnormal heart-sounds or aneurismal bruits since the last operation; but at that time there were no physical signs of aortic aneurism.

He had not been able to find any probable cause for the arterial condition which existed in this case. The patient being a man of thirty, apparently in full vigor, with no history of syphilis, either present or remote, and not intemperate, he could only accept the fact that there was an atheromatous condition of the arteries which predisposed to aneurism, and finally led to his death. The heart was normal in size, and the lungs and liver healthy in appearance, but the spleen and kidneys were very much enlarged.

Dr. Janeway presented a specimen of

PERFORATION OF THE INTESTINE IN A CASE OF TYPHOID FEVER.

Peritonitis was present for two and a half days before death, but the usual flatness of the liver on percussion was not replaced by resonance sufficiently early to permit of any possible hope from a resort to exploratory laparotomy. The gas in such cases sometimes escaped very slowly, and the difficulty in regard to the operation was, that unless the liver flatness was lost, and there was severe pain, we could not feel assured that peritonitis was present. Indeed, in all cases there was some degree of uncertainty, since cases of supposed perforation and peritonitis had been known to recover. In reality, however, they were cases of enteritis or of gastritis. Such cases, therefore, should make us hesitate to perform laparotomy, unless the diagnosis were very clear.

The Pope's Model Cholera Hospital in Rome.—A correspondent of the *Globe* gives an interesting account of the "model cholera hospital" which the Pope has caused to be erected in Rome for the accommodation of cholera patients in case of an epidemic. Contact with the outer world is carefully guarded against by grated windows, telephones, and by a revolving barrel with half its circumference open, by which provisions are taken into the hospital. The water-supply is drawn from a well, and is quite separate from the city supply. The drain is formed of an iron tube sixteen inches in diameter, the joints being hermetically sealed with lead. There is a disinfecting boiler in which corrosive sublimate is placed. There is a room called the "chamber of observation," which has a staircase leading up to the first floor. In this room dead bodies are placed for a given time, as it is well known that cholera patients often show signs of being quite dead when really only apparently so. The room is, by means of an electric apparatus, in communication with the director's office. The body being laid on a bed, both hands are put into a sort of copper muff; between the hands is put an instrument so sensitive that, should there be the slightest movement of the hands or any other part of the body, this instrument would instantly close the electric circuit, and the bell in the director's office would be set ringing; at the same moment another instrument registers the number corresponding to the bed upon which the body is lying. The chamber is warmed by steam so as to facilitate resuscitation. The laboratory is provided with a gasometer for the storage of oxygen, which is taken to the wards for administration in gas-bags. On the ground floor are four wards for doubtful cases; should they get worse, they are sent up in the lift to the cholera wards above, their clothes and bed-linen being immediately burned. Another room is set apart for women in childbirth, and there are two more for undressing patients, so that the infected clothes may be destroyed, the Pope furnishing new clothing for all recovered cases. The cubic space allowed for each bed is thirty-six cubic metres. The ventilation is carried on by means of funnels with gas jets below. The chapel is in communication with the sacristy of St. Peter's, so as to form an easy access for the Pope should he wish to visit the hospital; but before returning into the sacristy his Holiness and suite would have to go into a room near it for disinfection. In the event of there being more cases than the hospital can hold, provision has been made for building large sheds in the garden. This hospital was begun in October, 1884, and finished in April, 1885. When the cholera was raging with such violence in Naples, Leo XIII. determined upon making preparations should the scourge visit Rome. It has never been necessary to use it, but it is always ready in the event of an outbreak, and would prove of much use in extirpating it.

Cremation in Australia.—The legislature of New South Wales has passed an act which legalizes cremation in that colony. Crematoria are to be established. The plans must pass the Board of Health, and every applicant for a license must satisfy the governor that he is the owner in fee simple, and has general consent to allow of cremation upon the land.

Errors in Delicate Weighing.—M. Hennig, of Würtzburg, having noticed some incomprehensible differences in the weights of equivalent quantities, undertook some minute investigations, which showed that balances of precision are often influenced by the electric state of the glass cage which surrounds them. This electricity influences the small auxiliary slides which are placed upon the beam of the balance in order to make it more sensitive. The error resulting from this influence may amount to 600 milligrammes when the cage is strongly charged, and two hours afterward there may still be an error of ten milligrammes.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 16 TO NOVEMBER 20, 1886.

Greenleaf, C. R., *Major and Surgeon.*—Relieved from duty at Columbus Barracks, Ohio, and ordered for duty as attending surgeon at Headquarters of the Division of the Missouri and Examiner of Recruits at Chicago, Ills.—*S. O. 268, A. G. O.*, November 17, 1886.

Tilton, Henry R., *Major and Surgeon.*—Relieved from the duties of attending surgeon at the Headquarters of the Division of the Pacific and the Department of California.—*S. O. 96, Division of the Pacific*, November 9, 1886.

Waters, W. E., *Major and Surgeon.*—Ordered from Fort Spokane to Vancouver Barracks, W. T., for duty at that post.—*S. O. 197, Department of Colorado*, November 8, 1886.

Par. 8, S. O. 257, A. G. O., November 4, 1886, is so amended as to direct Major V. B. Hubbard, Surgeon, to report in person to the commanding officer of Columbus Barracks, Ohio, for duty.—*Par. 3, S. O. 268, A. G. O.*, November 17, 1886.

Caldwell, D. G., *Major and Surgeon.*—Granted leave of absence for one month, with permission to apply for twenty days extension.—*S. O. 150, Department of the Platte*, November 12, 1886.

APPOINTMENTS.

Moore, John, *Lieutenant-Colonel and Assistant Medical Purveyor.*—To be Surgeon-General of the Army, November 18, 1886.

Ball, Robert R.—To be Assistant Surgeon with the rank of First Lieutenant, November 19, 1886.

PROMOTIONS.

Baily, Joseph C., *Major and Surgeon.*—To be Assistant Medical Purveyor with the rank of Lieutenant-Colonel, November 18, 1886.

Heizmann, Charles L., *Captain and Assistant Surgeon* —To be Surgeon with the rank of Major, November 18, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 20, 1886.

Nash, Francis S., *Passed Assistant Surgeon U. S. N.*—Ordered to special duty Smithsonian Institution, November 26, 1886.

Rhoades, A. C., *Medical Inspector U. S. N.*—Ordered to special duty attending officers and families New York City.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL LECTURES.

ON SOME ODD-LOOKING DISORDERS OF THE SKIN, PRODUCED BY COMMON CAUSES; AND THEIR TREATMENT.

A Lecture delivered at the Clinic for Skin and Venereal Diseases, Rush Medical College, Chicago.

BY JAMES NEVINS HYDE, M.D.,

PROFESSOR OF SKIN AND VENEREAL DISEASES IN RUSH MEDICAL COLLEGE, CHICAGO.

GENTLEMEN: The first patient presented to us to-day is a fair-skinned English woman, thirty-five years old, the mother of three healthy children, two of them, as she says, victims of the disorder from which she herself suffers. Three weeks ago, after a steerage passage across the Atlantic, she arrived in this country; and, though never before similarly affected, has ever since been suffering from a disease of the skin. The parts affected are the face, the arms, especially the forearms, the hands, and, to a much less extent, the feet. The children, not present, are described as exhibiting the disorder in the same regions of the body. A physician who was consulted in order to procure relief from the severe and incessant burning and itching sensations of which she complained, is reported to have declared that she had syphilis, and to have ordered a solution of the iodide of potassium to be taken internally. The mere recital of these facts alone should lead every one of us to the diagnosis of the malady.

When we examine her with care, we see that her skin presents a picture of really serious mischief. The arms are enormously distended, the integument being infiltrated, tense, shining, hot, and of a bright reddish hue, strongly suggestive, indeed, of the erysipelatous skin. It is covered here and there, more particularly the skin of the forearms, with superficial pea-sized to finger-nail sized, discrete, and moderately distended blebs. Some of these are filled with a clear serum; others are ruptured. Among them may be recognized erosions made by the nails in scratching, thin and superficial crusts, and the detritus of the stratum corneum where blebs have existed. Looking at the face, it is plain that here the skin is less tumid, but thickly sprinkled with minute, engorged papules of the "pruriginous" type, and also with bullæ, the latter fewer than over the arms, and yet similar as to their general characteristics. Here also are crusts, the débris of ruptured blebs, and erosions from the play of the hands over the part. The erysipelatous appearance is here much less suggestive.

As several patients in nearly this same condition have been shown here during the last few weeks, and the eruptive phenomena have been remarkably alike in all, you will, some of you, be quite prepared for what is to be said of them all. First, however, I desire to admit very frankly, that five years ago I was greatly perplexed by cases of this sort, and that my attention was first directed to their real nature by my friend, Professor James C. White, of Boston.

Now, as we look at the skin picture before us, we revert naturally to the somewhat long list of maladies characterized by a bullous efflorescence, such as erysipelas, hydroa, pemphigus, pompholyx, and the several herpetic disorders. Yet here we have a malady of much simpler etiology than the most of those named. It is an eruption produced exclusively by the depredations of the mosquito, upon the sensitive and tender skins of women and children who are totally unacclimated, and thus unprovided with that kind of protective inoculation which is furnished by generations who have endured, and thus secured partial immunity from such attacks.

The American mosquito, related to the *simulium pertinax*, is not found in Great Britain, the "gnats," of which the people of that country occasionally complain, being a more harmless variety of the *culex pipiens;* and these inflict only the most trifling damage upon the skin.

I take it that you are all familiar with the picture of the face and arms bitten by mosquitoes. It is the bullous lesions of the integument exhibiting the erysipelatous appearance, that furnish the peculiar features here, and are quite characteristic of the skin of the newly arrived immigrant who has been assaulted by these insects. However, I call your special attention to the fact that in some regions of the West and Northwest, not settled by lately arrived immigrants, this form of eruption may be occasionally recognized. Nor is it only the English, Irish, and Scotch, who give us the portrait you have before you. It may be observed (though in my experience less frequently) among the Germans, the Scandinavians, and others coming here chiefly from the northern European countries.

The history is usually the same, the features of the disorder being modified in different cases: A midsummer or fall passage across the Atlantic, usually in the steerage; occurrence of the eruption speedily after landing; residence in one of the poorer class of tenement houses, unprovided with screens and nettings to prevent the incursions of the marauders; and appearance of the lesions only upon the exposed parts of the body, the face, the hands, and, to a less extent, the feet. Then comes a visit to the public dispensary, where too often the administration of arsenic, the iodide of potassium, or mercury, intensely aggravates the irritation of the tormented skin. Fortunate the patient, thus afflicted, when he falls into the hands of a physician who, though ignorant of the disorder with which he is confronted, is wise enough and judicious enough to refrain from aggravating the disease, if such it may be called.

Women and children of the class described are often huddled together with scanty bed- and body-clothing, which may be tossed off in the unconsciousness of sleep and in the agitation produced by the mosquito stings. In this way is to be explained the occasional occurrence of the rash we are studying, on the belly, and even on

the back. Do not be put off your guard by statements as to the existence of the eruption in unusual localities. I have seen the bullæ now shown you, over the skin of the penis in the male. I think you can now understand why I said at the outset that the history alone of this odd-looking eruption points to its diagnosis.

The treatment is simple; First, the removal of the cause, which our patient, now that her attention is called to it, admits, with some laughter, has operated in her case. After the sleeping apartments have been protected by screens, which even the poorest are glad to use when informed of all the facts, we shall make a solution of starch precisely as the laundresses make theirs, first with cold water then with the addition of hot, the paste being well cooled before its application. To each pint of this, we will add a drachm of the zinc oxide, mixing it thoroughly with the whole. This will be grateful to the skin, and, when some relief is obtained, we shall direct merely the use of a dusting-powder of dry starch. For the milder cases, weak lotions of camphor, or of the potassic chlorate are popular and efficient topical remedies.

Our next patient is a vigorous man, twenty-seven years of age, and unmarried, who comes to us all the way from Kansas, to be relieved of what he says is there called "the prairie itch." He has suffered greatly for a fortnight; and is really alarmed at his condition. He complains of an intense itching, with nocturnal aggravation, produced by an eruption affecting the trunk and thighs chiefly, but also generalized, the face, hands, and feet escaping.

On removal of the clothing, the skin is found to be soaked in sweat, and in the regions named covered with minute, bright-red papules, excoriations, thin superficial crusts, scratch-marks, and some larger, raw erosions. Inflamed, and acutely inflamed regions of the skin are conspicuous, especially in the groins, over the belly, the upper thighs, the popliteal spaces, and the axillæ. The integument of the trunk, in large areas, all other lesions excluded, is of a bright red hue, in fact, of altogether too bright a red to enable us at a glance to classify it with the shades we commonly recognize in a hyperæmic skin. It has a suspicious scarlet quality in its tint.

I ask you to look closely at this color, for you will perhaps need to recognize it one day when you may not have, as here, the opportunity of comparing it on the spot with the color of the material from which, chameleon-like, its hue is gathered. Notice that even in the temperature of this fine weather, the patient is wearing next his skin thick flannel under-garments, dyed in the popular scarlet shades produced by the cheaper dyes made of aniline and picric acid. Outside of these brilliant garments, his white shirt at the waist, armpits, neck, and nether flaps is deeply tinted by these dyes, which his profuse sweating has in part dissolved. In the same way the skin beneath, is not only reddened by a hyperæmia resulting from the irritation induced in it, but is, beside, actually dyed to a shade scarcely less brilliant than that of the clothing. The misfortunes of our patient, as we now discover by questioning, date from the wearing of these garments, which were first purchased in the effort to secure relief from a "rheumatic" attack. Thereafter, came the profuse sweating on a hot day in the State where he was working; then the irritation of the skin, both by the sweat, the flannel, and the dye; then the scratching and the consequent traumatisms; lastly, the composite picture, the details of which we have been endavoring to study separately.

What is the so-called "prairie itch? Who can answer? It is a name—that and nothing more. In one mouth it means one thing; in another, another. All popular names have a similar indefiniteness. The folk-speech that gives us to-day, the "rheums," "tetters," "scalds," "cradle-cap," "itches," "manges," etc., includes syphilis, lichen planus, eczema, all the dermatitides, and even disorders produced by vegetable parasites. It is, I believe, within bounds to say that, in the majority of cases, the words "prairie itch," describe cases of more or less generalized cutaneous pruritus, occurring in a given community more or less extensively, and produced by many and different causes. In one place, sudden and severe temperature changes may be responsible for it, such change being usually from the higher to the lower degrees; in another place, acari; in another, these and other causes coöperate, as where the coarse flannel under-garments worn by the poorer classes in cold weather, the traumatisms of scratching, and improper internal or topical treatment have greatly complicated the whole etiological question. Here is a man who says that he has this disease, and that it is extensively prevalent in the place from which he comes to us; yet we find that he is suffering from a dermatitis venenata—the skin poisoned by a dye externally applied. If he had come to us from Boston, or Philadelphia, he might never have heard of the "prairie itch," and might then have given us some other popular name for his malady, having no more significance than that actually on his lips.

Cases of dermatitis from these cheaper dyes, have been reported by a number of observers, for example, by Dr. Duhring, of Philadelphia, who has seen the feet of women thus affected by the red lining of their boots, even when a stocking was interposed. Few have seemed to call attention to the color of the skin when in this way it is actually dyed. My first observation of this accident was upon the neck of a young man recovering from a syphilitic exanthem, who became greatly alarmed by the appearance he presented. He exhibited a conspicuously brilliant, and tolerably well defined collar, of a vivid red hue, encircling the neck, which, after some investigation, I discovered to be the result of a profuse sweating when he was naked and wrapped in a blanket, the bright-red edge of which had been gathered closely about the neck. It seems that at last our English brethren are awaking to this source of trouble in similar cases, for a recent correspondent of the *British Medical Journal*,[1] under the title "Socks of Nessus," calls attention to severe eruptive symptoms, even in one case of erysipelas, resulting from these dyes in both woollen and silk stockings of the popular red, yellow, and striped colors. In some of these articles he detected not only the cheaper aniline and picric acid dyes, but also arsenic, and, like a true Briton, calls upon his Board of Health to stop the sale of these garments.

In the way of treatment, we shall order for our patient, first, the wearing of soft, white under-garments (the best is the "Lisle-thread" of the shops), outside of which can be worn the woollen which his supposed "rheumatism"

[1] October 16, 1886, p. 729.

requires. Next comes the local treatment of the skin. It is to be bathed in water as hot as is grateful to the sensations, without soap, and a muslin bag filled with common bran is to be squeezed into the water before its use. Too much bathing is harmful to a skin as acutely affected as is this; but it is well to make occasional use of the hot bath, when there has been accumulation of physiological and pathological products on the surface. We shall not attempt to scrub off the dye in this first bath, because our efforts would aggravate the disorder we are treating, and would, beside, be fruitless, even if we employed alcohol to aid in this removal. It is best, in most of these cases, to let the color of the skin remain unchanged, as the worst harm is already done, and the indications are urgent for soothing the surface.

After the bath, the skin will be anointed with a salve composed of one part of Hebra's diachylon ointment to two of vaseline, the whole containing ten grains of salicylic acid to the ounce. This will serve for relief of the skin until much of the disorder is at an end, after which it will be well to apply a simple salve, such as cold-cream, followed by dusting with a finely powdered starch. He is to keep his hands from wounding the skin as far as possible. We shall find that a few days' rest in bed will be an excellent way of beginning the treatment in all these cases.

I think that you will agree with me that our next patient has an "odd-looking" disorder of the scalp. He is unmarried, twenty-three years of age, and is sallow-faced, thin in flesh, and hollow-eyed, with the facial expression we are apt to discover in the morbid mental state of the confirmed sexual hypochondriac. His scalp is, for the most part, covered with short-cut hairs, but, parallel to the sagittal suture, and somewhat to the right of it, stretches a fairly well defined, riband-like space, about two inches in width, extending from the upper line of the forehead to a point somewhat behind the vertex, where it is gradually lost. This space, he tells us, has been for many years the seat of a disease which has defied the skill of many physicians and the potency of many drugs. It began with some "sort of a worm eating the roots of the hairs" in a space which was originally epilated by a physician, whose advice was sought but who was unable in this way to check the progress of the disease. Since that time the patient has found it necessary to perform the same operation himself.

When we examine this area of the scalp, we are only able with the naked eye to discover a few irritative papules, similar to those seen in a mild case of acne of the face, existing in the bare epilated patch which, in its definite outlines, suggests the swath cut by the mower in a field of tall grass. There is absolutely nothing more. I will add, however, that before this hour I carefully removed and examined with the microscope specimens of the few hairs left in the bald patch, and also others in its vicinity, without being able to detect the slightest trace of a parasitic or other disease of the part.

What is the nature of this trouble? I have presented this patient to you to-day because I have lately had another consult me privately for a similar affection, and occasionally every physician is confronted with a class of patients of whom this one may be regarded as a type. Is it possible that any parasite, vegetable or animal, could continue for years to mow down a swath of hairs in this manner, the outlines of the swath always the same, parallel to the sagittal suture, and slightly to the right of the median line? Such a possibility can scarcely be considered. But it is not at all difficult to understand how a right-handed man (and I will add that this is a right-handed man), after acquiring the trick of epilating his own sound hairs with his right hand, could keep as bare as this the island of his scalp which is so deforming. This is the explanation, and the only explanation, of the singularity of this case. Now you see why the bare patch is parallel to the sagittal suture and nearer the right temple.

Originally, there may have been here some disease of the scalp. There may have been a tinea capitis, a patch of localized seborrhœa, possibly a disorder actually requiring the epilation it received at the hands of his physician. That is neither here nor there at present, for we pronounce the scalp free from all disease save that it is the seat of the incessant irritation produced by the action of the fingers.

It is a curious element in the case, as in so many others of similar import, that this patient was dimly conscious that he and he alone was the cause of all the mischief; and yet that he never made a confession of the fact to any one whom he consulted. When in private, I probed his supposititious secret to its very bottom. He was not a little shamefaced over the whole matter. He admitted, when once I had gained his confidence, that he had shaved his beard merely because he had acquired the vicious habit of plucking that out also; and that he was almost unconscious of the play of his fingers over his scalp, seeing that even after protecting his head with a bandage, he had discovered himself pushing it up and away, and dragging out every hair in the reach of the fingers.

In brief, this is one of those wretched perversions of habit that afflict a few men in every thousand, who, in other respects, seem to have tendencies toward uncleanliness and filth. Picking the nose, titillating the genitals, boring out the ears, cracking the knuckles, epilating the eyelids with the fingers, scratching the anus, these are but a few of the tricks played upon themselves by persons who are never content when not manipulating their own persons. The next morbid craving of their souls, is to perplex a few inexperienced physicians into treating them from the wrong side. In the latter event, their mental process is a curious and pitiable one, being a strong hope that they can find some one who, in spite of their feeble resistance and secrecy, will penetrate to the real basis of their disorder, and also a dim conviction that, everything said and done, they are really morbid in mind and body, and need help.

More than half of the treatment is the establishment in the mind of the patient of a conviction that he is under the direction of a man who has got at the core of his case, and who has the courage to be merciless in driving him out of his habits while pitying his condition. A judicious admixture of scolding and encouragement is always needed. We may have to shave this scalp before we break up the habit he has formed; and shall certainly see that the hands and the brain are busied with exacting labor. Toil, daily, absorbing, exacting, and rewarded by its legitimate fruits, is Nature's great panacea for these singular morbid states.

Our last patient for to-day is an unmarried man, twenty-nine years of age, somewhat pallid with anæmia, who gives us the history in his case, of an eruption enduring for ten years. Originally, the face only was involved, but soon after the trunk was also affected; and, for the most part, since the beginning, the trunk only, as now, is the seat of a cutaneous disorder. The treatment he has pursued, has exhausted, he says, his means, his patience, and his vigor. It has been varied, received at the hands of many physicians, and in several of the popular health resorts of this country, but always without benefit.

The posterior surface of the trunk of his body being now fully exposed to the view, it is not perhaps strange, considering the oddity of its appearance, that no one of you can determine the nature of the malady,

You see that the back is practically symmetrically involved, from the shoulders above to the upper border of the lumbar region below, in a singular change. The predominant result is declared in multiple, whitish, indurated, irregularly disposed, and elevated bridges of cutaneous tissue, these bridges varying in size from half to full finger-nail, abutting on sound skin, or other smaller bridges, or on other lesions less numerous and conspicuous. These others are irregularly disposed among the scar-like bands, and may be described as giant pits, the orifices of which are only rarely plugged with gigantic comedones; pigmented, purplish, and dirty-colored blotches, and indolent nodules of irregular form. The general picture, however, of this odd-looking back is produced upon the eye of the observer by the scar-like puckerings which, seen from a short distance only, suggest a field of skin so ploughed up in every direction as to form elevated ridges resembling in point of color those parts of the same field where the furrows lie. The other colors visible bear no considerable proportion to the dull whiteness of these embankments.

Rather than as a disease, this condition would be better described as the relics of a disease that has been. It is a form of keloid following severe acne. I will not say the "acne cachecticorum" of the books, for the appearance of cachexia in cases like this is often the fruit of mismanagement of a disorder in a man who is not cachectic.

We will not discuss the distinction between idiopathic and cicatricial keloid in this connection. It must suffice for us to note now, that the cicatricial variety of keloid occasionally follows the simpler as well as the severer forms of acne. It is a serious and practically irremediable deformity when seated upon the face of a young woman, and the prudent practitioner should never once lose sight of the possibility of its occurrence after the treatment of any case.

It is surprising how many otherwise excellent chapters have been written on the subject of acne, without reference to this one of its complications. When you are tempted to take a bistoury and incise fifty or more acne papules on the face of a young woman, remember the possibilities of future mischief in the production of cicatricial keloid, and ask yourselves whether a properly disinfected needle in a firm needle-holder, its point neatly rounded on the emery-wheel, will not answer the purpose equally well.

But in this connection, the point of chief importance is not to be slighted. We have here an object-lesson on a large scale, in the picture upon the skin of the vast damage to it which may result from the indescribably vicious practice of attempting to cure a disease by "driving it out." Our patient, with a rough eloquence not unmixed with indignation, describes how, year after year, he has been subjected to this method of treatment by the aid of the iodide of potassium. The definite limitation of the disease to his back, soon after the date of its appearance, was probably due to the fact that he was a day laborer, wearing coarse under-garments, sweating profusely, and began by local treatment of this region. The more profuse the eruption induced by the drug he swallowed, the more he was led to believe his disease was being "driven out," and thus eliminated. We need not gather the numerous details he gives us as to the several devices, local and general, which have been actively tested in his case. It is sufficient for us to know that he presents no evidence whatever of syphilis; that he denies all syphilitic infection; and that there is not the slightest indication in his case for the use of such a drug as the iodide of potassium. I have said so much lately on this same point, that I merely remind you at this time that the iodine salts are actually excreted by the sebaceous glands; and that we are almost ready today to concede that every one of the primary lesions of the skin, from the macule to the bulla, in every conceivable combination and disposition, may be by this means alone, both begotten and fostered. The expert of the future may be able to demonstrate to others all the external features of the disorders assigned to dermatology, by the aid of a single drug, exhibited to a single patient!

I will not say that cicatricial keloid in the extensive development we have here, is due solely to the administration of the iodide of potassium. But I will say that the severer forms of acne are those where we may look for cicatricial keloid; and that the severer forms of acne are usually those aggravated by the internal use of the iodide of potassium.

For this patient the worst is at last over. Not all the sebaceous glands in his back are sealed with scar-tissue; but the exceptions are few, and represented for the most part by the wide-mouthed pits visible here and there, distended with giant comedo plugs. The pigmented and colored maculæ represent the points where the last vestiges of the storm raged, the fury of which abated chiefly because it had worked its worst over the only accessible field. Nothing can be done to relieve the back of these relics of what is past, since even surgical interference is liable to aggravate the condition by new sequelæ of cicatricial keloid.

What we can do is to insure against future trouble by excluding all improper medicaments from his stomach; and by administering a ferruginous tonic for relief of his anæmia. We shall teach him a needed lesson on the hygienic management of his skin, that of the back included; and the future will have no such terrors for him as the past.

And now, gentlemen, glancing over this group of cases in which odd-looking symptoms have been exhibited, it seems to me that the lesson taught is a clear one. When unusually strange or odd-appearing features are displayed in any case, do not commit the blunder of supposing that, for that reason alone, the disease is rare of

occurrence, or obscure in character. In the majority of all such cases, the truth lies in precisely the opposite direction. Oddity, irregularity, non-conformity to the rule, may, it is true, be due to the existence of rare and formidable disease. But, in the large proportion of all cases, such oddity is due to the interposition of a simple cause which lies right at hand, and which some common sense and moderate skill will drag to the light.

If, for example, a woman infected with syphilis, exhibits as many and as formidable mucous patches in the mouth as does the most inveterate tobacco smoker, the result is not due to any peculiarity in her syphilis, but may be, as in a case lately shown here, owing to the fact that the woman is an inveterate smoker of a common clay pipe. Or, if we find an eczematous patient with a well-defined bracelet-patch of the disease on each wrist, instead of referring the disorder to some peculiarity of the eczema, it is a great deal safer to assign as a cause the fretting of the affected surface by the stiffly starched edge of the linen cuffs, which are rather more sharply effective in the production of these symptoms when they are both stiffly starched and somewhat frayed at the edges.

Remember, lastly, in your search for these efficient factors for the production of odd-looking characteristics of any disease, that from the moment a man rises in the morning to use his razor over his chin, and a woman to lace her corsets about her waist, throughout the entire day, whether engaged in eating, drinking, swallowing medicine, or applying liniments, whether wearing spectacles that bind the ears, or a truss that offends the groin, whether tormented by louse, bug, or acarus, in all the occupations, trades, and employments of life, up to the hour when, the day's labor ended, the clothing is removed from the body, and the hands in sheer idleness proceed to scratch the shins and other accessible parts, in order to relieve the faintest grade of pruritus—from first to last, there are a thousand vulgar sources of mischief for the skin, to one that is called by a very learned name and has been studied only in a foreign country. There is no better study for the modern physician than the interpretation of the apparent mysteries of every day's experience.

STRANGULATED HERNIA, WITH A REPORT OF THIRTY-THREE HERNIOTOMIES.[1]

By P. S. CONNER, M.D.,

PROFESSOR OF ANATOMY AND CLINICAL SURGERY IN THE MEDICAL COLLEGE OF OHIO, ETC.

Its frequency of occurrence and the existing possibility in any case of its becoming dangerous to life make hernia an affection deserving and demanding the careful consideration of every practitioner.

At the best it is a positive annoyance, and a grave obstacle to success in many vocations; at the worst it is an almost certain cause of death. No ruptured person, so long as there is an existing protrusion, is safe against its strangulation; and strangulation, if unrelieved by art, in the great majority of cases terminates fatally. Spontaneous reduction occasionally takes place; a few patients recover after an artificial anus has been established by gangrene; but neither the one termination nor the other is to be looked for or calculated upon.

Of three-quarters of a million (756,893) deaths reported to the Census Bureau in 1880, and analyzed in the volume of Mortality and Vital Statistics, one in 600 was from hernia; and, strange to say, one-ninth of these 1236 deaths, 141, were of children less than a year old, the whole number in persons under thirty being only 293. Hernia is common enough in infants, but the occurrence of strangulation is very exceptional. Here in Cincinnati, in twelve years past, the deaths from rupture, as reported to the Health Office, have been 109, and they are now averaging one a month. Unquestionably the actual mortality from this cause is greater, the fatal result being oftentimes attributed to other affections.

Though the symptoms of strangulation are ordinarily clearly manifested, they may be ill-defined and doubtful. In every case of acute constipation, vomiting, and abdominal pain, careful examination of the hernial regions must be promptly and thoroughly made; every suspicious lump, be it never so small, should be regarded as a hernia until proved to be otherwise. Many a life has been lost because a supposed lymphatic gland was not uncovered; and not simply uncovered, but opened up. I have seen a small mass of omentum in the right inguinal region so closely simulate in shape, size, and color an enlarged gland that it was not until it was cut into that I was satisfied of its nature; and yet that small mass had within a knuckle of bowel tightly constricted. In a very fat subject a small protrusion may be detected with great difficulty, or not at all; but in ninety-nine cases out of a hundred an inguinal or femoral hernia can be discovered if proper search is made for it. Even if the bowel obstruction be not complete, if the other symptoms are present, and there is an abnormal fulness just above or just below Poupart's ligament, an exploratory operation should be made. A patient in the medical wards of the Cincinnati Hospital, eight years ago, had vomiting, with abdominal pain and tenderness, but not fecal obstruction. As there was a small suspicious lump in the left inguinal region I cut down upon it, and exposed the gangrenous top of a knuckle of bowel, the constriction involving only the anterior wall of the sharply flexed gut, leaving free enough of the lumen of the tube to permit the passage of thin fecal matter, and the patient had four stools during the forty-eight hours that he was in the hospital before I was asked to see him.

The hernia recognized, it must be reduced. Taxis, if it succeeds, accomplishes the desired purpose without exposing the patient to the risks of an open wound; but, if the return of the bowel is effected only after long-continued severe manipulation, dangerous and usually fatal inflammation may be the direct result of the violence done; the taxis having, instead of putting in order, sadly put out of order. Fortunately the bowel oftentimes recovers from the effects of much violence.[1] Sometimes, though no

[1] Read before the Cincinnati Academy of Medicine, November 15, 1886.

[1] Perhaps unfortunately, for, if it were true and thoroughly well understood that the exercise of other than gentle pressure would

undue force has been employed in the reduction, a general peritonitis is soon developed by direct extension from the previously nipped and already inflamed intestinal loop, such extension rarely taking place so long as the tight constriction remains. If the protracted, or repeated, or violent manipulation fails, and recourse must be had to the knife, the probabilities of a successful issue are greatly diminished by the delay and the local injury from undue pressure.

What is proper taxis, as respects both time and force? It is impossible to say. Judgment and knowledge should in every instance direct and control the manipulation. One thing is certain, taking numbers of cases together, there is very much more danger in severe prolonged taxis than there is in herniotomy. So far as patients are concerned, it is better to cut too soon and too often than to delay too long in the hope that further and more forcible efforts may secure reduction. While it seems to me unwise to fix any arbitrary short limit, whether it be five minutes or half an hour, beyond which manipulations should not be prolonged—for what is right in one case and to one person may be altogether wrong in and to another,—yet I am not sure but that fewer lives would be lost than are now if it was the rule to operate at once on every case that was not speedily relieved by the efforts of the patient himself. No ruptured person is liable to damage himself seriously, though he may occasionally do so; but the same cannot be said of the inexperienced practitioner, especially when working upon an anæsthetized patient.

The more I see of hernia the more I am convinced that, if the protrusion does not go back readily and speedily, the best interests of the patient will be subserved by an early operation. If the constriction is outside the sac, and the lesser operation is all that is required, there is almost no risk in its performance, and a speedy recovery, often by first intention, may be expected. One of my patients on the ninth day walked a mile and had a truss fitted. If the sac must be opened, the danger is increased; but, under present methods of treatment, not greatly so. Of the fatal cases that I have had, in but one was death due to the wound; and in that case it was tetanus, a rare complication, that interrupted what had been for more than ten days, and promised to continue to be, a steady progress toward recovery. So little is the danger now directly due to the opening of the sac, and so great is the risk to life if an ulcerated or dying knuckle is returned into the peritoneal cavity, that I believe it is the wisest course in all cases other than those of very short duration to expose and examine the constricted bowel or omentum; especially since, by including a stump of the sac in sutures passing through the margins of the external inguinal or femoral ring, early reprotrusion is prevented, and a radical cure of the hernia may often be effected.

But, it may be said, why talk of the little risk of the operation for strangulated hernia, when from one-half to two-thirds of those operated upon die? Granting the mortality, is it in any considerable measure due to herniotomy? No; but almost always to shock and peritonitis, in the production of which the prime factor is the prolonged period of strangulation. We can well understand why a severe intestinal injury produces a most profound impression upon the sympathetic centre, the abdominal brain; and what to a loop of bowel can be a graver traumatism than a long-continued tight constriction. I have found a man after only a six hours' strangulation in a moribund condition; and in no other class of cases have I seen more severe shock. The majority of those who die with an unreduced hernia do so from this cause, aided, it may be, by the poisonous action of absorbed ptomaines; and it is shock as much or more than inflammation of the bowel that generally in cases of delay puts the patient in so bad a condition for the performance of an operation. Cut the constriction, and free the bowel or the omentum, and (as Hutchinson showed twenty or more years ago) peritonitis by continuity may be rapidly developed; and no antiseptic operation or after-treatment of the wound can altogether prevent such extension. If the strangulation has lasted so long that the gut or the omentum has become gangrenous, the ordinary depressing effect of local mortification is further added; and occasionally it happens (I have myself twice seen this) that, as the consequence of the tight constriction, persistent paralysis of the engaged part of the bowel is produced; the peristaltic action remaining arrested, the vomiting continuing, and the patient dying just as he would have done if no operation had been performed.

Intercurrent affections will sometimes directly or indirectly cause death. Twice in patients suffering from senile bronchitis I have known a severe paroxysm of coughing force out again the replaced bowel, and the existing lung disease contributed in no small degree to the production of the fatal result. Does not ether inhalation have a decidedly injurious effect upon those subject to chronic cough, asthmatic or bronchitic? Shock, peritonitis, or gangrene, is, in the vast majority of cases, the cause of death, and peritonitis is the only one that can in any manner be attributed to the operation, while each and all are favored by delay.

Wound complications—erysipelas, cellulitis, septicæmia, tetanus—are responsible for but a small fraction of the mortality percentage, and the first three, certainly, can be largely prevented by proper wound-treatment.

Speaking generally, it is not the operation that kills, but the delay in its performance. Of the 33 patients upon whom I have operated, 12 (6 males and 6 females, 36.4 per cent.) recovered, 21 (14 males and 7 females, 63.6 per cent.) died. Of the former, in but 3 had the strangulation existed more than twenty-four hours; of the latter, in but 2 had it lasted less than that length of time; in the remaining 19 its duration having been, in 2, seven days; in 2, over six days; in 1, over four days; in 4, over three days: in 4, over two days; in 4, more than thirty-six hours; and in 2, more than twenty-four hours. Of the 33 herniotomies, 20 were done

certainly rupture the intestine, there would be vastly less crowding and pushing and squeezing done than now, and the death-rate without, and especially with operation, would be greatly lessened.

upon men, 13 upon women; 17 for inguinal ruptures, with 4 recoveries; 15 for femoral, with 8 recoveries; and 1 for umbilical, fatal. The youngest person operated upon was twenty, the oldest eighty-three years of age; the former dying, the latter getting well. Two of the patients were between twenty and thirty years old, 4 between thirty and forty, 13 between forty and fifty, 6 between fifty and sixty, 6 between sixty and seventy, 1 between seventy and eighty, and 1 over eighty. Of those that died, 1 lived thirty-eight days (dying of a low grade of septic fever), 1 fifteen days (dying of tetanus), 1 nine days (dying of pneumonia), 1 five days, 3 less than four days, 3 less than three days, 5 less than two days, and 6 died within twenty-four hours, 2 of them in less than one hour, being *in extremis* at the time of the operation.

In three cases the bowel was gangrenous when exposed, having been strangulated respectively seven, six, and three days. In one case, though the strangulation had lasted but six hours, three bloody stools were passed after the operation, and, on autopsy, much coagulated blood was found in the intestine below the level of the upper constriction, due possibly to injury done during the efforts at reduction made before the man was admitted to the hospital. This was one of the two cases, already referred to, in which there was paralysis of the constricted part of the bowel continuing up to the time of death, two and a half days after the operation was performed. In one case there was congenital absence of the right half of the scrotum, with retention of a much flattened and wasted testis in the inguinal canal; the hernial pouch pushing out toward the iliac spine. In another case the hernia had descended to the right labium, the right ovary being below it in the labium. This is the only case of inguinal hernia in the female among those operated upon.

Three of the herniotomies were for femoral rupture in the male, the sac contents in two being intestine, in the other, omentum.

SUPRAPUBIC CYSTOTOMY FOR SCARCOMA OF THE BLADDER.

By ROBERT F. WEIR, M.D.,
SURGEON TO THE NEW YORK HOSPITAL.

The uncertainty which has attended the removal of vesical growths has been greatly diminishd by the recently revived use of the suprapubic section of the bladder, an operation which has not only been made more safe and easy by the elevation of the bladder from the pelvis by its own and by a rectal dilatation, but the entire surface of the vesical cavity is now placed at the command of the surgeon. For the removal of a calculus the high operation has been resorted to in America not unfrequently, but for the removal of a tumor its employment is yet quite rare. The following case may, therefore, in this light be of interest:

Mr. G. A. T., of a family and residence free from taint of neoplasm, and aged fifty-five, was referred to me by Dr. C. A. Loring, December 24, 1885, for relief of a severe hemorrhage from the bladder, which had then occurred for the first time, though the patient had had frequent micturition for more than two years, and had complained of rectal pains during that time, which he attributed to hemorrhoids. By bimanual examination an increased fulness was felt in the left side of the bladder, but as no anæsthetic was used, this examination was not considered satisfactory. A slight equal enlargement of the prostate existed. Nothing abnormal was found in the clots discharged by the vesical tenesmus. This latter was severe enough to demand large doses of morphia by suppository. The hemorrhage was controlled by plugs of ice frequently passed into the rectum, by ice over the bladder, and by the internal use of ergot and gallic acid in large quantities.

On the 29th of January, 1886, a recurrence of the bleeding took place, but nothing distinctive was found in the clots. After this had stopped, an exploration of the bladder with a sound revealed nothing decisive. Twice during this time the urine became almost jellied from effused fibrin, a condition considered by some pathognomonic of a tumor, but which I have found in a case of cystitis for which perineal cystotomy was done, and in which no tumor existed.

In April a severe hemorrhage occurred, distending the bladder to the umbilicus, and exsanguinating the patient greatly. Ice in the rectum and gallic acid again helped to control the bleeding, and the bladder gradually emptied itself of the clots in the course of two weeks. The patient finally consented to have an examination under ether, to be followed by an operation if a tumor was discovered. I therefore made arrangements to have him placed in a private room in the New York Hospital, and on May 11th anæsthetized him. With the finger of one hand in the rectum, and the other hand firmly pressing above the pubis, a resisting mass was felt to the left of the median line, and the rather forcible use of a sound confirmed the diagnosis, by the resistance offered to its movements to the left. Suprapubic cystotomy was thereupon performed after the following detail:

1. A large rubber dilator, pear-shaped, made by Weiss, of London, was folded into a cone, oiled, passed into rectum and slowly filled with sixteen ounces of warm water, by a bulb syringe. Then through a soft rubber catheter which had been previously passed into the bladder, seven ounces of warm (1:20,000) bichloride solution were injected in a similar manner, when, the catheter having been withdrawn, the penis was firmly compressed at its base by a piece of rubber tubing tied around it. All the lower portion of abdomen was thus caused to bulge forward, and on percussion in the hypogastric region, dulness for nearly two and a half inches above the symphysis was obtained. An incision three and a half inches long in the median line, with its lower end just above the pubes, was made through the skin and subcutaneous fascia, the deeper tissues were torn apart with handle of scalpel, the *linea alba* nicked and divided on a director, and dissection with the scalpel handle to the level of the bladder resumed. Here was rather profuse bleeding from numerous small veins, which required ligature. The bladder was thus

exposed, pierced, and pulled forward by a tenaculum, and opened by a median incision two inches long; two loops of silk string were then passed through the edges of this incision and the abdominal wall on either side, and by use of these and blunt retractors, subsequently introduced into the bladder, the edges of the wound were held apart. Immediately an irregular, reddish, friable tumor, about two inches long, one inch wide, and half an inch in thickness, and situated just posterior to the outlet of the left ureter, came into view, and, so superficial had it become by the rectal pressure that the tumor could readily be made to project outside the bladder by depressing the walls of the incision.

The mass was so soft that it broke down in the attempts to remove it, and considerable oozing of blood thus occurred, promptly arrested, however, by the pressure of a sponge. The attachment of the tumor was three-quarters of an inch in diameter, circular in shape, and with depressed and irregular edges. It was thoroughly and forcibly scraped with a sharp Volkmann's spoon; considerable bleeding also came from the adjacent mucous membrane, which somewhat interfered with the precision of the operation. This was finally checked by pressure and hot sublimate douches (1 : 20,000), and more particularly by the emptying of the rectal dilator, which, it was also noted, immediately changed the level of the ureteral orifices from just behind the symphysis to a point beyond the reach of the finger, part of this depth being from the thickness of the abdominal walls. So complete a view and control of the deeper parts of the bladder was had that no reason was present for the inversion of the patient, as had been suggested by Trendelenburg, for the purpose of drawing the bladder upward. A rubber perforated tube, with a short crossing tube at the bladder end, to hold it *in situ*, was introduced to the bas fond; the edges of the wound were packed with sticky iodoform gauze and a light and loose antiseptic gauze dressing applied, through which the drainage tube ran. The patient was directed to be kept on his side.

May 12. He passed a comfortable night. To the drainage tube another piece of tubing was connected by a curved glass-tube, to prevent kinking, and by this means the urine was conveyed to a receptacle and the patient kept fairly dry. He rests easily on right side, and urine flows freely away. Pulse 100; temperature 99.5°.

27th. Pulse and temperature have been normal since the 13th. To-day the tube was removed from the bladder, having given rise to no irritation. The iodoform gauze was also changed, and the wound dressed with balsam of Peru.

By the 25th, granulation of the wound was fully established, and its edges were strapped together, and he began to pass water through the penis. By June 3d all the urine was passed *per vias naturales*. By June 11th he left the hospital for his home, voiding a clear urine about eight times in the twenty-four hours, free from pain, and gaining flesh and strength, with the wound thoroughly healed.

About the first of July he began to experience difficulty in passing his water by the urethra, and in the course of a week thereafter he had a temporary retention which was relieved by the giving way of the lower end of the cicatrix and the establishment of a small, suprapubic, urinary fistula, which has continued, with occasional closures, and is probably due to a reappearance of obstruction in the natural outlet of the bladder. He was last seen on November 1st, when a decided increase in prostatic fulness on the left side could be felt, which with his emaciation told that recurrence had undoubtedly taken place. He has had no further hemorrhage. The microscopical examination by the pathologist of the hospital, Dr. Peabody, revealed the tumor to be a sarcoma.

Remarks.—The operation in this case showed (1) the difficulty that could arise from wounding the veins immediately external to the bladder, even though a blunt instrument was used in the deeper dissection. It is better, I now think, when a vein is exposed, to pass a double ligature under it, tie it, and then divide it between the ligatures. Also, should the bleeding be free from small vessels, instead of stopping to secure these, and thus disturb the connective tissue in front of the bladder all the more, it would be wiser to open the bladder and relieve the congestion, when the hemorrhage will cease. This was noticed in the present case, and several other surgeons have observed the same fact.

2. In the distention of the rectal balloon, which should be done first, the fluid was pumped in slowly, and as soon as decided resistance was felt, no more was forced in. By fairly distending the bowel and putting less than usual in the bladder, it was believed that the risk which Pousson[1] had called attention to —namely, rupture of the bladder—could be avoided. This observer narrates three cases wherein the rectal and vesical distention had been practised according to the method of Peterson, and in which 200 grammes (less than 7 ounces) of fluid were in each case injected into the bladder, and subsequently, in two of the cases, 300 and 400 grammes (9½ to 14 ounces) respectively were forced into the rectal bag without raising the bladder above the pubis. In two of the cases the operation was proceeded with satisfactorily, and in one of these two the extravasation of fluid anterior to the bladder proved the rupture; in the third case, even after the catheter had evacuated only a few drops of fluid, another quantity was forced into the ruptured bladder, and further procedure abandoned, only a catheter being left *in situ*. The patient died twenty-two hours after, and at the autopsy a rent twelve millimetres long in the median line of the bladder anteriorly was found, which a hypogastric incision would probably have relieved. I was, therefore, unwilling to go as high as Thompson advises in the distention of the bladder, to wit, from 8 to 10 ounces, and halted at 7 ounces, carefully feeling above the pubis to keep watch of the increasing bulging, and trusting rather to the somewhat generous rectal pressure I had created. That this will sufficiently raise the bladder was well seen, even after the vesical wall had been divided and the fluid evacuated.

[1] Pousson, De deux variétés peu connues de rupture de la vessie Rev. de Chirurgie, 1885, p. 873.

Further experience has also lately been recorded by Dittel,[1] who publishes two cases of rupture from overdistention of the bladder. One of these, his own, took place in a boy five years of age, into whose bladder only 100 grammes of water were injected. The operation (epicystotomy) was proceeded with, though it was noticed that no elevation of the bladder had occurred, and a stone removed. The patient died six days later, and the rent was found situated posteriorly and on the left side of the bladder. The second case occurred in the practice of Weinlebred, in a man aged sixty-seven, on whom suprapubic cystotomy was resorted to for the removal of a calculus. 200 grammes of fluid were used in the rectal bag, and then 300 grammes introduced into the bladder; this failing to distend the viscus satisfactorily, 200 grammes more were pumped in with the same negative result. A rupture was suspected and the operation carried out. The bloody fluid found in the prevesical space sustained the diagnosis. The patient died at the end of twenty-four hours. The split in the vesical wall was on the posterior surface and ran circularly forward. Dittel thereupon experimented upon numerous cadavers to ascertain the bursting-point of the bladder with air and with fluids. He found that with air from 1200 c. c. to 3000 c. c. were required; with fluids, in adults, 300 c. c. or more were necessary. Though these demonstrations are less valuable than the results unintentionally obtained in the living subject, they have elicited the interesting surgical fact that in nearly all the cases where the tearing of the bladder resulted from the static pressure of the air injected, it took place in the posterior surface, while in about only one-half the tests the laceration from fluid distention occurred in this more dangerous region. As the reasons for a premature rupture, such as sacculation, cicatrices, and degenerative changes, are not recognizable beforehand, this surgeon further suggests the elevation of the bladder by some instrument introduced per urethram as safer than injection of fluids or air.

A high cystotomy lately reported at the New York Surgical Society, by Dr. Lange, for the removal of a tumor, has, moreover, exhibited the possibility of mishap from the rectal stretching. This surgeon found that the rectum had been partially split by the over-distention. The patient, however, made a satisfactory recovery. Cadge, in a discussion on this subject, quotes a fatal case, in which there was a circular rent in the rectum with a distention produced by 15 ounces of fluid; in this case blood followed the withdrawal of the rectal bag. In another case, Saint Germain mistook the inflated bag in the rectum for the bladder, and incised it. It is not easy to see how this error could occur.

It is evident from the recent reports on this subject,[2] that the subject of rectal distention lacks exactness, and that its employment is yet attended with risk, like the manual distention, to the dangers of which the writer called attention in 1875.[3] A number of surgeons speak of the slight bleeding coming from the rectum after using the distending bags. Some have attributed this to seams or other irregularities on the surface of the rubber bag. Is it not sometimes due to slight rectal lacerations? Individually I cannot help feeling that more care must be used in dilating both rectum and bladder, and that we must not seek to have the bladder raised more than one to one and a half inches above the pubes; this elevation will give ample space, and if more is required, the peritoneum can be carefully and easily peeled upward as far as may be needed. To avoid as far as possible an overdistention of the rectum, not more than ten ounces of fluid need be used, and I have had contrived a rubber bag with fine silk meshes outside, like the middle bag in the Paquelin cautery apparatus, to limit the distention of the contained rubber to a circumference of seven and one-half to eight and one-half inches, which my investigations have shown to be the limit of safe rectal dilatation.

3. No sutures were purposely used, though the temptation is strong to employ them. Van Iterson has sutured the bladder eight times with only one failure, his sutures not going through the mucous membrane, and a soft rubber catheter was retained in the urethra. I have too often seen, after an operation on the urinary passages, the irritation or plugging up of a retained catheter fail in its intended end, to trust to it willingly in a suprapubic cut. The majority of surgeons seem to favor the open treatment of the wound. To close the wound imposes a risk beyond the advantages claimed for it.

4. Should any suppuration occur and be detected of the prevesical tissues, the experience had in the treatment of rupture of the bladder,[1] and its attendant extravasation, must be kept in mind, and drainage be essayed by carrying downward a long dressing forceps behind the pubis, and cutting on its point in the perineum, and by pulling through this track a tube sufficiently large for the easy flushing and draining of the gravitating pus and urine.

A SIMPLE METHOD OF TESTING FOR COLOR-BLINDNESS.

BY HENRY SEWALL,

PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF MICHIGAN.

The genuine expert no doubt finds little difficulty in estimating, by the use of one of the recognized methods of testing for color-blindness, the color sensibility of persons presented to him. But probably few of those who desire to make such tests have had the advantage of such long and continued practice as does away with the necessity for more or less elaborate reasoning during the experiment itself. Every one who has engaged in such work according to the justly famous method of Professor Holmgren, has recognized that the individuality of the person experimented on offers the greatest difficulty in the way of making the test rapid and accurate. An in-

[1] Rupture of bladder treated successfully by perineal urethrotomy and pelvic drainage, Medical Record, March 29, 1884.

definite number of gradations lead through color-obtuseness down to color-blindness, and the fineness of color-perception in different individuals, determined simply by education, is notoriously of the greatest diversity. It is, therefore, not to be wondered at when, according to the Holmgren method, a skein of worsted is presented to a person under examination, and he is told to pick out all the pieces of a similar color from a bundle of skeins, he should hesitate between the meaning of "color" and "shade," and become still more perplexed if the examiner, in his desire to make matters clear, tries to indicate the difference between "tint" and "hue." All persons untrained in the use of colors whom I have examined for color-blindness have needed a more or less lengthy explanation of terms before understanding exactly what was desired of them.

The method which I venture to propose is a modification of that of Professor Holmgren, and appears to me to be in some respects an improvement, on account of its accuracy and the ease with which it may be applied. The only material employed in the tests is furnished in the folding sample-cards of worsted colors such as are used by dealers in worsteds and embroidery in making their orders for Berlin wools. The wools are fastened to narrow pieces of cardboard, five to fifteen shades of a single color being arranged in regular gradation upon each piece. Each tint or shade is represented by six or eight short strands of worsted set closely side by side, and separated by a blank space of one-fourth of an inch from the next lighter or darker shade. Anyone can easily make such a color-card by winding separately the various shades of any color around a strip of cardboard ten inches by one inch in size, taking care that each shade shall be separated by an open space from the adjacent ones. The woollen threads can be kept in place by tying, or fastening with a drop of mucilage on the reverse side of the slip of cardboard. The slips containing the different colors should be lettered, A, B, etc., and each individual shade should be numbered for the purpose of reference.

The book of samples chiefly used by me contains eighteen columns of colors, each of which is represented by five to fifteen separate tints in graded series. In practice so extensive a collection is not needed, but a single column each of reds, blues, pure greens, grays, pinks, royal purples and violets, is sufficient; to these, however, it is useful to add series of browns and yellows. Ten to fifteen shades of each color should be employed.

In making the color-test, the operator may proceed in the order indicated by Holmgren, investigating first the general color-sense, and afterward the special variety of color-blindness.

The examiner chooses a light green as a test color, and then, pointing the finger at the column of grays, asks the person under examination to pick out a shade which *exactly* resembles the test green. The same comparison is successively made between the green and the purples, reds, and blues. A person afflicted with any form of color-blindness will either declare that the test green is exactly like some shade of the comparison colors or differs from it only in brightness. The operator may now proceed to the second test, and this is really the first step pursued by the author, by choosing a pink, which is physically a combination of blue and red, and, pointing to the column of blues, ask the subject to select a shade which exactly corresponds to the test pink. The same comparison may then be made with the violets, grays, and greens. According to Holmgren,[1] "He who is color-blind by the first test," matching the test green, "and who, upon the second test, selects only purple skeins"—that is, makes no error by the second test of the method here detailed—"is *incompletely color-blind.* He who in the second test," matching the purple, "selects with purple only the blue and violet, or one of them, is *completely red-blind.* He who in the second test selects only green and gray, is *completely green-blind.*" The examiner may then go on and, using red as a test color, find out what saturation of gray, brown, or green exactly corresponds with it.

I have had no experience with the green-blind, but, in the case of red-blind persons who have been examined by me, the rapidity and certainty of this method have left nothing to be desired. In one instance, while still a novice in this kind of experiment, I found it impossible to determine, by the Holmgren method, just the nature of the defect of color-perception in a student who was being examined; but, on adopting the plan here detailed, it took but a few seconds to find the nature and depth, as it were, of his color-blindness.

In the case of feigned color-blindness, the deceit can only be practised successfully in this, as in the original method, when the person examined understands the laws of the defect as well as does the examiner.

Many examiners have had much wider experience than myself in making these tests, but I venture to believe that the plan here proposed has peculiar advantages, because—

1. It leaves nothing to the judgment of the person examined. He is asked simply to select some color which is *exactly* like one other. The large number of shades of color, and the simplicity of their arrangement, allows of this being done definitely and quickly. No color-name is used, and thus all confusion of meaning is avoided.

2. The method allows of a scientific accuracy equalled only by that of some others of a much more complicated character; the color-blind matches two different colors which *exactly* resemble each other, thus giving a clew to the completeness of the defect.

3. The time and worry of the examination are reduced to a minimum. An ignorant person might be taught in a few minutes how to conduct the test, or be trusted to depend on printed instructions, as "Does any number of column C look *exactly* like No. 3 of column A?" etc.

The whole number of color-slips may be fastened in a folding cardboard small enough to be conveniently carried in the pocket.

HOSPITAL NOTES.

The Treatment of Rheumatism in the Philadelphia Hospitals.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

Dr. Osler employs in mild cases, with only one or two joints involved and the temperature not above 102° F., the citrate of potash in ʒss doses every four hours. If there is much pain and the patient is restless, Dover's powder grs. x at night. In more severe attacks, with polyarthritis, and fever above 103°, he orders salicylate of sodium grs. xv every two hours, with a similar quantity of the citrate of potash. The important influence of the salicylate is believed to be in the reduction of the pain and fever. It is not thought to have much influence in lessening the duration of the disease; and, on the other hand, when pushed for many days and in large doses, it is thought directly to favor the occurrence of relapse. Hence, as soon as the pain is relieved, the amount of the salt is reduced, and it is stopped as soon as possible. It does not probably influence, one way or the other, the occurrence of endocarditis. When the temperature is above 103.5° antipyrin, grs. xx, is ordered. With fever of 105° the cold pack is employed. Lemonade and carbonated waters are allowed freely. An unstimulating liquid diet is given. Blankets are preferred for the bedding of the patient. Special care is enjoined in changing the clothing, and a wad of cotton-wool is placed over the front of the chest. The joints are wrapped in cotton-wool, or, when very painful, in spongiopiline, or flannel, soaked in Fuller's lotion (hot) (Liquor Opii Sedativus, ʒj; Potass. Bicarb., ʒiv; Glycerin., ʒij; Aquæ, ʒix). If the salicylate and the local application fail, as they sometimes do, to relieve pain, opium is freely given. During convalescence iron and tonic doses of quinine are ordered.

JEFFERSON COLLEGE HOSPITAL.

Dr. DaCosta treats his cases of acute rheumatic fever, as a rule, with salicylic acid, about a drachm in twenty-four hours; he does this especially in the cases of active, frank character, in which the joint affection is decided. Where marked cardiac complications exist, he greatly prefers the alkaline plan of treatment; indeed, has little faith in the use of salicylic acid either to prevent cardiac complications or to remove them. Nor does he, in any case, continue salicylic acid or the salicylates if no impression is made on the rheumatic malady in three or four days. When the remedy does good at all, his experience is that it does good quickly.

In cases of acute or subacute muscular rheumatism, or in subacute articular rheumatism with much pain and only moderate swelling of the joints, he often employs bromide of ammonium, or, if this fail, nitrate of potassium. He uses opium sparingly, and generally confines it to a moderate dose or two of Dover's powder, given at night.

He strongly insists, no matter what plan of treatment be adopted, on the addition of quinine, from twelve to sixteen grains daily, as soon as the more active symptoms have subsided, believing that thereby the patient's strength is sustained and relapses prevented.

From tincture of chloride of iron he has seen no good, except in pyæmic rheumatism or in kindred forms of rheumatism.

Locally, he uses little, enveloping the swollen joints, if very painful, in a thin layer of cotton-wool; where the joints are very much swollen he envelops them in cloths wrung out in a strong solution of nitrate of potassium, with morphia added.

The diet is always bland and unstimulating, chiefly milk, farinaceous substances, and very moderate amounts of broths, eggs, and fish. Alcohol is not given except in the so-called "typhoid cases," in which also high temperature is generally found.

Dr. Roberts Bartholow finds that the cases which come under his observation may be divided into three types: The robust nervo-muscular subject, often having a distinctly hereditary tendency to the occurrence of rheumatic inflammation; the obese, beer-drinking subject; and the pale, anæmic, feeble subject, most frequently female, living under unfavorable hygienic conditions, and leading a closely sedentary life.

His choice of remedies for these three classes of rheumatic subjects, when the seizure has actually occurred, is confined to the salicyl compounds for the nervo-muscular type, to alkalies and tincture of iron in the obese type, and to tincture of iron in the anæmic. The recent additions to our knowledge of the good effects of antipyrin in acute rheumatism incline him to its use in place of salicin and salicylic acid, and for the hyperpyrexia in any of the cases. Although he cannot agree with those enthusiasts who regard antipyrin as a specific in rheumatism, he cannot overlook the good effects obtained from it in appropriate cases—especially in the neuro-muscular group. As the disease manifests a tendency to relapse the earlier and the more abruptly defervescence and cessation of pain take place, he keeps up the use of the remedies for several days after all morbid manifestations have ceased. With these remedies he combines, *pro re nata*, quinine, morphine, and, more particularly, blisters in the neighborhood of the affected joints.

In the obese, beer-drinking type of rheumatics, the use of alkalies, or the combined alkaline and quinine treatment as advocated by Fuller, appears to him to be most efficacious during the existence of the acuter manifestations. When these have distinctly subsided, the tincture of iron freely administered becomes the most important remedy, and will do more than any other to prevent recurrences, which are particularly apt to take place in this type. Furthermore, the acute rheumatism of these obese subjects manifests a certain sluggishness of disposition, so to speak, and slowly glides into the subacute and chronic forms. Until he learned the value of tincture of iron in these cases, he had to observe this tendency of the malady only too often.

For the third group of rheumatic cases, he uses the tincture of iron with excellent results. The anæmia, the depression of the bodily forces, and the exquisite sensibility characteristic of this type, are conditions generally improved by iron; but as no other preparation manifests the same power in acute rheumatism, there must be a special action due to the hydrochloric acid in the combination. This view is the more probable, since the mineral acids have themselves been used successfully in the treatment of this disease.

The blister treatment, which has alone accomplished excellent results, may well be combined with any other special plan.

Whatever mode of treatment has been pursued, he finds it necessary to keep it up, somewhat modified as to quantity, for several days after the apparent cessation of the systemic and local disturbance.

PENNSYLVANIA HOSPITAL.

Dr. Morris Longstreth, in cases of decided articular manifestations and high temperature, orders salicylic acid to be given in ten grain doses every hour until six doses are given—*i. e.*, a drachm every twenty-four hours. The salicylic acid is given with the object of reducing the temperature, and the quantity and frequency of the dose are proportioned carefully to the end to be attained. In the large majority of cases it is successful. The temperature, and with it the frequency of the heart's action, diminishes. Cardiac complications, endo- and peri-carditis, do not seem to contraindicate its employment or its continued use. Occasional cases present themselves in which great depression of the heart follows the employment of the drug in large doses, even without evident inflammatory cardiac complications. In such cases, other medication must be employed; and occasionally restoratives have been required to overcome its effects. Usually its use is continued for one or more days after the subsidence of the temperature, in much reduced doses and at longer intervals.

In cases in which salicylic acid fails of its usual effect, or in cases with great anæmia or previous debility, salicin has been found very useful. It has been given in fifteen grain doses, four times a day. Its administration in smaller doses is often continued during convalescence, either alone or in connection with iron or other tonics.

The alkaline treatment Dr. Longstreth resorts to less frequently. When employed, bicarbonate and citrate of potash, in equal portions, are given in divided doses to the amount of one ounce daily.

Quinine and tr. ferri chloridi seem to be demanded during convalescence in nearly all the cases. The disordered digestive functions, evidenced by coated tongue and sluggish bowels, seem to be most favorably and promptly aided by the administration of small doses of calomel, gr. $\frac{1}{12}$, with bicarbonate of soda, gr. iij, given at frequent intervals during one or two days.

Locally, to the affected joints, three modes of treatment have been found of service. Joints hot and tense are covered with cloths wet with lead-water and laudanum, equal parts, and enveloped with waxed paper or gutta-percha sheeting. In some cases, the local application of a saturated solution of bicarbonate of soda is useful; sometimes the impermeable sheeting is omitted from the dressing—coolness from evaporation being more comforting than the heat. In other cases, the joints are enveloped in cotton, with or without the covering.

Cold-water sponging or packing is employed in cases of high temperature with delirium. Antipyrin has been employed in some of these cases, but without good results. Morphia or opium is always used as required.

PHILADELPHIA HOSPITAL.

Dr. James Tyson uses both salicylic acid and salicylate of sodium, but recently has confined himself rather more to the former. He gives it preferably in the form of a compressed five grain pill, of which two are ordered every two hours until the symptoms yield. This is generally within twelve hours, and almost always within twenty-four. After the pain has decidedly subsided he diminishes the dose one-half, or increases the interval to four hours. If the administration is cautiously continued for a week or ten days, he finds that it is comparatively seldom that relapses occur. Sequelæ and complications are less frequent by this than by the older methods of treatment. It is comparatively seldom that anodynes are required as adjuncts to relieve the pain, but when they are, the hypodermatic use of morphia is promptly efficient.

In giving the salicylate of sodium, he prescribes ten to fifteen grains every two hours, or half as much every hour until relief is obtained. Its sickening taste in solution is a great drawback to its use, but it, too, may be given in five grain compressed pills, although the larger bulk makes this method of administration inconvenient.

When salicylic acid or its salts fail, he finds that flying blisters to the painful joints are the next most efficient measure, and their effect upon the pain is usually very prompt.

Dyscrasic cases are, of course, treated with iron, quinine, and an abundance of nourishing food, and flannel garments worn next to the skin.

In muscular rheumatism salicylic acid is seldom efficient, although Dr. Tyson often uses it with results which lead him to believe that it is not totally without effect. By far the most satisfactory measure is dry heat, applied most conveniently by the hot-water bag.

In the treatment of chronic rheumatism Dr. Tyson has much more confidence in the use of local measures and manipulation. Salicylic acid is also sometimes useful, but the effect is more frequently temporary.

Dyscrasic conditions are treated with cod-liver oil and iron, which alone are sometimes curative. Counter-irritation by blisters and strong liniments are sometimes useful adjuncts, but are in no degree equal to manipulation.

Dr. J. C. Wilson has, during the past three years, used in acute rheumatism a mixed treatment, consisting of sodium salicylate in combination with sodium bicarbonate or sodium acetate. The formula commonly employed is as follows:

℞.—Sodii salicylatis . . . . gr. xv.
Sodii bicarbonatis . . . gr. xxx.
Aquæ menth. pip. . . . ℥ss.—M.
To be taken every third or fourth hour.

This dose is increased or diminished in accordance with the intensity of the pyrexia, the acuteness of the joint pains, and the condition of the heart, in individual cases. After the reaction of the urine becomes distinctly alkaline under this treatment, the sodium bicarbonate is stopped, and the salicylate continued alone at gradually increasing intervals until the pains and fever have

wholly ceased. The administration of iron then follows, usually in the form of Basham's mixture, the mistura ferri et ammonii acetatis, U. S. P.

Dr. Wilson regards this method as quite equal to the treatment by salicylic acid, the sodium salicylate alone or by salicin, as regards the rapidity with which the pain is relieved and the fever controlled, and as much superior to them in the diminished danger of producing the toxic effects of large doses of the salicylates, especially cardiac depression, epistaxis, tinnitus, headache, and maniacal excitement—phenomena which are very seldom observed, if we except slight ringing in the ears, under this plan of treatment.

The diet consists chiefly of milk; light broths are, however, occasionally permitted, to which, with beginning convalescence, are added bread, rice, custards, etc. Alcohol in any form or dose is scarcely ever given, except in emergencies, and forms no part of the treatment even during convalescence.

Serious heart complications developed under observation in the wards are comparatively infrequent, and relapses not very common.

In view of the frequency of recognizable cardiac lesions, especially in young subjects, and of the probability that some degree of implication of the valvular endocardium, not sufficient to manifest itself by satisfactory auscultatory signs, may be present in many cases, in which murmurs are not present, the patients, when practicable, are kept in bed for ten days or two weeks after the complete subsidence of the acute symptoms. The valves of the heart are thus saved wear and tear, the danger of relapse is greatly lessened, and the rebuilding of the blood hastened.

If, despite the steady use of iron in full doses, the anæmia persists, arsenic is given in small but gradually increasing doses, usually with good effect.

MEDICAL PROGRESS.

Rheumatism.—From an extensive paper by Immermann the following points of interest are abstracted:

The couplet,

> "What we cannot well divine,
> As rheumatism we define,"

expresses the multitude of varying conditions called rheumatic.

Acute joint rheumatism the author considers not simply the esult of cold but of infection, and the apparently specific action of sodium salicylate, the author thinks, points to a definite infectious cause which often manifests itself in *masked* rheumatism. Many cases occur which do not include in their symptoms the cardinal points of acute rheumatism, fever, joint-pains, and heart affection, which, in other parts of the body and with other symptoms, are caused by the same infection, as muscular pains, neuralgias, pleuritis, and chorea.

Again, one of the classic symptoms may alone be present, and an atypical picture be given; in these cases a previous rheumatic history will often be elicited. During an epidemic of rheumatism cases of acute endocarditis often occur when the failure of joint affections would not point to rheumatic infection.

Valvular lesions, so often found, the author considers the results of previous rheumatism, which attacked the endocardium but spared the joints; sero-fibrinous pericarditis, with fever, but without joint affections, is also due to rheumatism.

Neuralgic rheumatism and rheumatic neuralgia are masked forms; the latter is said to be the clinical equivalent of acute joint rheumatism. For these the writer has found not only sodium salicylate but also antipyrin a specific. As an illustration of its action, and as showing another class of these masked cases, the following is related:

A physician was taken with high fever and painful contractures of the muscles of the neck. Cerebro-spinal meningitis was feared, although it was not epidemic in the place at the time. Rheumatism, however, was epidemic, and, under the use of antipyrin, the patient speedily recovered.

The writer gives the following grounds for a diagnosis of rheumatism:

1. Individual liability to rheumatism: the fact that a patient has once had rheumatism makes a pericarditis, etc., occurring in such a patient undoubtedly of rheumatic origin.

2. The tendency of rheumatism to localize itself, next to the joints, about the heart and pericardium; a valvular lesion, not referable to atheroma, is to be suspected as rheumatic; a subsequent pericarditis, or endocarditis, or joint affection would confirm the diagnosis.

3. The tendency of acute rheumatism to epidemics: cases which would not, ordinarily, be suspected as such, would, in an epidemic, be so diagnosticated.

4. The specific action of the salicylate of soda and of antipyrin.

As *rheumatoid* affections the author mentions gonorrhœal and scarlatinal rheumatism; also, bronchiectasis and rheumatoid purpura.

In nervous diseases are rheumatic tetanus, Landry's paralysis, and poliomyelitis acuta anterior ascendens adultorem; also, polyneuritis; while beri-beri, or Kakké, the author thinks, are not of rheumatic origin.

The potency of cold in causing joint inflammations is admitted; rheumatism is so induced. The title *refrigeratory* is, however, suggested as much more proper for all the neuralgias and results of colds.—*Deutsche medicinische Wochenschrift*, October 14, 1886.

Boracic Acid as a Local Anæsthetic.—Dr. A. C. Ewing narrates the following case in *American Practitioner and News* of November 13, 1886:

George S., a railroad employé, came to my office October 19, 1886, with a deep suppurating wound in the palm of the left hand, having two weeks previously received the injury by being thrown forcibly against a moderately sharp instrument, which cut, or rather tore its way through to the bones. He was suffering excruciating pain; his hand being in a semiflexed position from involuntary, and, to some extent, voluntary contraction. Upon taking hold of the hand and making but a slight effort to straighten his fingers, he fairly cried out from pain. Taking about thirty grains of powdered boracic acid and dissolving it in half an ounce of water, I saturated a pad of absorbent lint in the solution and applied it directly to the wound, securing it by means of a splint and bandage. I directed him to return on the next day. In the morning I was agreeably surprised to find that he had not suffered in the least during the night. I took

off the splint and found, by using considerable force, that I could almost entirely overcome the contracted tendons and fascia, the wound gaping open as I did so, but without having given him the least inconvenience; in fact, he himself pulled open the wound to "see how deep" it was, squeezing out some pent-up pus, and in doing so felt no more pain than if he were squeezing healthy tissue. I am still using the same dressing once daily, because of its excellent antiseptic qualities, and the wound is healing rapidly by granulation.

TREATMENT OF METRORRHAGIA.—DOLÉRIS commends the following method of treatment in metrorrhagia:

Commence with friction, morning and evening, over the lumbar region, with

Spirits of camphor	120 grammes.
Ether	30 "
Chloroform	15 "

Internally.

Tincture cinnamon	15 grammes.

Daily,

And, per vaginam, the following application:

Glycerine	350 grammes.
Acid tannic	30 "
Tinct. iodine	4 "

Also general hydrotherapy, *not* used about the pelvis; douche in intermittent jets, fifteen seconds in duration. The vaginal application may be modified as follows:

Glycerine	350 grammes.
Laudanum (Sydenham's)	4 "
Extract belladonna	2 "

Not to be used when ulceration of the cervix exists.

Counter-irritants over the spine in the lumbar region; the cold douche, and should the indication arise, curetting the uterus, or sponging its interior.

In the case of exudates and uterine fibromas, digitalis may be used as follows:

Glycerine	120 grammes.
Extract of digitalis	4 "
Alcohol to dissolve	q. s.

Dissolve the extract in alcohol, and shake with the glycerine; not to be used if ulcerated cervix be present.

Also.

Glyceride of starch	120 grammes.
Extract of digitalis	4 "
Alcohol	q. s.

—*Gazette de Gynécologie*, November, 1886.

THERAPEUTIC ACTION OF ETHOXYCAFFEINE.—According to CHABAT, the following formula in the hospital experiments of Cochin and Dujardin-Beaumetz has yielded the best results:

Ethoxycaffeine	25 centigrammes.
Salicylate of soda	25 "
Hydrochlorate of cocaine	10 "
Linden water	60 grammes.
Syrup of maiden hair	20 "

The addition of the soda salicylate facilitates the solution of the salt of caffeine; the cocaine prevents gastric disturbances. A gramme of the drug in question in the above combination, taken in five doses, relieved an anæmic patient suffering from herpes. Three cases of obstinate migraine were cured by half a gramme in five doses. Chabat considers with Filehne that the drug is of value in migraine, and expects more precise indications for its use from further researches.—*L'Union Médicale*, Sept. 28, 1886.

THE POISON OF CHOLERA is shown by CANTANI to be derived either from ptomaines, from the secretion of Koch's bacilli, or from the bacilli themselves. Experiments show that the rapidly developed, dead and absorbed bacilli constitute the cholera poison. Therapeutic indications are (1) to hinder the increase of bacilli, in which tannic acid has proved useful by intestinal injections; (2) promotion of elimination of poison, by hypodermatic use of eliminative and stimulant drugs. In general the writer favors hot intestinal injections as the best treatment.—*Deutsche medicinische Wochenschrift*, Oct. 14, 1886.

THE AMMONIA TREATMENT OF FIBRINOUS CONCRETIONS.—In the October number of *The Asclepiad*, DR. B. W. RICHARDSON, after detailing a number of cases in point, formulates these rules for the exhibition of ammonia:

1. The ammonia is best administered either in the form of the strong aqueous solution, or of the saturated alcoholic solution. More than five minims at a time cannot easily be swallowed. The best menstruum for the ammonia is milk, and if the milk be chilled by ice, the patient takes the mixture with great facility.

2. The ammonia must be relied upon exclusively. Sedatives of all kinds are to be avoided as fraught with danger. Wines and spirits are most injurious; they produce a danger of movement of the fibrinous mass, they excite, and, in time, exhaust the heart.

3. The diet should be, as nearly as possible, of pure milk, with an occasional change to gravy soup or minced codfish, with bread or toast. Other solid substances do not digest readily; they create flatulency, and cause a restless movement of the body, which is detrimental.

4. With the medicinal and dietetic treatment thus enjoined, there must be combined the most perfect rest of the body in one position. The secret of success consists in producing solution of the obstructing mass while it lies sufficiently out of the course of the circulation. If it loosen from its hold and be carried into the pulmonary artery while it remains semi-solid, however small it may be, it will be a source of fatal danger.

5. Together with this physical rest every mental rest, every mental comfort, must be supplied. The patient must be harassed with no unnecessary fears, agitated by no unnecessary comments. Much of the success of the treatment depends on the gentle firmness with which the practitioner enforces that the greatest advantage is secured by absolute repose of the mind as well as the body.

6. When the secondary changes indicate the solution of the fibrin, and its distribution over the vascular system, the administration of the ammonia is not to be withdrawn. The alkali is indeed as important, under these circumstances, as in those which precede them.

7. The conditions warranting the withdrawal of the solvent are: entire subsidence of the difficulty of breath-

ing; relief of the tension of the veins; returning fulness of the pulse; normal temperature; restored mental and physical power; and steadiness of motion of the heart, with perfect clearness of the sounds. When these favorable conditions are proclaimed, it is fair to infer that no obstruction is present in the circulatory canals, and that the ammonia may be withdrawn.

But inasmuch as the ammonia, however far it may, with reason, be carried, does no injury that is not quickly recovered from, there exists no cause for hurry in withdrawing it. It may, therefore, be continued in less frequent doses for a few days, when every danger appears to have passed away.

Tannin in Inflammations of the Serous and Mucous Membranes.—Dubané, in clinical observations, has found that tannin, given by the gastro-intestinal tract, diminishes the violence of the symptoms in severe acute inflammations of the serous membranes; he has obtained success also in chronic pleurisy and localized peritonitis.

Dubané has used tannin in intestinal and bronchial inflammations and pulmonary congestions; he thinks, with Bichat, that the drug acts upon the epithelial elements themselves. The author prefers tannin prepared with ether, and gives daily doses of twenty or thirty centigrammes up to ten or twelve grammes, without ill effect. He has used tannin in purulent pleurisy, pelvic peritonitis, perityphlitis, puerperal peritonitis, cerebro-spinal meningitis, double pneumonia, and cerebral rheumatism, with a mortality, including cases of all grades and severity, of thirty-one and one-fourth per cent.—*L'Union Médicale*, September 30, 1886.

Dyslexia.—Dyslexia, as observed by Berlin, in six cases consists in the impossibility of speaking more than three, four, or five words consecutively. Patients read these words correctly, in whatever characters printed, but they are incapable of continuing to speak. Such patients have no other trouble with speech; they pronounce well words spoken in their presence, and are perfectly intelligent. Dyslexia has nothing in common with the visual heaviness of ophthalmic cases, for it accompanies no disease of the eyes; it is an incomplete and isolated verbal blindness.

It generally appears suddenly with various cerebral symptoms. In four autopsies lesions of the left cerebral hemisphere were found; in one case a softening of the gray substance of the lower portion of the parietal lobe; in others the centre of softening was not clearly defined. These changes were accompanied by extensive alterations in the bloodvessels.

Dyslexia will be, according to the author, an interesting clinical sign in diagnosis and prognosis, indicating a grave cerebral lesion occurring shortly before death.—*Archives Générales de Médecine*, November, 1886.

Cocaine in Obstinate Vomiting of Pregnancy.—Fraipont, in a paper thus entitled, presents the following points of interest:

Weiss, in 1884, gave teaspoonful doses every half hour of hydrochlorate of cocaine, 15 centigrammes to 150 grammes of water.

Engelmann and Holtz used a solution of from 3 to 10 parts in 100, and gave from 10 to 30 drops daily.

M. Bois has used an ointment, 1 centigramme of hydrochlorate cocaine to 50 grammes of vaseline, applied morning and night to the cervix uteri.

M. Fraipont prefers the hypodermatic method, and injects in the epigastric region the contents of Pravaz's syringe of a solution of 4 to 100. This treatment has cured nausea following the use of chloroform, and obstinate nausea following excision of portions of the cervix uteri.

The author prefers the exhibition of cocaine by the mouth when it is desired to allay the nervous irritation of the stomach. Walls's applications to the cervix seem indicated only when the stomach will not tolerate the drug.—*L'Union Médicale*, Oct. 2, 1886.

Treatment of Trigeminal Neuralgia.—Gussenbauer recognizes a large class of these neuralgias dependent on no direct irritant, but reflex in character. Such are neuralgias following sexual diseases, malaria, and tobacco poisoning. Especially has he observed these cases as a result of habitual constipation; in forty-five cases of neuralgia, thirty-three were of the trigeminus, on only four were operations made, the remainder were cured by cold water enemata and hydrotherapy. Cases generally recovered in one or two weeks, although they sometimes resisted treatment for five or six weeks.—*Centralblatt für Chirurgie*, October 16, 1886.

Herpes and Bright's Disease.—After discussing the correlation of the activities of the skin and kidneys, Séjournet questions various theories regarding an albuminuric diathesis, and concludes as follows:

1. Herpetism, a chronic tendency to herpes, may be defined as an arthritic diathesis.

2. Sufferers from chronic nephritis possess this diathesis, and the author believes that the cause for albuminuria and structural kidney changes, is generally to be found in herpetism.

3. By considering Bright's disease as dependent upon a diathesis, the writer thinks he has explained many obscurities in pathogenesis and symptomatology.—*Gazette Médicale de Paris*, November 23, 1886.

The Treatment of Periuterine Phlegmasia, as pursued by Gallard, is as follows: 1. Daily tepid sitz baths and injection of decoction of the leaves of the night-shade, hyoscyamus, belladonna, and poppy.

2. Linseed meal poultices over the abdomen, laudanum mixed with the meal.

3. Purgation once or twice weekly, with castor oil or soda sulphate.

4. At night, chloral hydrate, to insure sleep. Absolute rest during menstruation.—*L'Union Médicale*, October 26, 1886.

Quillaja Saponaria.—In July last Kobert, of Strassburg, recommended this drug as a remarkable adjuvant to seneca root. Merkel, in Nüremberg, has used saponaria extensively, giving to adults a teaspoonful of a decoction made with 5 parts of the drug to 180 of water and 20 of syrup, repeated hourly; to children, a teaspoonful, 3 parts to the same proportion of water and syrup. In profuse, and also in foul expectoration, the drug has given the best possible results without unpleasant after-effects; it is also inexpensive.—*Medicinisch-Chirurgisches Central-Blatt*, August 13, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 4, 1886.

INTUBATION OF THE LARYNX AND TRACHEA IN CROUP.

THAT intubation of the laryngo-tracheal canal, as performed in the ingenious method devised and practised by Dr. Joseph O'Dwyer, of New York, will render tracheotomy unnecessary in many cases of croup which, in all probability, would terminate in suffocation without the one procedure or the other, there is no reason to doubt. This opinion does not imply that intubation is competent to supersede tracheotomy in all cases of croup requiring surgical interference. No such claim has been made by Dr. O'Dwyer. The ultimate object of the procedure is to maintain an open passage for the currents of respiration during the period in which occlusion is imminent from accumulations of false membrane, or from intumescence, or from both; and to do so without exposing the patient to certain additional risks inseparable from the operation of tracheotomy and its consequences.

So long as it remains unoccluded, the presence of the tube in the air-passage insures the patient's safety from suffocation. Not so, however, should membrane be pushed down ahead of the tube. Results of this kind were reported in the course of a discussion on "Intubation" before the Chicago Medical Society, June 21, 1886. Similar occurrences have taken place during introduction of the ordinary canula after tracheotomy; and hence, the very important caution in tracheotomy for croup, to search for false membrane as for any other foreign body, and to remove it before placing the canula in position. Should such plugging with membrane accompany intubation, and relief to respiration fail to follow withdrawal of the tube, immediate tracheotomy would be requisite, with far less hope of success than if it had been done in the first instance.

In additional support of this argument we may relate the experience of a well-known practitioner, who several years ago was called to an urgent case of diphtheritic croup, in which he desired to perform tracheotomy, but was forbidden. As he was leaving the bedroom the suffocating child was struggling in the lap of its mother, who cried piteously, "Doctor! doctor! Surely you're not going without doing something more for us!" Tracheotomy was again proposed, and again refused. Turning to his assistant, the physician said: "Suppose we try catheterization. It is not likely to succeed, but we can make the attempt." The tip of a flexible catheter was then cut off square, and the instrument was introduced, without difficulty, through the mouth. Hardly had it penetrated into the larynx when the child became asphyxiated and black in the face. The trachea was at once incised in a single movement, forceps introduced, and a mass of membrane withdrawn, all within ninety seconds, as timed by the assistant. Still the child did not breathe. The catheter was then introduced through the incision, and the thorax was inflated by the assistant's breath; the thorax was compressed to expel this air, and then artificial respiration was performed in the ordinary manner, with resuscitation of the patient in a few minutes; all with the child in its mother's lap. A canula was inserted, and the child was left breathing comfortably. It died on the day following.

When such crowding of membrane may occlude the relatively large calibre of the ordinary canula, or of a catheter, how much more likely to occlude the much smaller calibre of the intubation tube? With intubation no attempt can be made to remove false membrane. Reliance is placed on the expulsive force of cough to drive it through the tube. This expulsive effort is much stronger than it is after tracheotomy; and, therefore, competent to expel delicate shreds, and sometimes thick ones. Should shreds of membrane plug the tube, then, it is contended, the tube will be coughed out. But suppose the child is unable to cough the tube out? If no skilled attendant be present to withdraw the tube at the critical moment, the child will almost certainly suffocate. Withdrawal of the tube is said to be far more difficult than its introduction. The danger here, then, is far greater than after a tracheotomy. Professional supervision of the patient is even more necessary. Occlusion of the tube with inspissated mucus and pus is not so likely to occur as after tracheotomy, because the inspired air has its full complement of heat and moisture.

From a scrutiny of the reports of intubation in croup it may be concluded that intubation will save

many lives in cases in which tracheotomy would not be permitted; that it will save many a patient from the need for tracheotomy, and that it will probably sacrifice a few lives which might have a better chance for preservation under tracheotomy. Hence the inference that intubation should be practised early in cases of laryngeal obstruction in croup, in the hope that tracheotomy may be avoided. Should subsequent tracheotomy become requisite, the tube in position will furnish a permeable obturator which, as found by Professor Jennings, of Detroit, will greatly facilitate the performance of the operation.

One objection urged against intubation is the difficulty in nourishing the patient; fluid food and sometimes semi-solid food entering the tube and the air-passage. This is probably due only to failure in occlusive depression of the epiglottis in deglutition, owing to the position of the head of the tube upon the ventricular bands. It is hardly to be doubted that Dr. O'Dwyer's ingenuity will eventually overcome this mechanical difficulty as it has overcome other difficulties. In view of the fact that objects relatively larger than the head of the intubation-tube have occasionally passed the glottis, the question arises whether the intubation-tube might not occasionally slip through. Thus far no accident of this kind has been noted. The shape of the instrument and its proportions have been carefully designed to prevent it. In conclusion, the modesty of Dr. O'Dwyer is to be commended in the character of his announcements of an invaluable addition to the resources of mechanical therapeutics.

HOT WATER AS A HEMOSTATIC IN OBSTETRIC AND GYNECOLOGICAL PRACTICE.

The value of hot-water injections in menorrhagia was proved many years ago by Trousseau, and for their general use in the diseases of women we are indebted especially to Emmet. Parvin, in 1876, called attention to the use of hot water in arresting hemorrhage from ruptured adhesions in ovariotomy. Courty first applied this agent as a hemostatic in plastic operations upon the external genitals and the vagina. The late Albert H. Smith was one of the first, if not the first, to advocate intrauterine injections of hot water in the treatment of post-partum hemorrhage. Yet it is probable that the value of hot water is not fully recognized by the profession, nor do all seem to know at what temperature the application should be made.

Within a few years one of the most distinguished of German obstetricians has asserted that relaxation of the bloodvessels was the remote consequence of hot-water injections, though contraction occurred at first. A very useful and timely contribution to the subject has recently been made by R. Milne Murray, in the *Edinburgh Medical Journal*. He studied, experimentally, the effects of water at different temperatures, and found that, at 110° to 120° Fahr., it constricts bloodvessels and arrests hemorrhage from small arteries; at a temperature of from 60° to 100°, it dilates small vessels and promotes hemorrhage; and at a temperature of from 30° to 50° it checks hemorrhage by constricting the bloodvessels, but this only temporarily.

In regard to its therapeutic application in inflammations, Murray claims that it is evident that in water at 120° Fahr. we have an agent of immense power in controlling the local circulation in an organ, provided we can bring the water to bear directly on the part. Accordingly, a stream of hot water injected into the vagina cannot fail to affect, in a very direct way, the circulation in the uterus. The smaller bloodvessels will respond in such a manner that their calibre becomes narrowed under the stimulating effect, the abnormal blood supply will, to a large extent, be cut off, and the resulting phenomena of inflammation checked.

Undoubtedly hot-water vaginal injections are useful in some cases of pelvic inflammation, but to claim for this treatment constant success and constant applicability is, we think, an error. Patients are met with in whom great discomfort follows its employment, when it should be discontinued.

In considering the use of hot water in obstetric practice, Murray divides the cases into those in which the contents of the uterus have not been discharged, and those of actual or threatened post-partum hemorrhage, the placenta having been expelled. He states, in referring to the first class, that in all cases in which the abortion is inevitable, hemorrhage going on, and the os dilating, he adopts hot-water injections as a routine practice. He regards the agent as being most valuable in those cases in which hemorrhage is occurring or is imminent after the contents of the uterus have been expelled, and that organ remains flabby and relaxed, Among the benefits claimed for hot water thus used are rapidity of action, duration of the tonus produced, and the absence of vascular reaction, and of exhaustion.

This agent in the treatment of post-partum hemorrhage certainly deserves all the commendation which it has received.

CHOLECYSTOTOMY.

Among the noteworthy papers read in the Surgical Section of the Brighton meeting of the British Medical Association is one by Lawson Tait, on the "Surgical Treatment of Diseases of the Liver," the full text of which may be found in the *British Medical Journal* for November 13th. In it are tabulated fifty operations, which include seven exploratory operations, with one death; thirteen hepatotomies

for cysts, all of which recovered; and thirty cholecystotomies, with one fatal issue from cholæmia. In two of the cases of removal of gall-stones, although the primary result was successful, the patients died subsequently, in consequence of the progress of carcinoma of the liver, respectively, in two and four months.

Not only is the success of Mr. Tait in cholecystotomy extraordinary, but the series of cases indicates great precision in diagnosticating gall-stones, there having been only four in which a mistake was made, a distended gall-bladder being present in three, and cholæmia from carcinoma in one.

In connection with the diagnosis of gall-stones, it is dogmatically asserted, in opposition to the generally received opinion, that intense jaundice is not only not a symptom, but that it is conspicuous by its absence. When present, Mr. Tait shows that it depends upon coexisting carcinoma, and as his experience is extensive, we are forced to conclude that he is correct in his positive assertion. Indeed, it is supported by a case from the practice of Mr. Haslem, narrated on page 925 of the same journal, in which jaundice being present, and over two hundred concretions having been removed, on death, two months subsequently, the liver was found to be cancerous. Hence, the absence of jaundice is of great importance from the standpoint, not only of diagnosis, but also of surgical interference.

That these cholecystotomies "establish beyond dispute that the operation, when properly performed, is as devoid of risk as any surgical proceeding possibly can be," is unquestionably true of the procedure in the hands of Tait. As other surgeons, however, have practised it in at least forty-two cases, of which we have a record, with eleven deaths, four being from hemorrhage, three from collapse, three from peritonitis, and one from suppression of urine, thereby affording a mortality of 26.19 per cent., it must be regarded as an eminently risky procedure, nearly as fatal, indeed, as cholecystectomy. Thus, of eleven cases of the latter operation, two, or 18.18 per cent., died, while of the seventy-two cases of incision of the gall-bladder, from the practice of Tait and other operators, twelve, or 16.66 per cent., perished

In connection with the operation of cholecystotomy, we may refer to a most interesting case of hepatotomy for gall stones, recorded by Knowsley Thornton in the periodical above quoted. On cutting down upon what appeared to be the distended gall bladder, the concretions could be felt in the substance of the liver, the gall-bladder, empty and atrophied, but otherwise perfect, being situated behind the mass. Through an incision, one inch long and half an inch deep, four hundred and twelve concretions were removed from the cavity, and a large one seated in the common duct was crushed with Lion forceps and removed piecemeal. In explaining the pathology of the case, Mr. Thornton thinks that "the large stone was originally in the gall-bladder, and then became impacted in the common duct, so as to abrogate the function of the gall bladder, and that the other stones were formed in the hepatic duct, and above it, in the substance of the liver, where they gradually hollowed out the cavity" in which they were contained.

CORRELATION OF TONSILS AND GENITALS.

It has long been held by certain writers that the tonsils and genitals are in some way correlated. An opinion prevails that wasting of the testes may follow excision of these organs. At a recent meeting of the Hunterian Society, of London, Mr. Pearce Gould presented a man aged twenty-seven with congenital absence of the tonsils, in whom the genitals were imperfectly developed and sexual desire absent. The man had a feminine appearance, and had neither beard nor moustache. The tonsils were represented by two small nodules between the pillars of the fauces. Mr. Gould held that there was no evidence for the popular belief in England that excision of the tonsils before puberty influenced virility, and he referred to a practice in Zanzibar of removing the tonsils from all male infants, which seems, in that country at any rate, to be without influence on the development of the testicles. It would be interesting to know of any genuine cases of failure of development of the sexual organs in persons who had been subjected to tonsillotomy. The tonsils were found normal in two women in whom the ovaries were congenitally absent. It was the general opinion of those who took part in the discussion on Mr. Gould's case, that a relationship between the two organs had not been established.

Tonsillitis occurs with special frequency in adolescents, and in a recent Aberdeen thesis on this subject by Haig Brown, the author refers, without details, however, to the occasional atrophy of one testicle after removal of the corresponding tonsil.

An interesting point bearing on this question is the frequency with which acute tonsillitis occurs in newly married people. We have known the honeymoon interrupted in several instances by this painful affection, to which also Shepherd, of Montreal, has called attention, suggesting that it bears out the old idea of the intimate association of the tonsils with the genitals.

THE PAINS OF PREGNANCY.

It is now generally known, since Braxton Hicks called attention to the fact, that there occurs constantly, during pregnancy, an intermittent contrac-

tion of the uterus which can be distinctly felt at intervals of about ten minutes, as soon as the organ becomes easily palpable through the abdominal walls. So constant, indeed, is this phenomenon that Playfair assigns to it a high place among the diagnostic signs of pregnancy. Some recent observations made by Schatz, of Rostock, show, moreover, that for a period of about twenty-four hours, at a certain time, sometimes four weeks, more frequently three weeks before true labor begins, these contractions become exaggerated to such a degree as closely to resemble the pains of labor; they occur, at first, once in the half-hour, gradually increasing, however, in frequency, until, finally, they recur every three minutes; from this maximum point their frequency decreases, and they are gradually merged again in the normal intermittent uterine contractions. The force exerted by this muscular contraction is sufficient to dilate the os, often as much as a centimetre or more, so that a careful observer might be led to suppose that true labor had begun.

These observations of Schatz might be of considerable practical importance, should it be desired to bring on labor a few weeks before the normal time, without resorting to operative interference, for it is well known that certain drugs—notably ergot, gossypium, and pilocarpin—while unable to produce uterine contractions, can much increase their force when they have once begun, so that, as soon as these pains of pregnancy have become well established, the administration of such remedies might be begun with some hope of converting the false into the true labor pains.

Splenectomy for floating hypertrophied spleen was successfully performed on the 21st instant, by Dr. J. R. Nilsen, at the New York Post-Graduate Hospital. At the last report the patient was doing very well, feeling better than she has for years, and there has not been a single untoward symptom since the operation.

The College of Physicians of Philadelphia will celebrate the Centennial Anniversary of its foundation on January 3d and 4th.

The Medical Society of the County of New York has recently expelled a member, by a unanimous vote, in accordance with the recommendation of the Comitia Minora. *The New York Medical Journal* says the charges brought against him are understood to have been the result of certain exposures made in the columns of The Medical News a month ago.

The Alumni of the University of Pennsylvania, residing in New York City, recently held a meeting, at which Dr. Meredith Clymer presided, and at which a local society was organized.

The Graefe Medal, founded in honor of the great ophthalmologist by the Ophthalmological Society of Heidelberg, is to be awarded every ten years to the person, irrespective of nationality, who has done most to promote the progress of ophthalmology, and the first award has just been made to Professor Helmholtz, the inventor of the ophthalmoscope.

By an ordinance of the Bohemian Government, all district physicians are now obliged to pass through a course of studies in practical bacteriology.

Through the recent death of Lady Wilson, the Royal College of Surgeons becomes entitled to the legacy of £200,000, in accordance with the conditions of the will of Sir Erasmus Wilson.

REVIEWS.

?Quiz Compends? No. 8. A Compend of the Diseases of the Eye; including Refraction and Surgical Operations. By L. Webster Fox, M.D., and George M. Gould, A.B. 12mo. pp. 150. Philadelphia: P. Blakiston, Son & Co., 1886.

Recently the "quiz compend" has shown dissatisfaction with the restriction of its function to the helping of the medical undergraduate to his diploma; and a disposition to extend the benefits of its cheap binding, thin paper, small type, and over-worked wood-cuts, to all portions of the domain of medical science. The reason of this is not far to seek. Cheap medical schools have caused a demand for cheap medical literature. To supply the demand we have the reprints of foreign works of long-established reputation in our annual "libraries," "encyclopædias" that undertake to supply all valuable medical knowledge in a single cover, "manuals," and "practical handbooks;" and should not the "*? Quiz Compend?*" enter this promising field? The authors of this one evidently think it should. They say: "Our second object has been to give the busy general practitioner, who has never considered the importance of this knowledge to himself, or has relied on his neighbor, the oculist, to do all such work for his patients, a few outlines of the science." Unquestionably the effort of cheap medical literature to make up for the deficiencies of cheap medical schools, is praiseworthy. We do not mention it with the least disfavor, but only to make clear the *raison d'être* of the "*? Quiz Compend?*"

The work before us is ambitiously comprehensive in its scope, generally sound in its teaching, and well up to date. Each disease is treated of in several short paragraphs; each of which has its separate heading, printed in heavy-faced type. These headings are usually synonyms, definition, causes, varieties, symptoms, diagnosis, prognosis, and treatment. The illustrations are mainly of surgical instruments and pieces of apparatus. Appended to the book are some statistics of the frequency of blindness, and the principal diseases of

the eye, and of the proportion of successes in cataract operations at the hands of various operators. The book is not free from errors very suggestive of haste, and there is a certain amount of metaphysical froth upon the current of its teaching that the "busy general practitioner" could well dispense with.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, November 4, 1886.

The President, B. F. Baer, M.D., in the Chair.

HYSTERORRHAPHY.

Dr. Howard A. Kelly read a paper upon a new operation which he called hysterorrhaphy, or the *suspension by suture* of a *viciously posed uterus;* that is, an organ prolapsed or retroflexed, which it is impossible to relieve by treatment per vaginam. He first applied this method April 25, 1885, upon a patient who had been under the care of several specialists, and under his own care for nearly three years. The uterus had lain acutely retroflexed, with a large soggy fundus in Douglas's pouch below the level of the cervix. Months of rest in bed, combined with careful packs and counter-irritation, and for a long time application to the endometrium, failed to cure the flexion even temporarily.

The patient had been operated upon a year previously, and a very tender ovary removed per vaginam. On this occasion the left tube and ovary were removed, and as the right tube could not be felt it was concluded it had atrophied. The uterus was then raised and a sharp band of cicatrix-like tissue felt half encircling it in the angle of flexion, when the futility of any attempt to relieve the condition from the outside was at once evident. Silk sutures were passed through the left horn of the uterus and the body suspended from the anterior abdominal wall about one and a half inches above the pubis to the left of the incision. The suspensory sutures were passed between two ligatures encircling the horn and the base of the pedicle to avoid the dangers of tearing out and of bleeding. The uterus thus suspended remained in place one year, when the right tube enlarged to a hydrosalpinx, and just before the operation for its removal dragged the fundus over.

Dr. Kelly urged that in future both cornua be utilized and attached between one and a half and two inches above the pubis to allow room for free expansion of the bladder; and again, that while in most instances the disease will have been of such long standing as to involve chronic incurable disease of the appendages necessitating their removal, yet in some cases the good effects of drainage of these latter, which are raised with the body, should be tried. The operation is to be urged where the long retroflexed infiltrated uterus is unable to stand up straight alone after removing diseased ovaries and tubes, and if adhesions bind the fundus down they should be carefully severed. He also insisted that the operation for shortening the round ligaments was not admissible for retroflexion alone, as owing to enormous mechanical disadvantage the slightest degree of relaxation would allow a reproduction of the deformity.

While in simple prolapsus, if a suprapubic operation of any sort were ever necessary, which the speaker doubted, he would prefer a simple, aseptically made, abdominal incision and direct support by attaching the fundus to the anterior abdominal wall, to an operation which has a doubtful and possibly a high rate of mortality, and of which the ratio of success is even more problematical.

The operation has been devised and performed independently by a number of prominent gynecologists in various parts of the world, among whom are Kœberle, Bardenhauer, of Cologne, Hennig of Leipzig, Czerny, of Heidelberg, a surgeon in the north of Italy, Lawson Tait, and probably Keith, and he had the record of two cases, not published, which Dr. Sänger, of Leipzig, kindly gave him during the past summer.

Dr. Drysdale remarked that he had performed a second operation upon a lady upon whom eighteen years previously Dr. Atlee had performed ovariotomy for the removal of an ovarian tumor; at the first operation the uterus was found prolapsed. In this operation Dr. Atlee had used the clamp to secure the pedicle, and at the second operation the uterus was found attached to the original wound. The prolapse had been effectually cured. He thinks both cornua should be secured to the abdominal wall. He had never met with a case of retroversion that could not be relieved by pessary after curing the accompanying endometritis. Many years ago, a lady who had been for eight years under the care of Dr. H. L. Hodge for retroversion, and in whom the presence of a pessary excited such expulsive efforts that it could be worn for only a week at a time, came under the care of Dr. Drysdale; he treated the endometritis first, and when it was cured a pessary could be retained and complete relief was secured.

Dr. J. Price remarked that Tait considers it dangerous to stitch the fundus uteri to the abdominal wound and has abandoned it. In some operations he introduces sutures to draw the uterus high up that he may more readily remove the tube close to the cornua.

Dr. Baer thought it seemed the most natural method to stitch the fundus to the abdominal wound. He asked for what reason Dr. Tait considered it dangerous. He thought the field of Dr. Kelly's operation would be small, as, when the endometritis was cured, a pessary or other support would relieve the retroversion or flexion. After laparatomy or removal of the uterine appendages it might be advisable in some cases to draw the uterus up. He has had no experience with such a procedure. He does not like the Alexander operation; he considers it unscientific, and in many cases it has failed to cure the displacement.

Dr. Longaker said that granting that anteversion could be secured by Dr. Kelly's method, he feared the bladder would not be allowed to expand—a fixed anteversion would itself be pathological. He would hesitate to stitch the fundus to the abdominal wall even after removal of the appendages. Retroflexion does not necessarily produce discomfort as some cases have no symptoms to call attention to the condition.

Dr. Harris recalled the case of Mrs. Reybold, whose uterus was suspended for fifty years. She died at eighty. The senile organ was drawn out into a tongue-shape; the uterine attachment was one and a half by three-fourths inch at time of death, the uterus was four and a half inches long and the vagina was lengthened and

card-like. There had always been a tender spot in the cicatrix, probably from tension.

Dr. Kelly stated, in reply, that he considered the main points which had been raised had been already answered in the paper. He considers these cases *rare*, and by no means recommends a resort to section and suspension without first trying every other known expedient likely to relieve, and then only in those cases in which the local disorder causes such pain or disability as to render life a burden. He considers the operation established, however, in those cases in which, after removal of the appendages, the flexed organ fails to remain upright when lifted into position. An occasional resort to hysterorrhaphy will not affect the table of recoveries from operation, but will affect the list of patients *cured*, which is not always made so prominent after abdominal section.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, November 15, 1886.

The President, James T. Whittaker, M.D., in the Chair.

Dr. P. S. Conner read a paper on

STRANGULATED HERNIA.

(See page 621.)

Dr. W. H. Wenning stated that the last case reported was one of a great deal of general interest, but of especial interest to himself. He was called a week ago to see a lady with strangulated hernia. On the day previous, as he was told, the hernia had been reducible in part. She had had the hernia for ten years, and had always been able to reduce it in part. On the morning in which he was called, however, she did not succeed in its reduction. She went to bed, thinking that she would succeed in the recumbent posture. When he saw her there was considerable swelling of the right labium. Below this swelling the right ovary could be distinctly felt. He tried to reduce the hernia, but failing, deferred further efforts. Returning in an hour he found the swelling much increased. Considering further delay dangerous, he advised an operation and Dr. Conner reduced the gut without difficulty. Everything looked promising, and continued to do so until the next morning; from that time on, however, the temperature continued to rise, until, after the expiration of thirty-six hours, death occurred. Everything indicated that the death was a result of shock. There had been no vomiting during or after the operation, except slight vomiting from the ether. As the ovary was so low down, he had examined the uterus, which he found somewhat lower than normal, but the axis was normal. The woman menstruated regularly up to the time of operation, and the flow came on after the operation. This, he thought, might have had some influence in hastening the fatal termination of the case.

Dr. T. A. Reamy stated that he had done the operation for strangulated hernia twelve times. All were cases of femoral hernia in women; ten recovered, two died. In one case, that of an old German, the strangulation had existed for five or six days, the bowel was much discolored, but a good recovery was made. He makes it a rule whenever there is much effusion or discoloration, to open the sac. He used silver wire for the purpose of drainage in all his cases.

Dr. R. W. Stewart remarked that there is one kind of hernia in childhood which has not been referred to, that is, in which the bowel pushes down through the lateral wall of the vagina and presents at the vulvar orifice. The last case he had seen was a child with a tumor presenting in one of the vaginal walls, with all the symptoms of strangulated hernia. It is exceedingly difficult to explain how this form of hernia can occur, for the vaginal wall, reinforced by all the other structures of this region is usually sufficiently strong to prevent the exit of the organs above it.

Dr. J. Ransohoff thought that a great deal more harm is done by delaying the operation too long than by early operation. He had formulated a rule to govern his own conduct in cases of strangulation. It was simply to make very feeble taxis, unless he had a supply of ether at hand, and to use very little force, even with the aid of an anæsthetic. As a rule, the patient himself can return the hernia much better and more safely than the surgeon can return it. He knows just how much force he can use. If the first attempt at reduction is unsuccessful, he generally makes a second attempt under an anæsthetic, after giving the patient to understand that if taxis is not successful the operation will be made then and there. If the reduction cannot be made by taxis, the result of the operation after it has been attempted largely depends on the force used and the delay after it. The bowel is often irritated by it, the sac distended with fluid, and loaded with germs that have migrated from the intestinal canal. We can understand, therefore, how readily inflammation of the peritoneum may develop.

He called attention to the trick which is practised a good deal in Scotland and to some extent in Germany and France. This consists in using the finger much as a hook, getting it underneath the constricting band, giving it a slight jerk, and in that way tearing some of the fibres and permitting the bowel to return. He knew that the old statistics collected by Gay and Steen have shown that the chances of death are much greater after the sac has been opened. That was unquestionably true at the time in which the statistics were written, but under the present management of cases it is different. The sac should be opened in every case in which the strangulation has existed for more than from twenty-four to thirty-six hours. If we do not take this precaution, we may later find that strangulation has existed within the sac as well as outside. He referred also to the radical treatment of strangulated hernia, by excising the sac and tying the stump. Very excellent results have been recorded from this method of treatment, but it is yet too soon to determine whether these radical cures will be permanent.

Dr. D. Young stated that from his experience he had concluded that it required a good deal of rough handling to injure the bowel, and hence he does not hesitate to use considerable force in attempting to reduce the hernia. He is in the habit of attempting restoration by taxis for five minutes; failing, he applies cold for three or four hours, then makes another attempt. If this is unsuccessful, he administers an anæsthetic. He has tried the method of exerting forcible pressure with the tip of the finger, but without result. In performing

taxis, he is always careful to include a large mass of the tumor in his hand, and this, he thinks, diminishes the danger of injuring the bowel.

DR. CONNER, in concluding the discussion, remarked that the difficulty and the danger, in most cases, lie undoubtedly in the delay, and not in the early operation. Of the thirty-three cases reported, twenty-one died; six of them within twenty-four hours, three after living a long time, and nearly all of the rest were cases in which there had been a delay of from three to seven days. The cases were not all hospital cases; only six out of the entire number occurred in hospital practice. If there is, in a given case, room enough in the ring to admit the finger, that ring is not making obstruction. The trouble in these cases is that the nature of the case is not understood, or is overlooked, and the strangulation of the gut is not recognized. If more cases were operated upon in this vicinity we would have fewer deaths from the disease. The operations are not dangerous in themselves, but only from the conditions that necessitate them. An apparently healthy bowel may be in such a condition as to go on to destruction within the peritoneal cavity, but this is not often the case.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 8, 1886.

DR. C. MCBURNEY IN THE CHAIR.

DR. ABBE presented a case of

TRIGGER FINGER,

occurring in a child ten years of age. On closing the right hand and then opening it, all the fingers are at once straightened, except the little one, which remains flexed upon the hand, being held there by a small obstacle in the flexor tendons. At the flexor crease of the palm of the hand, over the little finger-joint, a small nodule can be felt on the tendon; the little finger can, however, be straightened out readily with the other hand. The patient first noticed about a month ago,

FIG. 1.

while knitting, that when she wanted to put the needle down and open her hand, the little finger would still remain flexed; and since that time no great change has taken place.

The first of his five cases of trigger finger he saw in 1882, in a lady fifty years of age. The middle finger (Fig. 1) being involved caused great annoyance by catching around the handle of the hair brush; when using this, she was compelled to release the finger with the other hand.

The second case (Fig. 2) was that of an artist, eighty years of age, also occurring in the middle finger; this

FIG. 2.

bothered him exceedingly while stropping his razor; it remained so for a year and a half. The treatment consisted in encircling the middle of the finger by a band to prevent it from closing to the catching point, and by thus avoiding irritation of the node in the sheath of the tendon, the finger was restored to perfect condition.

The third case (Fig. 3) was an attack of the ring finger in the same hand of this patient, one year after the middle finger was cured. The symptoms were the same, and he is still under treatment.

FIG. 3.

The fourth case (Fig. 4) was that of a girl aged ten, previously referred to, whose little finger of the left hand was affected, causing annoyance when knitting. It catches itself and has to be released constantly.

A fifth case (Fig. 5) occurred in a lady fifty-five years of age, also the middle finger of the right hand, which especially annoyed her while carving.

Fig. 4.

Fig. 5.

He then showed the accompanying drawings in illustration of the subject. He stated that some writers believed it to be owing to an obstruction in the joint rather than to a thickening of the sheath; the more recent views being that it is owing to a thickening of the sheath of the tendon with perhaps a slight periostitis. Of the cases he had seen, only two presented distinct nodes—the lady of fifty-five and the patient now shown; the others presented a small thickening of the sheath but there were no nodes. The only new feature he had to advance in these cases was the method of treatment. If the finger could be so fixed as to prevent irritation at the seat of the thickening or of the node, he believed the patient might be cured; it had been successful in the one case, and the other patients were being treated in the same manner.

Dr. Stimson called attention to the fact that the patient could close the distal and middle phalanges without locking the finger; and that the locking was only of the metacarpo-phalangeal joint. He did not see, at first sight, how a locking of the tendon would account for that fact, and inquired whether any displacement of the joint-surface had been noticed.

Dr. Abbe replied that he had noticed it, and that there seemed to be a little rim which got on the rim of the metacarpal.

Dr. Stimson then asked if the node could not be felt when the finger was extended, and if it was not at the level of the metacarpal joint.

Dr. Abbe replied that it could be felt, but not so distinctly, and it did not seem to be directly over the joint.

Dr. Stimson asked if there had not been operations for this difficulty.

Dr. Abbe replied that there had, but they had been very unsatisfactory. Nélaton first claimed the cause to be a thickening of the tendon sheath, but, in his later papers, he stated his belief that a foreign body was the cause.

Dr. Lange reported a case of

TUMOR OF BLADDER; SUPRAPUBIC SECTION; EXTIRPATION OF TUMOR FROM THE FUNDUS; SUTURE ON BOTH PLACES; RECOVERY.

Mr. B., fifty-three years of age, from a healthy family, and previously always in good health, suffered since about four or five years ago from hemorrhage after micturition. The quantity of blood was mostly small, sometimes, however, quite abundant. There had never existed much pain or abnormal frequency in micturition. Lately, small fleshy lumps of tissue have been discharged with more or less inconvenience, but better condition following. Previous examinations of the bladder had been followed by severe feverish reaction.

Dr. Lange saw the patient on the first of October. He looked anæmic, but was well nourished, and did not present a cachectic appearance. He had just passed with his urine a fleshy piece about the size of a small cherry. The microscopical examination of the soft, very brittle tissue, showed numerous disintegrated cells of pretty large size, in advanced fatty degeneration, only the rather large nuclei could be distinguished with certainty. Another smaller piece, brought out in the eye of the catheter, showed distinct papillary structure, with a regular lining of columnar epithelium, the origin of which it is difficult to trace. Neither by palpation through the rectum, nor by means of the catheter, could the existence of the tumor be corroborated. On October 11th, in the presence of Dr. Keyes, and with the assistance of Drs. Kelley, Slager, and Lange, suprapubic section was done. A balloon in the rectum, filled with about 250 c.c. of water and about 300 c.c. of boracic solution, in the previously washed bladder, failed to raise that organ noticeably above the pubes. An additional tighter filling of the rectal balloon, and more fluid in the bladder, also helped very little. The peritoneum had to be stripped back, and it was found that the bladder was very flabby, and, apparently, paretic. After it had been opened, the patient was brought in the elevated pelvic position, as recommended by Trendelenburg. This procedure cannot be too much recommended. The intestines running against the diaphragm, the bladder becomes distended by negative pressure, like the vagina in Sims's position. With light from above, and an opening in the bladder of sufficient size, even the posterior wall of that organ becomes easily accessible.

The tumor was found about one centimetre behind the right ureter, and did not occupy a larger area than one of about two centimetres in diameter. It was flat, its superficial layers soft, and easily yielding to the sharp spoon. It was thoroughly scraped, and then the basis with some apparently healthy tissue all around, extirpated. The wound was sewed up with iodoform catgut-etage sutures. The anterior section in the bladder was likewise closed by catgut sutures, which did not pass through the mucous membrane. The abdominal opening was left open in its lower portion, and loosely packed with iodoform gauze. A Nélaton catheter was permanently left in the bladder. Not a drop of urine escaped through the abdominal wall, and at the end of three weeks the patient was sent to his home. The catheter became repeatedly

clotted with blood, especially about the fourth or fifth day, when some hemorrhage from the bladder took place. Cold injections, and tinct. fer. muriat. easily checked this. I must mention one accident with reference to the rectal balloon. About three-quarters of an inch above the anus the anterior wall of the rectum was ruptured, happily the peritoneum was not torn.

Dr. Lange exhibited the balloon he had used, and thought that its somewhat resistent walls and stiff shape when filled, were a source of danger. He advised balloons of thinner and softer rubber, and also of greater length. He had so far used suture of the bladder after suprapubic section in five cases, in four of which the operation was done for stone. In all of these cases primary union had taken place, and no urine had escaped through the abdominal wall. The wound in the latter he hadmostly left open, and only in the last mentioned case partially closed. He had always used the catgut suture, and thought that dry iodoform catgut was the safest material. He thought it a point of some importance that the mucous membrane is not taken into the suture, that fine needles and thin thread are used, the latter as dry iodoform catgut, which, after being soaked within the suture canal, will exactly fit the same, and not easily allow of the entrance of urine. He had always applied the first and last sutures exactly corresponding to the upper and lower angle of the wound, or rather beyond it, and tied the sutures, while some slight traction on the edges of the wound was made parallel to the direction of the wound. The elastic wall of the bladder will afterward become shorter and thicker, and the closure of the wound will be a very accurate one.

His first case was treated in this manner six years ago, before the general discussion had been taken up with reference to the advisability of sewing up the bladder or not. He left the permanent catheter in the bladder as long as it was well borne—if possible, six or eight days. He gave fluids in ample quantity, and kept the patient moderately under the influence of opium.

The microscopical examination of the tumor, by Dr. F. Heppenheimer, revealed the following interesting points: The *muscularis* contains numerous bloodvessels with thickened walls, and also free hemorrhages into the tissue. The unstriped muscle-cells contain a great number of round cells, of the size of white blood-cells, irregularly strewed between them. Thirty or forty of them are sometimes seen to congregate around a blood-vessel. Toward the free surface they are accumulated in thousands, lying thickly together. Only in some places it can be noticed that they are attached to each other by fine connective tissue, as berries to a stem. They contain, also, capillary bloodvessels. In the middle of this small, round-cell, sarcomatous mass, bulbs of large-cell sarcoma are to be seen. These have no connection with the small-cell sarcoma, and while in some places they are completely mixed and interwoven with the small cells, only the bulbs of the large cells have distinct boundaries. But they are always surrounded by the small-cell sarcoma. As the number of small cells is by far greater than the large cells, he calls the neoplasm a small-cell sarcoma. In his search in the literature of neoplasms of the bladder he has found neither a small nor a large round-cell primary sarcoma mentioned as being found in the bladder, those described being all fibro-sarcomas. The scrapings consist of the same cells thoroughly mixed, but mostly of the large-cell variety. They are not so densely congregated, but are separated by a myxomatous intercellular substance. They all bear evidences of rapid growth.

Dr. Lange remarked that the microscopical examination of the tumor was extremely interesting, as the conditions shown had been found in but very few instances.

DR. WEIR said that he had had to resort to the operation last May. He distended the rectum and bladder according to the mode of Petersen, and exposed a tumor in the bladder which was lying in the region of the left ureter, and which allowed itself to be readily seized by its base. This tumor, the size of a hen's egg, was removed, the parts thoroughly scraped with Volkmann's spoon, and nothing further done. Microscopic examination showed that it was a sarcoma. The wound was left open and the patient placed on his side with a drainage tube left in the wound. It healed in six weeks. Recurrence has since occurred.

DR. LANGE remarked that probably the bleeding came from the internal surface of the bladder where the edges of the mucous membrane had not been united.

DR. WEIR asked Dr. Lange whether he was much annoyed, in his case, with bleeding from the pre-vesicular tissues, as had occurred in his case, though the handle of the scalpel was principally used.

DR. LANGE replied that he was not, as he carefully ligated even the smallest bleeding vessels.

DR. GERSTER stated that he witnessed the operation by Dr. Weir, and was astonished at the profuseness of the hemorrhage when the pre-vesical fat was divided; and he believed the recommendation of Thompson, to tear the parts which contain large vessels, is not a very good one, for the hemorrhage from a torn vein is more difficult to check than one that has been cut.

DR. WEIR remarked that Thompson states he pushes the vessels on one side.

DR. GERSTER replied that that was true, but one is very apt to tear them while doing so. He much preferred the method of Dr. Lange, as there was less hemorrhage, and was of advantage in examining the bladder.

DR. WEIR remarked that the use of the rubber balloon in the rectum, resorted to by Dr. Lange, revealed another risk of this method of Petersen, viz., splitting of the rectum; Pousson has already shown that there is also danger of producing rupture of the bladder.

DR. WYETH stated that in one instance where he was assisting in a case of ovariotomy, the bladder was pierced and its floor fully brought to view, and yet there was no balloon in the rectum. The urine escaped into the peritoneal cavity, which was washed out with 1 : 20,000 sublimate solution. The edges of the wound of the bladder were stitched to the edges of the wound in the integument, and in six weeks was healed. He mentioned the case simply to show with what ease the floor of the bladder may be seen without using the balloon, and that extravasation of urine into the peritoneal cavity is not necessarily fatal.

DR. LANGE thought the position of the patient had very much to do with the ease of examining the floor of the bladder.

MONTREAL MEDICO-CHIRURGICAL OCIETY.

Stated Meeting, November 5, 1886.

The President, James C. Cameron, M.D., in the Chair.

EXPLORATION OF THE KIDNEY.

Dr. Shepherd related the history of a case where he had cut down on the kidney some two weeks previously, in the hope of relieving urgent uræmic symptoms. The history of the case was as follows:

Samuel B., aged thirty-eight, was admitted into the hospital July 13, 1886, complaining of frequent and painful micturition. These symptoms first appeared three months before, and he had been treated by several physicians for catarrh of the bladder. Had always been healthy up to three months ago, and was formerly very stout, but had lost considerable flesh lately. He made water every fifteen minutes, night and day, and each time the pain was severe; it commenced in the small of the back on the left side, and extended down the groin and along the urethra to the point of the penis. He complained of continuous dull aching pain in the left lumbar region. Had never passed any blood; urine contained a small amount of pus but no mucus; sp. gr. 1.005; contained albumen and only two grains of urea to the ounce; quantity passed daily sixty to seventy ounces. A careful examination of the abdomen was made, but no tumor could be made out in the lumbar regions. Bladder sounded for stone with negative results. From the condition of the urine and general symptoms Dr. Shepherd concluded that he was suffering from some affection of the kidney. He remained in the hospital some weeks, but left no better than he entered, treatment having no effect whatever. Dr. Shepherd afterward attended the man at his own house, and the symptoms still continued as before, viz., frequent and painful micturition, with pus in the urine. The quantity of pus now rapidly increased and the urine diminished; he passed twenty to thirty ounces of urine daily, thirty per cent. of which was pus. He also became rapidly emaciated, and there was occasionally an elevation of temperature in the evening. The patient went to some mineral springs in the neighborhood, and was not seen by Dr. Shepherd for several weeks; not, in fact, till the latter end of September. He was then much emaciated, and seemed to be in a stupid, drowsy condition; he was passing now only twenty ounces of urine daily and fifty per cent. of this was pus. A tumor could now be indistinctly made out in the left lumbar region. It was aspirated, and at first a little thick pus was drawn off, and then thin bloody serum.

He was again admitted into the hospital October 11, 1882, and the day after admission passed only six ounces of urine from which all pus had disappeared. His condition was serious; he had well-marked uræmia, and Dr. Shepherd, thinking that the arrest of urine might be due to a stone blocking up the ureter, determined to cut down and explore the kidney, a proceeding which could do no harm and might possibly do good. The horizontal lumbar inclsion was practised, beginning posteriorly at the edge of the erector spinæ and extending downward and outward below the twelfth rib. The kidney was soon reached and found to be enormously enlarged and non-fluctuating, the finger easily went through some tissue to the depth of an inch at the upper end. A large aspirating needle was thrust in several directions into the kidney, but failed to reach either a stone or pus. From the great enlargement and general appearance it was thought that a neoplasm existed, and considering that the man was secreting only six ounces of urine daily, the conclusion was arrived at that the other kidney was also diseased, so a drainage-tube was introduced and the wound sewed up. The man recovered from the immediate effects of the operation, but died comatose that night. No post-mortem examination was allowed, but after death the wound was opened and the kidney was taken out, at the same time the kidney of the opposite side was searched for but could not be found; it had probably been affected with a similar disease and undergone atrophy. On cutting through the greatly enlarged kidney numerous pockets of thick tenacious pus were found, also some large cysts distended with clear serum; the cortical substance was studded with small suppurating points and was much thickened. Dr. Wyatt Johnston examined the case and came to the conclusion that it was a tuberculous kidney —the tubercle bacillus was found.

Dr. Shepherd drew attention to the fact of the great obscurity of these cases in the early stage, and that pyelitis was occasionally attended by frequent painful micturition. The pain was, in this case, a very prominent symptom. He did not consider that the man had died in consequence of the operation but from uræmia. He also said that this case taught an important lesson, viz., that the condition of a kidney cannot be accurately ascertained without cutting into the kidney itself, a mere external examination giving negative results. If the pus cavities had been emptied the result would have been the same, but he would in future always perform a nephrotomy on a kidney which he had cut down upon, even if, as in this case, the condition did not seem to warrant it.

REMOVAL OF A LARGE CALCULUS FROM THE KIDNEY.

Dr. Shepherd also exhibited an enormous calculus weighing four ounces seven drachms, which he had removed a week before from a young man, aged twenty-six, who had suffered from lumbar pain for some seven years. The patient was doing well and a full report was promised at the conclusion of the case.

Dr. Gardner then read a paper entitled

GLIMPSES OF ABDOMINAL SURGERY IN EUROPE DURING THE PAST SUMMER,

in which he described the procedures followed by Schröder and Martin, and by Lawson Tait, with whom he spent a month, and for whose wonderful results he could vouch. He mentioned having seen Mr. Tait open the abdomen and evacuate a fetid abscess about the uterus in a woman who was apparently dying from puerperal peritonitis. The cavity was drained but not washed out. The patient made a rapid recovery. He attributed Mr. Tait's wonderful success partly to the small incision he made and to his great manipulative skill and rapidity in operating. He frequently completed an ovariotomy inside of ten minutes.

CORRESPONDENCE.

DIAGNOSIS AND TREATMENT OF TOBACCO AMBLYOPIA.

To the Editor of The Medical News,

Sir: I have read with much interest the report, in The News of November 13, of the discussion on "Tobacco Amblyopia" in the Philadelphia Neurological Society, and would like to add a word thereto.

It has been my practice for several years to use inhalations of amyl nitrite in all amblyopia cases, and I have found it of great value, especially (if not exclusively) in the cases of tobacco amblyopia. I believe that it is of great assistance in differential diagnosis, for thus far it has proved that, in progressive atrophy from other causes, no benefit is derived from the exhibition of the amyl, while in tobacco amblyopia vision is immediately and markedly improved.

For instance, a patient presents himself with a history of rapidly failing vision, without pain or inflammation, and examination discovers a dirty grayish hue of the disk, with diminution of circulation, and S.$=\frac{20}{CC}$. Inhalation of a few drops of amyl, pushed only to the point of lively hyperæmia of the face and headache, will cause a decided increase in the circulation in disk and retina, and within five minutes S.$=\frac{20}{XL}$. This evidence that vision is not permanently lost is of great value in fortifying the patient for the abstinence which is necessary to his cure. The sudden improvement is, for the most part, temporary, as, after an hour or two, S. recedes to perhaps $\frac{20}{C}$, but it is not wholly lost, and daily inhalations, combined with tonics and abstinence from tobacco and alcohol, have, in my hands proved much more rapidly curative than the strychnine and electrical methods. As the only action of the amyl seems to be to increase the blood supply, it would seem that tobacco amblyopia is due simply to a loss of function from anæmia, which may result in atrophy if long continued.

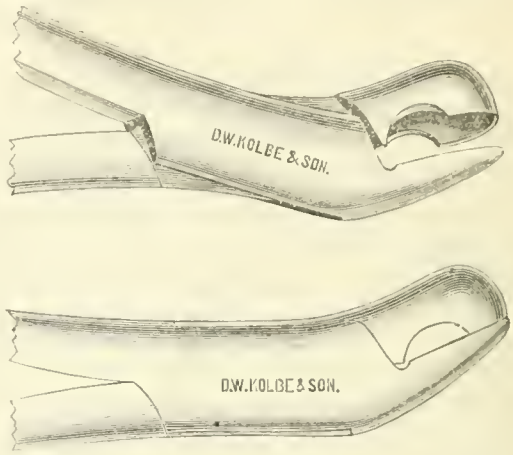
NEW INVENTIONS.

TREPHINING FORCEPS.

By WM. BARTON HOPKINS, M.D.,
of Philadelphia.

The instrument here represented is designed to cut away the sharp, ragged edges of bone, especially of the internal table of the skull, which frequently remain after trephining depressed fractures. Though constructed expressly for the purpose of working close to the dura mater without pressing upon or bruising it, this instrument is well adapted for connecting two trephine cuts, either in extensive operations upon the skull or in removing sequestra from the long bones.

In order to do its work properly, to cut a clean chip of bone without jarring or crunching, it must be made very differently from the ordinary gouge forceps. The chip with this instrument is cut wholly by the upper jaw, the lower jaw acting simply as a counter. The interior of the upper jaw must therefore be sufficiently hollowed



out to render the internal face of the blade perpendicular for at least an eighth of an inch above its edge. The lower jaw is slightly hollowed out to prevent slipping, and both jaws are set at an angle with the handles.

2018 Spruce Street.

OBITUARY.

JOHN PURDUE GRAY, M.D.

Dr. John Purdue Gray, Medical Superintendent of the New York State Lunatic Asylum, Utica, N. Y., died at the Asylum on Monday, November 29th, aged sixty-one years. The immediate cause of death was Bright's disease, and its complications. In 1882, he received a gunshot wound at the hands of an insane man, not an inmate of the asylum, who entered his office and discharged a pistol ball from a heavy navy revolver, which entered the left side of the face, passing along the floor of the nasal passages, making its exit through the right cheek. Although Dr. Gray recovered from the immediate effects of the injury, it is well known he suffered from the shock received, and the consequent impediment to respiration from obstruction of the nasal passages, to the day of his death.

Dr. Gray was a native of Half Moon Township, Centre Co., Pennsylvania. He received his academic training at Dickinson College, and was graduated from the medical department of the University of Pennsylvania, in 1848, soon after which he was appointed on the staff of the Philadelphia Hospital. Following his chief, Dr. Benedict, after his appointment as Medical Superintendent of the State Asylum at Utica, he was appointed third assistant physician September, 1850, and succeeded Dr. Benedict on his resignation in 1854. He served the State of New York in this office thirty-two years.

During this long period, in addition to his administrative and professional duties, he was the editor of the *American Journal of Insanity*, scattered through the pages of which, and in his annual reports for thirty-two years, are to be found his many contributions to the literature of his specialty, and his views upon many questions pertaining to the care of the insane. He furnished

the plans for the Michigan Asylum for the Insane, and of the Buffalo State Hospital, and was one of the Commissioners appointed for the location and erection of the Hilliard Asylum. He was at various periods President of the Association of Superintendents of Asylums for the Insane; the New York State Medical Society; New York State Medical Association; honorary member of the British and Italian Psychological Associations; Chairman of the Sections of Psychological Medicine of the International Congress of 1876 and 1887; and Lecturer on Mental Diseases in the Albany and Bellevue Medical Colleges. He was also an active member of other medical societies.

He was frequently called into the courts, and commissioned by the Governor to make special examinations, as an expert, and his exhaustive and important public services upon the trial of Guiteau are still remembered. Of an active, resolute, and aggressive mental organization, he was constituted to be a leader. This temperament naturally led him to combat the views of others with his own convictions, which he strongly adhered to and as vigorously defended.

As early as 1857 he urged upon the managers a plan for the prosecution of microscopical research in brain disease, which was not matured, however, until 1871. He steadfastly upheld the honor of the profession in every relation to his work, and exerted himself to elevate the medical service of his hospital by the selection of assistant physicians who had the previous training of a general hospital. The news of his death will be received with sorrow in this and other lands, and will be regarded by his special *confrères* as an irreparable loss.

NEWS ITEMS.

CINCINNATI.

(*From our Special Correspondent.*)

Changes in the Colleges and Hospitals.—During the last summer, the clinical department of the Cincinnati Hospital was incorporated as the Clinical Department of the University of Cincinnati. It is understood that a medical department will soon be established, probably in one of the colleges already in existence.

Dr. E. W. Walker, formerly of the Medical College of Ohio, has accepted the Chair of Principles of Surgery and General Pathology at the Miami College.

Dr. James M. French has been appointed Lecturer on Morbid Anatomy and Demonstrator of Pathology at the Medical College of Ohio.

Dr. Frederic Kebler, Lecturer on Pathology and Hygeine, and Instructor in Histology at the Medical College of Ohio, has received the appointment of Pathologist to the Cincinnati Hospital.

During the present winter, each member of the adjunct Faculty of the Medical College of Ohio is required to conduct a quiz on the lectures of the professor with whom he is associated. The quiz classes are free, and have been universally attended by the students, whose enthusiasm for study they appear to have greatly aroused.

An Addition to the Building of the College of Physicians of Philadelphia.—In order to carry out fully one of the provisions of the will of the late Dr. Mütter, who, in bequeathing the valuable collection of medical specimens to the Philadelphia College of Physicians, stipulated that a proper room should be provided for them, a third story has been placed on the College building at the northeast corner of Thirteenth and Locust Streets. The additional story covers the whole of the building, its dimensions being fifty-three by one hundred and three feet, and affords ample room for the valuable museum which has hitherto occupied two rooms on the first floor; these will now be devoted to the purposes of the library.

The height of the story to the peak of the iron roof is forty feet, and about seventy-five feet back from the front an additional story is made, providing three rooms, two of which are on the main floor, one of which is intended for a dissecting room and the other for a study. The room overhead will contain special specimens from the museum. The room is exceedingly well supplied with light, numerous windows piercing the walls on three sides, and a large skylight running along the whole length of the ridge pole.

Around the four sides of the room a gallery runs, and the cases containing the specimens will line the walls, and are approached from the main floor and from the gallery. An iron and marble staircase runs from the ground floor to the additional story, and an elevator, conveniently located, designed for the careful conveyance of specimens to the rooms, is also provided. At the south end of the room is a spacious fireplace, which is ornamented with a handsome stone mantel. Hot air will be used to heat the building. Efforts have been made to have the building as nearly fireproof as possible, and, in addition to the non-burning material already mentioned, the floors are of brick and covered with tiling. The cost of the improvement was about $28,000.

The Austrian Medical Association.—The Austrian Medical Association, which now comprises twenty-six branches, with a total of 4500 members, recently held its seventh annual meeting at Innsbruck, and resolved to petition the Government to make vaccination obligatory throughout the empire by imperial statute, also to restrict the privilege of private practice to medical men who have already served in a hospital. The Association expressed an opinion that considerable changes were desirable in the regulations concerning the training of medical students; and, lastly, a request was preferred that a law should be made assigning substantial pensions to the widows and orphans of medical men who might meet with their death through attending to their duties during an epidemic.

Dangers of Water Gas.—A committee of the Medical Society of the County of Albany, New York, have recently presented to that body a report on hygiene, of which the concluding paragraph reads as follows:

It must be admitted that water gas, with its thirty per cent., more or less, of carbonic oxide, is a more dangerous substance than coal gas with its five to seven per cent. of carbonic oxide, and that the only question that can be raised is, "how much practical importance is to be attached to this poisonous character?"

Professor Henry Morton says that the burning of water gas produces fifty per cent. more carbonic acid gas than

is produced by the burning of coal gas; hence the air becomes sooner vitiated with water gas.

Upward of fifty deaths were reported in New York, from water gas, from October, 1878, to January, 1883; six in Toronto; eight in Brooklyn.

About one-half of the gas used in New York is water gas, Brooklyn uses it largely, and many other cities. Albany is soon to be supplied with it.

Massachusetts has a law prohibiting the sale of gas containing above ten per cent. of carbonic oxide; New Jersey makes the limit two per cent.

Brooklyn coal gas contains 7.9 per cent. of carbonic oxide; its water gas 28.25 per cent.

Activity of the New York Health Department.—Dr. Cyrus Edson, of the Health Department, has seized and condemned 5280 gallons of wine at a factory in the lower part of the city, and asked the authority of the Board for its destruction. He reports that the wine is made by macerating low grades of dried fruits in water, fermenting the product, and then adding four or five grains of salicylic acid to the pint as a preservative. Dr. Edson believes the wine to be deleterious to health, in which opinion he is supported by other officials of the Board; and the matter has been referred to the counsel for the Department and Sanitary Superintendent.

The Danger of Wakes.—An instance of the reckless practice of holding wakes was recently reported to the coroner of Dublin. A physician stated that he found a number of men, women, and children assembled at a wake in Blackhall Street, Dublin, where two children had died of malignant scarlet fever. The coroner made an order for immediate burial, and dispensed with the holding of an inquest.

Appointment of a Commission on the Mode of Capital Punishment.—The New York legislature, at its recent session, passed a law of considerable general interest. It provided for a commission to investigate and report to the legislature, on or before the fourth Tuesday of January, 1887, "the most practical and humane method known to modern science of carrying into effect the sentence of death in capital cases." The following persons were appointed commissioners: Elbridge P. Gerry, of New York City; Dr. A. P. Southwick, of Buffalo; and Matthew Hale, Esq., of Albany. This law is the outcome of a determined effort on the part of many citizens to have a competent commission investigate and see if a better method of inflicting the death penalty than hanging could be devised. There is no public sentiment in New York averse to the infliction of death as a punishment for murder, but hanging is repulsive for many reasons. The Medico-Legal Society has discussed the subject, and many methods have been proposed in place of the scaffold and noose. The report of the commission will be awaited with considerable interest.

Duhring's "Treatise on Diseases of the Skin" has just been published in the Russian language. This is an additional compliment to a Philadelphia author, whose work has already appeared in two editions in English and has been translated into French and Italian.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 27, 1886.

Law, Homer L., *Surgeon U. S. N.*—Ordered before the Retiring Board December 2, 1886.

Lippincott, Geo. C., *Passed Assistant Surgeon U. S. N.*—Ordered before the Retiring Board December 6, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM NOVEMBER 23 TO NOVEMBER 29, 1886.

Irwin, B. J. D., *Lieutenant-Colonel and Assistant Medical Purveyor.*—Relieved from temporary duty in New York City, and of the charge of the Medical Purveying Depot in that city, and ordered to San Francisco, Cal., to take charge of the Medical Purveying Depot in that city.—*S. O. 270, A. G. O.*, Nov. 19, 1886.

Town, F. L., *Major and Surgeon.*—Ordered from Fort Clark, Texas, to Post of San Antonio, Texas, to relieve Surgeon J. P. Wright.—*S. O. 159, Department of Texas*, Nov. 15, 1886.

Gibson, Joseph R., *Major and Surgeon.*—Ordered for duty as Post Surgeon at Fort Logan, Col.—*S. O. 134, Department of Missouri*, Nov. 20, 1886.

Mosely, E. B., *Captain and Assistant Surgeon.*—Relieved from duty as Attending Surgeon in San Francisco, Cal.—*S. O. 99, Division of the Pacific*, Nov. 19, 1886.

Mosely, Edw. B., *Captain and Assistant Surgeon.*—Directed to take charge of the Medical Purveying Depot, San Francisco, Cal., until the arrival of a proper bonded officer.—*S. O. 99, Division of the Pacific*, Nov. 19, 1886.

Powell, J. L., *Captain and Assistant Surgeon.*—Ordered from duty as Post Surgeon at Fort Supply, Indian Territory.—*S. O. 134, Department of Missouri*, Nov. 20, 1886.

Egan, Peter R., *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Clark, Texas, Nov. 22, 1886.—*S. O. 162, Department of Texas*, Nov. 22, 1886.

Wakeman, Wm. J., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended three months.—*S. O. 274, A. G. O.*, Nov. 26, 1886.

McCaw, W. D., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, to take effect when his services can be spared.—*S. O. 274, A. G. O.*, Nov. 26, 1886.

Walker, Freeman V., *First Lieutenant and Assistant Surgeon.*—Assigned for duty at Fort McIntosh, Texas.—*S. O. 159, Department of Texas*, Nov. 15, 1886.

Clendenin, Paul, *First Lieutenant and Assistant Surgeon* (recently appointed).—Ordered to report to Commanding General Department of Texas for assignment to duty.—*S. O. 271, A. G. O.*, Nov. 20, 1886.

Johnson, Henry, *Captain and Medical Storekeeper.*—Will, in addition to his present duties, assume charge of the Medical Purveying Depot in New York City, as Acting Assistant Medical Purveyor.—*S. O. 270, A. G. O.*, Nov. 19, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING NOVEMBER 27, 1886.

Williams, L. L., *Assistant Surgeon.*—Granted leave of absence for twenty-four days, to take effect when relieved Nov. 15, 1886.

McIntosh, W. P., *Assistant Surgeon.*—Granted leave of absence for twenty-seven days, Nov. 26, 1886.

Norman, Seaton, *Assistant Surgeon.*—When relieved, to rejoin station (New York); granted leave of absence for twenty-three days, Nov. 27, 1886.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

ON THE TREATMENT OF PLEURISY WITH EFFUSION BY HAY'S METHOD.

Abstract of a Clinical Lecture
Delivered at the Hospital of the University of Pennsylvania, December 2, 1886.

BY WILLIAM OSLER, M.D.,
PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

GENTLEMEN: You have had in the ward classes during the past month, several interesting cases of pleurisy, which have familiarized you with the clinical history and physical signs of the disease, and I shall, to-day, first direct your attention to certain points in the plan of treatment which we have followed. Let me briefly summarize the history of the cases.

CASE I.—A. B., aged twenty-three; admitted on the 21st. He had been a healthy man. Three days before admission he was caught in a rain-storm and remained all day in his wet clothes. The following morning he had pain in the head, neck, and right side; in the latter situation the pain was of a sharp, stabbing character, and increased by drawing a deep breath. He had fever, lost appetite, had also a sore throat and diarrhœa. When admitted the face was flushed, the respirations 34 in the minute, pulse 100, and temperature 101°. He lay on the left side. Examination showed deficient expansion on the right side, with jerky, inspiratory movements. There was a distinct friction fremitus to be felt and heard below the right nipple, and there was slight dulness in lower axillary and infrascapular regions. On the fourth day the temperature was normal, and there were signs of effusion to the level of the fifth rib.

CASE II.—J. M., aged twenty-four, a well-nourished young man, was admitted on November 12th. In 1883 he was poisoned with arsenic, and is now ataxic, the result, apparently, of a peripheral neuritis. His present trouble began three weeks before admission. Four or five days after exposure to cold and wet, he felt a pain in the right side and had a cough, with fever and occasional sweats. He did not go to bed, but gradually got short of breath, and for this symptom he sought relief at the hospital. Shortly after his admission I called your attention to the characteristic physical signs in this case. The effusion was in the left side and reached as high as the lower border of the second rib. The heart was displaced and there was an impulse near the right nipple. You saw him in clinic two weeks ago to-day.

CASE III.—William G., aged twenty-three, admitted to the Philadelphia Hospital October 12th with shortness of breath. He had been ailing for seven weeks. Had never had a chill or pain in the side. Had been feverish at times; had sweated and had been gradually getting short of breath. Though not able to work, he kept about and had not been in bed. There was left pleural effusion with absolute dulness reaching to the clavicle and displacement of the heart to the right; with the hypodermic needle the fluid was determined to be serous. He had been drinking before admission, and for nearly ten days there was mild delirium tremens.

The effusion in these cases varied from the slight amount in Case I., which would probably have disappeared in time without medication, to the large exudation in Case III. filling the side of the chest. In treating pleuritic effusion we have to choose between medicinal and operative measures, and these cases illustrate the rules which I have already laid down for your guidance. In the first two cases the symptoms were not urgent, the condition of the patients good and the duration of the disease not prolonged. In Case II. we were in doubt whether or not to aspirate, as the line of dulness reached to the second rib; but I am glad we decided to try first the effect of medicines.

Now the usual routine in treating pleural effusion is to give purgatives, diuretics, and diaphoretics, but the plan to which I wish specially to call your attention this morning is the use of concentrated solution of saline cathartics introduced by Professor Mathew Hay, of Aberdeen. We have employed his method extensively in dropsies from various causes and with very satisfactory results.

Dr. Hay found, when investigating the physiological action of saline cathartics, that if the salt was given in a very concentrated form, when the intestines of the animal contained very little fluid, it produced a very rapid concentration of the blood owing to the abstraction of water to form the intestinal secretion excited by the salt. If the saline was not given in concentrated form or was administered at a time when the bowel contained much liquid, the action upon the blood was very slight. The effect is very rapidly produced; in one instance, in a man after giving six drachms of sulphate of soda, the number of blood corpuscles per cubic millimetre rose from 5,000,000 to nearly 7,000,000, owing to the great loss of liquid in the free purgation. A few hours later this increase was no longer apparent, as the blood had rapidly abstracted the tissue fluids and so replaced the amount lost. You know that the pinched, shrivelled aspect of a person who has had a severe choleraic attack is due in large part to the absorption of the tissue lymph to supply the rapid waste caused by the liquid stools.

It is on this principle that the use of cathartics in dropsical effusions is based, and Hay's method is new only in the application. In the administration of the salt, the solution must be concentrated, and taken at a time when there is very little fluid in the intestines. Our usual plan is to order the patient to take nothing after the evening meal, and then, an hour or so before breakfast, the salt is given dissolved in as little water as possible. The sulphate of magnesia is preferable to the sulphate of soda, as it is more soluble. Four or six drachms in an ounce of water is the usual dose, but two ounces, or even more, may be given. The patient must not drink after it. This usually produces from four to eight

watery stools, without pain or discomfort of any sort. It very rarely disagrees, though you remember in the case of Mrs. C., the patient with extensive anasarca from Bright's disease, we had to give up this plan on account of the vomiting it induced. Dr. Hay calls attention also to another point which we have repeatedly verified, namely, that the salt acts also as a diuretic. He found experimentally that the blood underwent a second concentration, not so marked, but lasting for the greater part of the day, and this he rightly attributed to the diuretic action of the absorbed salt.

Case II. is a striking instance of the value of this plan of treatment. Two weeks ago I demonstrated to you that the fluid reached as high as the third rib, and was rapidly subsiding. He has been given every second morning, since his admission on the 12th, half an ounce of sulphate of magnesia in an ounce of water, and, as you can see by the chart, this has produced from three to nine watery stools. His diet has been restricted somewhat in liquids, but he has had no other medicine. We find now, on examination, good expansion on the left side; the heart has returned to its normal situation; on palpation a distinct friction can be felt in the axillary region; tactile fremitus is present; on percussion the note is clear in the antero-lateral regions, and posteriorly it is resonant almost to the base; the breath sounds are heard well over the whole side, with the exception of the extreme base, where they are still feeble. The patient was discharged the day before yesterday to go on duty as night watchman on the surgical side. We may regard this as an exceptionally good result. It is the third instance in which I have seen a large effusion disappear rapidly treated by Hay's method.

Exudations of less extent will sometimes disappear in a few days. Case I. we saw early in the acute stage, and, to relieve the distress, he was wet-cupped with marked benefit. This is a measure which I do not often employ, as I find that morphia subcutaneously fulfils the indication; but here the pain was rapidly relieved and the breathing became much quieter. The effusion in this case reached only to the fifth rib. He had four or five doses of the concentrated saline solution, and was freely purged. To-day there is scarcely a trace of fluid, and you notice that, on percussion, the lung is clear almost to the extreme base.

In Case III. saline cathartics were also employed, but other and more prompt measures were indicated. The left chest was full, the percussion note on the clavicle was absolutely flat, and the fluid had been accumulating for at least seven weeks. Under such circumstances the withdrawal of some of the fluid was imperative. It is a good rule to aspirate when the fluid reaches the second or third rib. The removal of from twenty to thirty ounces will often suffice, and you can trust to medicines to remove the balance. When you find the fluid at the level of the clavicle, aspirate at once, as connected with this condition there are certain dangers which we cannot ignore. Such patients are liable to sudden and alarming attacks of dyspnœa. This occurred in Case III., and my house physician, Dr. Donohue, wisely withdrew at once between two and three pints of fluid. There are instances, also, of sudden and fatal collapse under these circumstances. Such a case occurred last spring in the Philadelphia Hospital, when I was on duty for my colleague, Dr. Tyson. A woman was admitted, stated to be suffering with pneumonia. I saw her for a few minutes at the conclusion of my visit, and made a rather hasty examination, and determined the existence of dulness on the left side. She died suddenly and unexpectedly the next day, and, to our mortification, we found the left chest full of fluid, the lung greatly compressed, and the heart pushed far over. We could not determine the cause of the sudden collapse, but I feel certain it might have been averted by timely aspiration.

In Case III. we would not trust to the saline cathartic alone as the patient's general condition was not good. He was aspirated twice subsequently, and had an occasional morning purge. At present he is convalescent, has gained in weight and strength, and although there is still dulness at the left base, I believe it is due chiefly to thickened pleura and not to fluid.

My experience with this method is sufficient to justify a strong recommendation of its merits. In the general dropsies—renal or cardiac—the results have been equally good. There have been failures, to one of which I have already referred, and I have on several occasions heard complaints of nausea following the strong and bitter solution. In another case, last summer, the patient, a young man, thought the daily purgation and a rather dry diet terrible hardships, and he escaped from the hospital.

The essence of the method lies in getting the strong salt into the intestine at a time when the fluid contents are scanty. The concentrated bitter solution excites a copious secretion from the intestinal glands, which distends the intestine and induces rapid peristalsis. Saline, as well as other purgatives, have long been employed in the treatment of dropsies, but this plan of Hay's is so simple, produces so little irritation, and at the same time acts powerfully, and, as you have seen, effectually, that with us it has superseded other methods in cases in which we wish the action of a powerful and prompt cathartic.

ORIGINAL ARTICLES.

LAPAROTOMY AS A DIAGNOSTIC RESOURCE.[1]

By T. GAILLARD THOMAS, M.D.,

CLINICAL PROFESSOR OF DISEASES OF WOMEN IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

During the last century medicine has been slowly but steadily rising from the lower level of the arts and gradually assuming its place among the sciences. Empiricism has gradually given way before logical deduction; the dogmas of the schools and the dicta of the masters have gone down before clinical research and experimental demonstration; and the theorist of the closet and the bookworm of the library have been replaced by the chemist, the anatomist, and the microscopist.

Up to this period the opinions of the masters were all powerful; since that time abstract principles have become worthless: facts capable of demonstration to our senses rule the hour and control professional thought. As this salutary change has developed, every observer must have been struck by the fact that one of

[1] An essay read before the New York County Medical Association.

its chief factors, and, at the same time, to a certain degree, one of its direct results, has been the great development of the art of diagnosis accomplished by the subordination of theoretical methods of exploration and investigation to those which are purely physical.

Our knowledge of diseases of the chest entered upon the road to rapid advance under the influence of percussion and auscultation; of affections of the larynx under that of the laryngoscope; of those of the eye under that of the ophthalmoscope; and cutaneous diseases are only now fully experiencing the great boon of the microscope. For diagnosis instruments of precision have done fully as much as clinical thermometry has accomplished for the practice of medicine, the microscope for minute anatomy, or medical chemistry for the clinical study of renal disorders.

Some philosopher has said that if to-day the production of iron were suddenly to cease society would at once and rapidly retrograde, and in a few centuries would have reached, in its downward progress, the level which it occupied in the bronze and stone ages. That this bold and comprehensive postulate is correct no reflective mind will, I think, be inclined to doubt. It is equally true that, if the instruments of precision just mentioned were taken away from medicine, our art would steadily go backward until it reached the level of empiricism which it occupied in the days of Rhazes, Hally-Abbas, and Avicenna.

What I have said, so far, is prefatory merely to the proposition that if we are in our day to advance in the art of diagnosis there is but one avenue open to us—that which leads directly to the subordination of theory to fact; which replaces abstract surmise, however ingenious and plausible it may be, by physical demonstration, and which substitutes the blunt evidence of our senses for the most polished processes of ratiocination.

Throughout the domain of surgery there is no field in which diagnosis is more surrounded with difficulties that that of abdominal neoplasms. This is due to three facts: first, the superposition of the intestines; second, the great thickness to which the abdominal walls commonly attain; and third, the accumulation of gases in the intestines, which increases all preëxisting difficulties of exploration. Previous to the time when antiseptic precautions rendered the opening of the peritoneum a safe and warrantable procedure, even when the case was not one of life and death, the diagnosis of abdominal tumors was allowed to rest upon deductions capable of being drawn from rational and physical methods, the latter of which were limited by the abdominal walls without and the pelvic roof within. To day, surgeons devoting themselves to this department of our art fully agree as to the propriety of opening the abdominal walls for the purpose of exploring the viscera fully by touch, and, to a limited extent, by sight.

It appears to me that no more important era has of late years marked the advance of abdominal surgery than the general recognition of the fact that when doubt exists as to the diagnosis of abdominal neoplasms or the significance of certain pathological conditions within the peritonum, the question at issue should be settled by explorative incision. So fully am I individually convinced of the propriety of this practice that, were I called upon to select a motto for the walls of a hospital devoted to abdominal surgery to-day, I should, without hesitation, select this one: "When a doubt as to the diagnosis of an abdominal neoplasm of serious character or of certain obscure pathological conditions of the abdominal cavity which threaten life exists, give the patient the benefit of explorative incision." And this mural legend should always stand before the eyes of the doubtful diagnostician, that it might prove a constant reminder of a most important duty.

After an experience yielded by seven or eight hundred cases, approximately, of laparotomy for various causes, extending over a period of twenty-three years, I am very sure that I can say with entire truth that I have never once regretted opening the abdomen, and that I have in a dozen cases, at least, deeply regretted having failed to do so. It is in my mind certain that in the future explorative abdominal incision will become the rule in all cases of the following conditions which do not yield to medical means, and concerning the etiology of which there is great doubt: first, wounds and injuries of the abdominal viscera; second, intestinal obstructions; third, the presence of stones in the gall-bladder or kidneys; fourth, the accumulation of blood, pus, or serous fluid from any cause; fifth, the existence of a neoplasm in any part of the abdomen; sixth, the occurrence of serious organic changes in certain of the viscera of the abdomen, such as the kidneys, the uterus, the Fallopian tubes, the ovaries, or the spleen; seventh, ectopic gestation.

It is a remarkable fact, and one which constantly excites the wonder of the uninitiated, how grave errors of diagnosis in reference to abdominal tumors are made by men of the largest experience, the maturest judgment, and a life-long devotion to the work of gynecology. The truth is, that all over the world, errors in diagnosis in the field of abdominal tumors are, and probably will forever be, common, unavoidable, and, except in rare cases, entirely excusable. He who declares that he does not frequently err belongs to one of two classes: that of those who lack the intelligence to appreciate their shortcomings or the courage to confess them, for it is only the good diagnostician who can afford to own to diagnostic errors, or to that of those who by *suppressio veri* or *suggestio falsi* are short-sighted enough to hope to deceive the community which watches their careers.

It is for the purpose of avoiding such errors that explorative incision is peculiarly valuable. It may be that there is doubt as to whether a neoplasm is a fluid tumor of the ovary or a solid one of the uterus; or whether an abdominal dropsy is due to incurable hepatic disease, or to some tumor no larger than an apple situated deep down in the pelvis; or as to the benign or malignant nature of some growth about which nothing positive can be settled. In such cases the results of opening the abdomen are most striking and gratifying; they beam upon the

existing obscurity as the rays of an electric light upon previous darkness, and even although the result of the incision may serve to assure us merely that death will very soon close the scene, this certainly is better than the cruel uncertainty which previously existed, and the grief of relatives is assuaged by the feeling that "no stone has been left unturned" to procure a relief which science is powerless to bestow.

I know of no way in which I can better convey my views and give my experience upon this subject than by mentioning first some cases as examples of the class in which I have had to regret non-interference on my part, and then relating others in which more active measures have produced happier results.

Case I.—About seventeen years ago I was called to Fordham by the late Dr. Wohlfarth, to see a strong, healthy young coachman, about twenty-five years of age, who had been suddenly seized with obstruction of the bowels, which had resisted all medical means, and which was, evidently, going to result fatally. The abdomen was immensely distended, and, except when under the influence of opium, the patient suffered great agony. The question of laparotomy was carefully canvassed, and, unfortunately, we decided not to perform it. The patient died, and, on a post-mortem examination, a loop of intestine was found constricted by a false membranous string, the result, probably, of some long-past peritonitis. This, as was apparent as soon as the abdomen was opened, was the sole cause of the obstruction, and could at once have been overcome by the snip of a pair of scissors. At that time laparotomy, had it failed, would have met with universal condemnation; we probably lacked moral courage to meet the issue, and we let the poor fellow die, "hoping aginst hope," for a relief which became less and less likely to occur with every hour that elapsed.

Case II.—About fifteen years ago, Prof. F. N. Otis asked me to see, with him, a woman who for years had suffered from a uterine fibroid. This had gone on growing until, when I saw the patient, it weighed forty pounds. It filled the whole abdomen, and pressed so much upon the viscera under the diaphragm that it was evident that the patient would soon be exhausted unless the neoplasm was removed. The question of extirpation of the tumor was carefully considered, and the decision was left to me. At that time the operation was very rarely performed, and still more rarely was it successful. I decided against operation and the patient died. Upon autopsy, a tumor weighing forty pounds was found, entirely unattached, in the peritoneal cavity, and connected with the uterus by a pedicle not larger than the ring and middle finger placed side by side! Removal would have been easy, and recovery would have been likely; but, influenced by the spirit of the times, which frowned upon the removal of large, solid tumors of the abdomen, the operation was not put at the patient's disposal. An explorative incision would have made the practicability of the operation quite evident.

Case III.—In the early part of my experience as an ovariotomist, a lady, suffering from a very large abdominal tumor, called upon me, with the statement that she had consulted the three most eminent operators living in this country at that time; that they had all agreed that her tumor was a solid one connected with the uterus, and had all advised against operation. Before deciding fully to abide by this advice, she had come to consult me. After a careful examination I agreed to the opinions already expressed. The patient went home, and in about a year died. Upon post-mortem examination the neoplasm was found to be a multilocular ovarian tumor, entirely free from adhesions, with a small pedicle, which could have been removed with every prospect of success. The reasons for the obscurity of the diagnosis were the following: the tumor was composed of innumerable small cysts; the walls of these were thick, and the fluid within them colloid.

Case IV.—During the early portion of my service as visiting physician to Bellevue Hospital, a strong and healthy young Irishman was brought into my service suffering from intestinal obstruction. This resisted all the means that could be resorted to except only laparotomy, and this, after careful consideration with some of my colleagues, was rejected. The man died, and upon post-mortem examination the following very curious condition of things was found to exist: the transverse colon, at its middle, was distended into a kind of a sac, which was filled with hardened fecal matter, held in an indissoluble mass by a quantity of hay, such as is fed to horses, which penetrated it in every direction. It is certain that, upon abdominal section, this would have been readily discovered, and it is probable that, by a process of kneading, it could have been dislodged and pressed onward toward the rectum. I made every effort to find out what could have induced the man to swallow the hay; all that I could learn in explanation was that he was subject to periodical debauches, during which he did the most extraordinary things. His friends thought that during one of these, either upon a bet or from mere bravado, he had swallowed the hay, although they had no positive information about the matter.

Case V.—I was called in great haste to see, in consultation with three other physicians, a nulliparous lady who, after having suffered from absence of the menstrual discharge for three months, was suddenly taken with severe abdominal pain, faintness, and exhaustion. Physical examination, which could be practised only at great disadvantage, revealed the presence of an obscure, fluctuating mass in the pelvis. I was convinced that the case was one of extrauterine gestation, which had resulted in rupture of the fœtal nidus and in hemorrhage, and I urged the propriety of explorative incision. My colleagues differed from me in diagnosis, and another physician was added to the consultation. At our final meeting the vote stood two in favor of laparotomy and three opposed to it. The patient died, and upon post-mortem examination a three months' fœtus was found in the Fallopian tube, at its fimbriated extremity. The amniotic sac was unbroken, but a slight rent had occurred in the muscular covering of the sac, which had opened an artery of sufficient size to cause death by hemorrhage in the three days which elapsed

between the inception of the accident and the fatal result.

I regret to say that I could more than double the number of cases illustrating this part of my paper, but I will not tax the patience of the Society by doing so. In my own defence, I will remind my hearers that almost all of this variety of my cases occurred fifteen or twenty years ago, and that this number of years, so rapid has been the recent advance of abdominal surgery, carries us back into the ancient history of the subject. Few such cases occur to me now, for the very reason that I am a strong advocate for explorative incision as a diagnostic resource.

Turning now to more pleasant recollections of my past experience, I will give a few cases illustrative of the brilliant results which commonly attend upon the practice of explorative incision as an aid to diagnosis. I ventured to number the unfortunate results which have occurred in my experience from a neglect of resource. Were I to record even a tithe of the cases in which life has been saved by a resort to it my time and your patience would alike be exhausted.

Case VI.—A patient was brought to me for abdominal dropsy, for which paracentesis had been repeatedly practised, and in whose pelvic cavity a solid tumor, the size of the adult head, could be distinctly felt. This was regarded as a large uterine fibroid, the presence of which had induced ascites, and the removal of which was regarded as entirely impracticable on account of the weak and exhausted condition to which the patient had been reduced. I proposed explorative incision, agreeing with the relatives that I would be governed by the light which this shed upon the case as to my subsequent action. As soon as my hand passed into the abdomen what before was obscure became perfectly plain. The abdominal fluid was not the result of ascites, but was ovarian fluid poured forth from a ruptured ovarian cyst, which, in its collapsed state, now occupied the pelvic cavity, giving rise to the belief that it was a fibroid. The operation for the removal of the sac was an exceedingly simple one, and the patient made a rapid recovery.

Case VII.—An unmarried woman was sent to me by Dr. Woodward, of Brandon, Vermont, for almost complete amenorrhœa and such agonizing pains at menstrual periods that the most powerful anodyne medicines were inadequate for her relief. Upon vaginal examination what appeared to be a uterine fibroid as large as a goose's egg, could be felt on each side of the uterus and filling the iliac fossæ. The patient's family were told that a positive diagnosis was impossible without explorative incision, and this was made. Upon introducing my hand the tumors were found to be due to excessive distention of the Fallopian tubes with blood, constituting perfect specimens of hemato-salpinx. The overdistention of these muscular canals gave rise to the sensation of solidity. Both tubes, with their corresponding ovaries, were removed, and the patient was entirely cured.

Case VIII.—This case I record as illustrating the fact that cases of abdominal tumor are sometimes utterly beyond the realm of diagnosis. Mrs. W., a woman of forty-five years, had been married fifteen years, but thought that she had never been pregnant. Early in married life she was supposed to be so, but she had never miscarried, and never borne a child. She came to me with a cyst the size of the head of a child a year old, and a hard round tumor which I supposed to be a calcareously degenerated fibroid behind the uterus. In three months from the time when I first saw her she fell suddenly into an almost collapsed state, and suffered greatly from pain in the tumor, which nearly doubled in size in a day or two. Her condition became so desperate after this that I operated to give her the only chance for life which presented itself.

A large blood cyst was emptied, and from the distended pouch of Douglas I shelled out the skull of a fœtus of probably six months' of intrauterine life. She had suffered fifteen years before from abdominal pregnancy; the child had died, and all but the skull had disappeared by absorption.

The patient did well until the sutures were removed on the tenth day, when she developed cardiac thrombosis, and died of it. The sudden increase in the size of the tumor and the accompanying collapse, were due to hemorrhage from the cyst wall.

Case IX.—Some years ago I removed from a lady in Brooklyn two large ovarian sarcomas. She recovered and went to Oswego to live. About three months afterward she was taken with constipation, which soon ended in complete obstruction. The patient was thoroughly convinced that I had occluded the intestines by encircling them with a silver wire, and I went to Oswego to see her in consultation with her physician, Dr. Clark. She had not at that time had an alvine evacuation for a fortnight. I at once performed laparotomy, and found a considerable portion of the large intestine encircled by a malignant mass, probably sarcoma. The whole peritoneum was studded with the same. The wound was closed and the patient died at the end of a month.

There is one class of cases in which in my hands explorative incision has yielded such brilliant results that, even with the fear of making my paper too long, I shall devote full consideration to it. I allude to cases of ascites in the female.

This condition is universally regarded both by the medical profession and by the public as a prognostic sign of the gravest significance and most important bearing. This is true of the condition whether it presents itself as an independent, isolated, and perhaps entirely solitary pathological state, or as one secondary to dropsy of the extremities beginning in the face or in the feet. But it is to dropsy limited to the peritoneal cavity that my remarks in this connection will have reference.

It is a clinical fact which teachers might well impress upon the minds of students as an elementary axiom that there are three great sources of dropsy: first, dropsy due to disease of the heart, which first gives evidence of its existence by œdema pedum; second, dropsy due to disease of the kidneys, which first marks its access by œdema in the areolar tissue beneath the eyes; and third, dropsy due to organic

disease of the liver, which causes accumulation of the watery elements of the blood within the peritoneal cavity. To all general rules in medicine, as elsewhere, there are exceptions, but there are few to this one; or at least I should say that my personal experience leads me to believe so.

The causes of ascites may thus be enumerated as to frequency of occurrence:

1st. Organic diseases of the liver.

2d. Chronic peritonitis.

3d. Tubercular peritonitis.

4th. Malarial spanæmia accompanying great splenic enlargement.

5th. The existence of neoplasms within the peritoneal cavity.

6th. The prolonged existence of excessive fecal impaction.

All these conditions, except the last, will so readily be admitted as common factors of the great symptom of which we are speaking that no special allusion to them will be necessary. The last will not be admitted by those who have not had personal experience of it. I will merely say that I have had such experience, and that I am as perfectly convinced of the truth of my sixth proposition as to etiology, as I am to that of the five which precede it.

Of these causes of ascites but one concerns us here; the existence of neoplasms within the peritoneal cavity. This class of causes will, as to its authenticity, be disputed by no one. We see it in rare instances active with all varieties of solid tumor of the uterus and of fluid ones of the ovary. This is so well recognized as a fact, that it requires no further consideration at my hands, so far as the general proposition is concerned. The special proposition which I would make in reference to it is this, that some cases of excessive ascites, which by repeated tappings prove fatal, are due to insignificant uterine or ovarian tumors, which are too small for recognition, unless specially and carefully sought for, and the removal of which relieves the fluid accumulation which by its exhausting influence destroys life.

These tumors are sometimes no larger than small apples, and cannot be recognized except by the careful examination of an expert. In stout women, or even in those that are thin, after accumulation of ascitic fluid, they cannot be discovered even by a master in diagnosis. And, as I have had sufficient evidence in my experience, in some cases even when a tumor in the pelvis, as large as a cocoanut coexists with ascites, no connection between the two pathological conditions as cause and effect are ordinarily traced by the medical attendant.

Should this be the case, should the existence of the neoplasm not be detected, or should its malign influence not be appreciated even when its presence has been diagnosticated, but two resources present themselves to the physician: First, to cause absorption of the effused fluid by pressing into action the three great emunctories of the body, the skin, the kidneys, and the alimentary canal; second, to remove the fluid by aspiration or by tapping. The first of these usually fails. If it does not fail, the cause of the symptom remaining after the symptom itself has been removed, frequently repeated resort has to be had to the plan, which in time impairs nutrition and exhausts the vital forces.

If tapping or aspiration is employed "the beginning of the end" soon shows itself; the practitioner has early demonstrated the converse of the old Hippocratic maxim "causa sublata tollitur effectus," and it becomes merely a question of time how long the system of the patient will bear the exhausting drain to which it is exposed.

I have met with a number of cases in which I have succeeded in completely curing aggravated cases of ascites, after tapping had been repeatedly resorted to, and after all hope of recovery had been given up.

I shall not weary the Society by a report of all these, for proof does not consist so much in a long array of cases as in the portrayal of a few select and characteristic instances which clearly point out the pathological conditions which have been assumed as factors, and give evidence of the restoration to health effected by their removal.

Case X.—Mrs. C., of Durham, Conn., came to me about ten years ago suffering from ascites, for which she had been repeatedly tapped, and from which she was rapidly growing weaker; so that death at an early period seemed certain. After each tapping a round hard tumor about as large as the head of a five year old child, could be readily detected in the pelvis, and this could be obscurely felt even when the dropsical effusion existed.

I opened the abdomen as an explorative procedure, and finding a fibroid attached to the fundus uteri, removed it. The patient is perfectly well today, the dropsy having immediately disappeared.

Case XI.—Mrs. B., of Canada, came to me with ascites, which was accompanied by the presence of a solid tumor over one ovary, as large as a cocoanut. She had been tapped once only. I removed a solid tumor of the left ovary, and she entirely recovered, and has remained free from dropsy for two years.

Case XII.—About a year ago Dr. Hurlburth, Jr., of Stamford, Conn., sent me a patient suffering from ascites, in whom I could detect, by vaginal touch, what seemed to be a pelvic neoplasm. I made an explorative incision, found a tumor in Douglas's pouch no larger than an apple, which I removed, and the patient recovered from the operation and from the abdominal dropsy. The tumor, examined by Dr. Coe, Pathologist of the Woman's Hospital, was pronounced sarcoma. I have just received the following report of the case from Dr. Hurlburth: "Since the operation the patient has been perfectly comfortable, but now a hard tumor can be felt occupying the pelvic cavity, and ascites is gradually beginning again to demonstrate its existence."

It is highly probable that without removal of the malignant growth the case would long ago have ended fatally.

Case XIII. was a counterpart of Case III., except that the post-uterine tumor was a benign fibroid attached by a rather slender pedicle to the posterior wall of the uterus. The patient, who was an inmate of the Woman's Hospital, left that institution at

the end of a month well; but since that time I have lost sight of her.

It is very difficult indeed, I may say impossible, to tell why in a certain small number of cases these tumors create ascites while in other cases they may occupy the peritoneal cavity for years, without causing any such trouble; but that such is the fact is beyond question.

Case XIV.—I saw some years ago, with Dr. Emil Noeggerath, a lady who suffered from severe enteralgia, which was created by the presence of an ovarian cyst as large as an adult's head, which was so migratory in its nature that it could be pushed anywhere in the abdomen from the pelvic roof to the diaphragm. As there was no urgency in the case, and as the patient and her friends dreaded surgical procedure to a morbid degree, we decided to avoid interference. Fourteen years passed and I was again called in counsel by Dr. Noeggerath. The tumor was only about double the size which it had been fourteen years before, but its nomadic tendencies had created ascites, which was greatly distressing the patient, who now clamored for relief by surgery. I assisted Dr. Noeggerath in the removal of a monocyst with the longest pedicle that I ever saw in an ovarian tumor. The patient rapidly recovered, and has been ever since free from ascites.

It is rare to find even a monocystic ovarian tumor running so long a course; but I have removed one which had lasted for twenty-four years, another of sixteen, and another of nine years' duration.

In Dr. Noeggerath's case doubtless the extreme mobility of the cyst had a great deal to do with the resulting irritation of the peritoneum, and the development of dropsy. Such a complication of ovarian cysts is extremely rare.

This array of cases represents just about half of those that I have seen which serve to illustrate this point. It appears to me that resting for justification upon them, I may assume the position that in cases of ascites in the female, before the patient is relegated to the usual practice of repeated tapping with its universally barren results as to cure, the most thorough investigation as to the possible existence of small neoplasms as important pathological factors should be made, and if signs of their existence be obtained, explorative incision should be practised as a "forlorn hope" that relief may be obtained. That brilliant results will often occur I do not maintain. But that they will do so with a frequency sufficiently great to make it a duty to give the plan a claim to consideration, I positively assert from the experience which I here place on record.

There are but two points connected with explorative incision which I would mention before closing. The first is the singular, and to me inexplicable fact, which I think every man of large experience will substantiate, that in certain cases of abdominal incision in which diagnosis only is practicable, and others in which removal of the tubes and ovaries proves to be impossible, great improvement sometimes results to the patient's general and local condition, from the explorative effort alone.

The second point which I would mention is the necessity for certain rules which should be observed in the performance of this simple surgical procedure.

RULES FOR EXPLORATIVE INCISION OF THE ABDOMEN.

1st. Every explorative incision should be made under the strictest antiseptic precautions. As to strict cleanliness all are agreed; if antiseptics of chemical character are valueless, they at least, in all probability, do no harm; while the question as to their utility is "sub judice," give the patient "the benefit of the doubt," and employ them.

2d. Always employ an anæsthetic, lest the complaints of the patient should frustrate the investigation, or at least render it superficial and uncertain.

3d. Always make an incision which will admit the whole hand; one which will admit two fingers only is hardly warrantable. If possible, let but one man's hand be passed into the abdominal cavity; in a multitude of counsel there is, in these cases, danger. The brain which guides the hand should be competent for deciding the question at issue.

4th. Never hurry an explorative incision, but never prolong one unnecessarily; let discussion as to diagnosis occur after the peritoneum is closed, not while it is open; and let the fact be appreciated that the clinical lecture, which is so common at this moment, is always a source of great danger.

INFLUENCE OF THE RECENT EARTHQUAKE SHOCKS IN CHARLESTON UPON HEALTH.

By F. PEYRE PORCHER, M.D.,
Physician to the City Hospital, Charleston.

In addition to the natural alarm and fright—especially among women and children—caused by the recent calamity, where so many persons were suddenly brought face to face with death under the most appalling circumstances conceivable, and in every variety of situation and condition, I have gathered the following facts from personal observation and inquiry. They are interesting because rather unique in our experience in this country.

As the result of the shocks, some persons were instantly attacked with nausea accompanied by vomiting, which recurred or persisted in several cases for days.

Mrs. M. was nauseated during the first shock (Aug. 31) and had repeated attacks afterward, with vomiting and nervo-electrical disturbance. Miss M. was nauseated at the first vibration, and before she could leave her chamber. Mrs. K. was absent Aug. 31, but in all the subsequent shocks she suffered from giddiness, with a feeling as if the floor was trembling under her feet, and experienced "instead of sadness, a tendency to laughter." There was no tingling or electrical disturbance. She was nauseated but once. Mr. S. and Mr. H. had nausea, and both had colic and diarrhœa following, on the night of August 31. Mrs. G. suffers from extreme nausea after every shock. She was sound asleep after the second shock (Friday, 28th Sept.), yet woke up nauseated. I could give numerous examples of a similar character.

Mrs. M., Mrs. S., and Mrs. D., experienced for a long time a feeling, whether real or imaginary, of

tremors—as if the floor or the earth were incessantly moving under their feet. Similar sensations were felt by persons living in the country. Many of those residing on the coast declare that delicate and almost imperceptible vibrations are constantly felt. Mrs. C., living some distance from this city, experienced a sensation "as if she was suspended in mid air." One of my patients, Mrs. B., remarked, "The earthquake leaves you powerless; a flush and tingling come on before a shock—the whole body pulsating, with tears; everybody cried on account of pain in their knees and legs!" Mr. F. informs me that he would constantly anticipate the recurrence of shocks by his sensations—nervousness, tingling, etc. Two young gentlemen, on the islands eighty miles from Charleston, had their eyes suddenly filled with tears (Aug. 31), not to be repressed, but not caused by alarm, or fears for their personal safety; for the danger there was not imminent. These examples could be multiplied by the relation of others, if more extensive inquiries were made.

The commotion, attrition, and tremblings of vast masses of earth might not only squeeze out water, sand, and gases, but very naturally generate electricity on a tremendous scale which would affect those who were specially sensitive.

I have the statements of many persons, that they experienced decided electrical disturbances, which were repeated upon the successive recurrence of the shocks. These were generally tingling, pricking sensations, like "needles and pins," affecting the lower extremities. A few may be cited: Judge ——, in a town far removed from this city, immediately after the great shock, inquired of Mr. A. "How do you feel?" The reply was, "As if pricked by needles and pins!" To which he rejoined: "That is precisely my experience!" The Rev. ——, when asked as regards the effects produced upon him, stated that it was "an electrical thrill—after and with all the shocks: exactly what he had before experienced in his frequent use of the electric battery." His sister was similarly affected. Mr. S. feels the nervous sensation *before* the shocks occurring at night—never in the day.

A child of one of my patients would give immediate notice of the approach of a shock, night or day, but oftener at night, by calling aloud; being far more keenly alive to them than the adult members of the family, or than his mother, who generally kept awake. The inability to move his leg, caused by a recent sprain of the knee from which he suffered, was greatly increased after each occurrence of shocks. His leg would then remain stiff and contracted. Another, Mr. B., assures me that he could always anticipate and know of the approach of a shock by his peculiar nervous electrical sensations. Miss K. says she could feel the effects of the shocks "beginning in her big toe" and extending with a tingling sensation upward. One gentleman has been completely relieved of his rheumatism; another, who for months was nervous, depressed, and entirely unable to attend to any business, has regained his former activity and energy through the influences generated by the repeated convulsions of nature.

A gentleman on a visit to Columbia, awakening from a dream, experienced such sensations as to inquire whether a shock had not just occurred; his daughter replied affirmatively, and "that every thing was electrified!" In another individual (Dr. F. informs me) the vibrations affected his dreams, and upon awakening he would announce what had occurred. In a recent attendance upon Mrs. D., she stated that on three occasions *before* a shock occurred, she became dizzy and sick, and grasped a post or other convenient object for support.

With regard to my own experience: Whilst seated in the N. E. R. R. depot, awaiting the arrival of friends, the great earthquake disturbance occurred, when the foundations of the earth were felt to move and surge under our feet. This drove us out of the room and across the open street. I sought the protection and support of a telegraph pole on the opposite pavement in order to avoid the flying horses and vehicles, which could scarcely be seen through the sudden darkness—not wholy caused, I think, by the dust, which latter attracted the attention of every one. In this position I was not conscious of the second shock, except that I experienced suddenly, great *nervous exhaustion* about the back and loins, and a sensation almost of pain. I am convinced, upon reflection, that it was wholly electrical, and similar to that experienced by others. I was not nervous, or particularly sensitive to the danger, as I wrote letters, and slept the remainder of the night, in a four-story brick dwelling which had lost every chimney, and was otherwise rent and injured. On another occasion, whilst engaged in adjusting a bandage for a fractured clavicle in a girl, aged thirteen, a pretty severe vibration occurred; I remained ("*impavidum ferient ruinæ*"), but the patient fled!

The following appeared in the *News and Courier* of a recent date:

"The concurrent testimony of the most trustworthy experiences indicates that there is an electrical accompaniment to the earthquake, whether as cause or effect. A lady, while she was in the market, felt the same tingling nervous sensation which she experienced during the disturbance on the night of Aug. 31st; she was again seized with the same sensation, but in a more pronounced degree. The electricity appeared to permeate her whole body, which was affected just as it would have been by the continuous discharge through her system of the fluid from a galvanic battery."

I have seen in my own practice two cases of miscarriage and one of premature birth, and have heard of several others, consequent upon the earthquake—though no special inquiries have been made.

Several cases of mental disturbance, owing to anxiety and prolonged loss of rest, some of them persistent, have occurred in my own experience. One of these has not yet recovered her sanity. Exposure in tents and to the weather has been productive of much general ill consequences as was natural,—namely: Catarrhal fevers, bronchitis, and an aggravation of lung diseases generally, and of those dependent on derangements of the nervous and uterine systems. Several persons have, by reason of the successive shocks, been reduced to a highly nervous condition, where their emotion could not

be repressed. Dr. F., of Georgetown County, reports two such persons who will require to be sent to a more quiet abode. One of these occurred in an active, strong, hardworking man, who was not unnerved by the first commotion, but who had finally to succumb, with his nerves completely shattered. He confessed with pain and mortification the deplorable state to which he had been reduced. Hysterical attacks have also been developed in those previously well.

The most important premonitions of the great movement of the earth were three: 1. Almost entire absence of storm, thunder, lightning, and other electrical disturbances during the entire summer, with a very prolonged drought, which still continues. 2. A peculiar appearance of the sky and the atmosphere on the evening of August 31, observed and commented on by several persons. Very bright orange sunsets still prevail (Nov. 18). 3. Very oppressive heat and sultriness experienced by every one just before ten o'clock P.M., August 31. The smell of sulphur and gas was plainly observed after the convulsion of nature. This was also noticed by those on the incoming train of the N. E. Railroad, and was probably caused by the emanations from the extensive marshes of this region. With the exception of a little sulphur in the "green sand," that substance does not exist in the geological formation; one hundred to one thousand feet of marl underlie the superficial strata. Notwithstanding, a strong smell of sulphur is repeatedly observed before and after each shock by many residents of the coast near Georgetown, as I am credibly informd.

One lady of very delicate nostril—"*femina emunctæ naris*,"—whom I attend in Summerville, where the premonitory rumbling and terraqueous disturbances are more marked, experiences a sensation of the smell of "sulphur and rhubarb" *before* each shock.

Dr. A. A. Moore, of Camden, S. C., in his report to the State Board of Health, September 23d, speaking of the effects of the earthquake shocks, says: "They at first naturally created much consternation among our population, and have undoubtedly had a very deleterious effect upon sick and feeble persons, being followed by much nervous prostration and other unpleasant symptoms. Even upon well and robust people their effects have been striking in some instances. Some have described their sensations as being similar to those experienced after a shock from an electric battery. Others have experienced a very marked feeling of debility in their lower extremities; others have had vertigo, nausea, etc. Some, again, who were not affected by these unpleasant symptoms in the beginning, are now troubled by them."

Dr. H. M. Stuart, of Beaufort, also reports that "It was a curious fact to note the number of persons, both male and female, particularly females, who were nauseated by the shock of the earthquake. This, I suppose, is attributable to fear, but these persons, although acknowledging themselves frightened at first, disclaimed any fear during the subsequent shocks, and continued to suffer from nausea. In a few other cases the effect of the nervous shock from the above cause was of a much more serious nature. In one case—that of a young lady—it caused hysterical convulsions."

It is several years since I read the *Kosmos*, but, if I remember rightly, Humboldt remarks therein on the "headache" and other morbid sensations which were experienced during the prevalence of earthquakes.

Domestic animals seemed to be exceedingly sensitive. Dogs howled, poultry were unusually noisy, and horses greatly alarmed. I give one instance which occurred to-day (December 2d). A very intelligent dog belonging to Mr. W., walked into the breakfast room about 8 A.M., got up from the fireplace, before which he had stretched himself, went into a corner of the room, and remained there trembling and shivering. His master remarking that the animal was mad, his little son, who had a similar experience previously, replied, "No; it is an earthquake." The true explanation was in a few moments realized in a well-developed trembling.

The same dog in awakening his master, who was asleep in a hammock during the disturbance of August 31st, nearly tore off his clothes, so great was his excitement.

ANTIPYRINE AND ARSENIC IN THE TREATMENT OF MALARIAL FEVERS.

By DAVID B. FRONTIS, M.D.,
of Wadesboro, N. C.

The physicians who practise in malarious districts, not rarely meet with a class of patients suffering from malarial fever in some of its forms, who from idiosyncrasy or from some complication of the case cannot take quinine or any derivative of cinchona bark.

Within the past four months I have met with cases manifesting this peculiarity in intermittent, remittent, and a more indistinct type, generally classed here as simple malarial fever. Having during the past twelve months used the new antipyretic—antipyrine—with most gratifying results in phthisis, I determined to try it in this class of malarial troubles, using it to control the pyrexia, and putting the patient on full doses of arsenic to counteract the malaria.

Numerous notes on the value of antipyrine in various febrile affections have appeared in current medical literature during the past year. The fullest record of clinical experience with the drug, that the writer has seen, is Dr. Reilen's article in the *Deutsches Archiv für klin. Medicin.* This is a report of the use of antipyrine in the Nuremburg City Hospital, on eighty-nine patients suffering from eighteen diseases. There is only one case of intermittent fever in the list, and no special remarks on this. Nothing seems to have been written on its use in malarial fevers, perhaps, because we have in quinine a remedy as specific as we can ever hope to have, and also because it was soon found that antipyrine probably possesses no curative value in any disease, but is simply a very potent antipyretic.

When debarred from the use of quinine, the phy-

sician has a long list of remedies which are more or less useful, arsenic, calomel, chloroform, capsicum, ipecac, rhubarb, etc. Arsenic, however, stands at the head. While Bartholow, Wood, and Stillé, in their respective works, all speak of the use of arsenic in malarial affections, Brunton, in his recent work on *Therapeutics, Materia Medica, and Pharmacy*, gives it the highest testimonial:

"Arsenic is a powerful antipyretic, nearly rivalling quinine; it seems less serviceable than quinine in well-marked cases of ague, but it is sometimes as good or even better than it in the irregular malarious manifestations." (Page 609, *op. cit.*)

This more nearly accords with the general estimate placed upon it by Southern physicians. Another testimonial from high authority which seems to cover the class of cases that I am speaking of, is from Dr. Solis Cohen (*Maryland Medical Journal*, Feb. 6, 1886.), who in considering some of the forms of malarial manifestations and their treatment, maintains that "when the most prominent symptoms are connected with the nervous system . . . arsenic is indicated."

I shall here relate the clinical history of a few cases in which I combined these two remedies, antipyrine and arsenic, omitting, however, minor symptoms and complications, and the measures used to meet them.

Case I. *Intermittent Fever, Quotidian Type.*—Adult, male, had chill at 8 A.M., July 10, second paroxysm followed by moderately high fever. Saw patient at 12 M., temperature 101.5° F.; fever had already begun to decline. This patient, quite an intelligent man, refused to take quinine or any derivative of cinchona, because it produced an eruption, which he described as "terrific" and far worse than ague. More to test its effect than because he needed it, I gave fifteen grains of antipyrine and directed that he take five drops of Fowler's solution every three hours for the next four days, and if the paroxysms were arrested then to continue it *t. i. d.* for several days longer, cautioning the patient to omit it for twenty-four hours if there should develop much swelling of the eyelids. Also left a fifteen grain dose of antipyrine to be given next day if there should be much fever. Patient reported a few days later that the antipyrine acted promptly in reducing fever. There was a slight chill next day, with a rise of fever, which was promptly checked by the antipyrine. After this no more symptoms of the ague. No unpleasant effects from the arsenic.

Case II. *Remittent Fever.*—Adult, female, seen August 14th, temperature 102.4° F. Previous history of a remitting fever of three or four days duration. She had been taking from four to six grains of quinine per day. She objected strongly to taking quinine in increased doses, from the cerebral excitement which it produced, or, as she expressed it, "it made her crazy." I prescribed, however, twenty-five grains in divided doses in twenty-four hours. Next day I was hastily summoned, and found her madly delirious, with a temperature only 101.5° Morphine to quiet delirium, ten grains of antipyrine to reduce temperature, one dose per day, and five drops of Fowler's solution, every four hours, from 6 A.M. to 10 P.M. Fever disappeared in four days, but convalescence was not complete for two weeks.

Case III. *Remittent Fever, Bilious Type.*—Adult, female, seen August 20th. This patient had fever for three days with a morning temperature of from 102° to 102.5°; evening from 103° to 104.8°. Took thirty grains of quinine a day. At 4 P.M., evening of third day, temperature 104.8°. Had given forty grains of quinine this day with not the slightest decline in fever. Conjunctiva injected, some delirium. Gave fifteen grains of antipyrine, at 5 P.M. temperature 103,° gave fifteen grains more of antipyrine. Shortly after this profuse diaphoresis was set up, and at 6 P.M. temperature was 98.5°. Stomach had been very irritable for three days, but patient now took some nourishment and passed a quiet night. Gave no more quinine or antipyrine, as there was no return of fever. Patient was up in her room in a few days, but in just one week there was a relapse. I then gave from fifteen to twenty grains of quinine every forenoon, and one dose of fifteen grains of antipyrine every afternoon. Temperature varied from 100° to 101.5° A.M. to 102° to 103° P.M. Antipyrine invariably caused a reduction of from two to three degrees, and there would not be a subsequent rise until the next morning. This attack lasted one week, and as the patient could not be induced to take quinine when there was no fever, was followed by another relapse. The same treatment was followed as in the last attack with the addition of five drops of Fowler's solution *t. i. d.* This was kept up until convalescence was complete.

Case IV. *Malarial Fever.*—Adult, female, temperature varied from 100° to 103°, with irregular exacerbations. Seen first July 19th. Twenty-five grains of quinine were given per diem for one week, until temperature did not exceed 100° at any time during the day. There was great nervous excitement. Patient had not slept for several days and nights, with the exception of short naps induced by one-eighth of a grain doses of morphia. The bromides and chloral had no effect whatever. I then gave five drops of Fowler's solution every four hours, and directed that fifteen grains of antipyrine be given whenever the temperature went to 101°. Nervous symptoms abated, appetite improved, and there was some return of strength. Temperature did not decline further, but on the fourth day of this treatment began to rise, and on the evening of the sixth went up to 102.5°. Went back to quinine, giving thirty grains from 6 A.M. to 12 M., and from ten to twenty grains of antipyrine every afternoon. Fever showed no disposition to yield at all, and quinine was gradually increased until sixty grains per diem were reached. Patient complained of very little deafness until this dose was reached. This was the eighteenth day of the treatment, and the twenty-first of her sickness. This dose was given for two days, with the effect of bringing the highest temperature marking down to 101.5°. Antipyrine was discontinued on the sixteenth day. It always produced a profuse perspiration, and seemed to depress the heart so much that I was afraid to use it any longer. After exhibiting sixty grains of quinine for two

days. the dose was reduced five grains a day until twenty-five grains were reached. After the middle of the fourth week temperature never went above 100°, but did not remain at the normal until the end of the sixth week. When quinine was resumed in this case, it did not produce the nervous excitement that it caused at first, even when one drachm daily was given.

In Case I. it might be objected that it was quite a mild attack, and the arsenic would have done just as well without the antipyrine. Probably it would, but if ever I have to treat a severe attack of intermittent in this patient, I shall have great confidence that I can keep his temperature under control with antipyrine until the arsenic shall have eradicated the malaria.

In Case III. the action of the antipyrine, in bringing the temperature to normal so promptly, was wonderful. Can we explain it by supposing that the quinine administered had already destroyed the malarial poison, but that the heat centre in the medulla remained so perturbed that the temperature did not decline until there was direct action upon this centre by the antipyrine? This may have been a coincidence, but the result was certainly most gratifying. I was strongly impressed that this case was about to assume a pernicious character, from the condition of the conjunctivæ and the delirium.

Case IV. is reported because in this instance the combined action of antipyrine and arsenic was not gratifying. The nervous symptoms quickly disappeared, although the fever did not subside, but rose again in a very intense form. Hence, it is important to recognize that this is not a specific treatment. But from these cases and a number of others in which I have used antipyrine and arsenic—when quinine either could not be used at all, or when it was best to suspend its use for a few days—I am convinced that the combined use of these two drugs meets a want that has long been felt by those who have much malaria to treat.

I have never seen any rash caused by antipyrine. Occasionally its administration is followed by nausea. I usually exhibit it in solution in ice-cold water. Given in this way the bitter taste is very transient. If ice water is not convenient it is best to give the drug in capsules.

It should not be forgotten that apart from the causes that may induce it, fever may be a source of great danger in and of itself. This is especially true of the hyperpyrexia of malarial fevers. The physician who has ever seen an ordinary case of intermittent or remittent suddenly take on the pernicious type, has a wholesome dread of this catastrophe. It is to be hoped that some one will soon try the virtue of antipyrine in a pernicious case, and report the result.

In children the effects of antipyrine in reducing malarial pyrexia are even more happy than in adults. Restlessness and tendency to convulsions caused by the fever are quickly replaced by quiet repose and slumber. So striking is the change that the physician is liable to be misled and think it permanent, but as soon as the effects of the antipyrine wear off, unless the cause has been removed the same threatening symptoms reappear.

Inasmuch as we do not yet know definitely what malaria is, it is impossible to explain the action of these remedies in the treatment. Fothergill says of arsenic, "it is a powerful alterative; it procures more perfect elimination of waste, and so more perfect nutrition of the body." (*Handbook of Treatment*, page 76.) This is about as definite an explanation as has been attempted.

It is possible that antipyrine, in addition to its well-known apyretic effects, has an action in malarial pyrexia that is especially indicated. Dr. Beyer (*American Journal of the Medical Sciences*, April, 1886, page 397), quoting Bettelheim, says "that the reduction in temperature, following the administration of antipyrine, is due to its causing a dilatation of the peripheral vessels and a contraction of the vessels of the viscera." In malarial fevers the congestion of the viscera is an important factor to be considered.

"No intelligent practitioner can watch a patient during the cold stage of a malarial paroxysm without realizing how important the attendant congestion is as a pathological state. . . . . The blood driven from the surface and extremities must be accounted for elsewhere, and the amount of blood which is lost from one part of the circulatory tree, must correspond with that accumulated elsewhere." (*Pepper's System of Medicine*, vol. i. page 605.)

This is preëminently the condition in the cold stage of intermittents, but exists, although in a less degree, in the continuous fever of remittents, as evidenced by the usual symptoms of portal congestion, congestion of the kidneys, or enlargement of spleen. Hence antipyrine fulfils an important indication outside of its specific influence on temperature. Dr. Beyer (*op. cit.*) sums up his own conclusions on the physiological influence of antipyrine in this sentence: Antipyrine, though largely dilating the veins, increases the power of contraction of both auricles and ventricles, and has no injurious influence upon the blood nor the muscular tissues, and, therefore, possesses all the good qualities of a perfect antipyretic.

Unfortunately my own clinical observations do not bear out this high testimonial of Dr. Beyer, that it increases cardiac impulse. There is generally some reduction in the frequency of the pulse corresponding to the reduction in temperature, but the former is by no means always proportionate. When the profuse perspirations caused by antipyrine come on in a case where vitality is already depressed, there may be alarming weakness of the heart. A case in point can be found reported by Dr. W. M. Welch, in The Medical News, January 2, 1886. While I think these cases will be found the exception in treating malarial fevers, they must not be forgotten.

HOSPITAL NOTES.

The Treatment of Rheumatism in the New York Hospitals.

new york hospital.

Dr. George L. Peabody treats his cases of acute rheumatism with a combination of salicylic acid and

iron, the formula for which was obtained in the following way:

About a year ago a nurse was pouring into a common receptacle some remnants of different medicines, when she noticed that a black precipitate formed by iron was turned into a transparent solution of a rich red hue as soon as she poured in the fluid contents of another bottle. Being a young woman of an inquiring turn of mind, she asked the house-physician the cause of this phenomenon. The house-staff, to help her in her desire for information, experimented with the drugs that she had been throwing out, and ascertained that her manipulation of chemicals had been this: She had first poured into the receptacle a solution containing salicylic acid. Into this she had poured a solution of iron, with the result of producing a black precipitate. To this she had added some sodium phosphate, with the result of producing a clear red solution.

This at once gave a clew to the means of combining iron and salicylic acid without forming a precipitate. The facts were submitted to the apothecary of the hospital, and from them he produced the following formula, which has been in constant use for nearly a year:

R.—Acidi salicylici	gr. xx.
Ferri pyrophosphatis . . .	gr. v.
Sodii phosphatis	gr. l.
Aquæ	℥ss.

This method of giving this drug in rheumatism has now been fairly tested. It may be said to agree as well with the stomach as any other, and it has the great advantage of not being followed, even if its use be long continued, by the severe anæmia that so often follows the use of salicylic acid, if it be given without iron.

The dose which is described in this formula is given every two hours until improvement justifies a diminution in the frequency, or until constitutional effects are pronounced.

Dr. Peabody has tried antipyrin in several cases of subacute rheumatism without satisfactory results; but has had too little experience with it thus far in acute rheumatism, for the cure of which it has such high celebrity in Germany, to speak from personal knowledge in regard to it.

There is nothing, beyond these trifling details, at all peculiar or out of the common way in the treatment of acute rheumatism at the New York Hospital.

BELLEVUE HOSPITAL.

Dr. A. L. Loomis recognizes in the treatment of acute articular rheumatism two classes of patients, the anæmic and the non-anæmic or robust. This distinction is made with great care, and, in cases of doubt, patients are usually treated as belonging to the first class.

The treatment employed with the robust patients is as follows: Salicylate of sodium in thirty-grain doses is given every two or three hours, according to the severity of the symptoms, until its effects are marked by decided ringing in the ears. The intervals between the doses are then increased to four or six hours, and its use is continued until the acute symptoms have subsided, and the articular inflammation is quiescent. When the salicylate is decreased, the administration of the sodium bicarbonate is begun, in doses of twenty to thirty grains every four hours. It is rapidly pressed until the urine gives a decided alkaline reaction with litmus paper. Every passage of urine is tested, and the soda is used throughout the acute course of the disease in quantities sufficient to maintain its alkalinity. In the earlier stages, and later if necessary, the pain is controlled by hypodermatics of morphia, and the bowels are kept freely moving by the use of Rochelle salts. The affected joints are wrapped in cotton sufficient to maintain a uniform temperature. The body is clothed in flannel, and great care is exercised to avoid exposure—examinations of the heart being avoided so far as possible. As soon as the temperature reaches normal, or nearly so, the patient is put upon iron and cod-liver oil. If fever runs very high it is controlled by aconite.

In the anæmic cases the salicylate is not given at all. The use of the alkalies is begun at once, and the amount graduated by the same test of the urine. Tincture of aconite in the liquor ammoniæ acetatis is used both to control the fever and as an anti-rheumatic, but its use is discontinued when the acute symptoms have subsided. In these cases cod-liver oil and iron are given in large doses from the very first, and continued for some time after recovery seems complete. Tr. opii deodorata is used for pain in these weaker cases, and the joints are protected as before; even more care is given to protecting the patient and avoiding exposure.

In all cases patients are put upon a milk diet throughout the entire course of the disease.

Oleum gaultheriæ has been used in a few cases, with marked success in some. It often relieves the distressing symptoms with surprising rapidity, but it is uncertain in its results, and its use has been attended at times with severe delirium and alarming symptoms of poisoning. It is seldom employed now.

Although salycilic acid is used in robust cases, its effects are believed to be such as favor cardiac complications.

ST. LUKE'S HOSPITAL.

During the past six years several methods of treatment of acute articular rheumatism have been carried out under Dr. Kinnicutt's personal observation in the wards of St. Luke's Hospital, and the effects carefully observed. Dr. Dechilly's and Dr. Herbert Davies's methods of encircling the limbs just above the affected joints with blisters have afforded more or less relief of the articular pain, much less prompt, however, than that obtained by the use of the salicyl compounds; the duration of the disease, and the implication of the peri- and endocardium, have not been apparently affected. Dr. Harkin's suggestion of applying large blisters over the præcordial region alone, has given wholly negative results, and the substitution of other treatment has invariably been rendered necessary.

In the winter of 1882, Dr. Kinnicutt introduced the treatment of acute articular rheumatism by the oil of wintergreen, a methyl ether of salicylic acid. The mode of administration consisted in giving the oil in fifteen or twenty minim doses in sealed capsules, or floated on water or milk, at intervals of two hours, to the extent of two and a half to three drachms in the twenty-four hours. The initial dosage was maintained during the first week of the disease, and then, in the absence of arthritic pains and fever, gradually diminished until the daily amount was reduced to one drachm, which was

continued throughout convalescence. With the establishment of convalescence, some one of the various preparations of iron invariably was combined with the above treatment, and during this period exposure, exercise, and dietetic errors were carefully guarded against. For the joint stiffness, which frequently persists after the disappearance of pain, the salicylate of lithium, to the amount of forty to sixty grains daily, in divided doses, was not infrequently found to give greater relief than was attainable by a continuance of the oil of wintergreen. The results obtained by this method of treatment were sufficiently favorable to warrant its continued use since that date. The average stay in the hospital, in a number of cases thus treated during the winter and spring of 1882, was twenty-four and one-third days, which average has since been closely maintained.

On account of the rapid elimination of the various salicyl compounds, their effects are of comparatively limited duration. The maximum benefit obtainable from their use in acute rheumatism will therefore be found, he is convinced, in conforming the doses to the rate of elimination, in so far as is possible.

The only other method of treatment which has been used in Dr. Kinnicutt's wards is the combination of alkalies with a salicyl compound. The rule has been to give indifferently the oil of wintergreen, salicylic acid, or its sodium salt, in one-half the customary daily amount, combined with four drachms of the sodium bicarbonate, or the potassium citrate in the twenty-four hours. Their use has been continued, in diminished doses, throughout convalescence. The mixed treatment has been found equally efficient with that of the salicyl compounds alone, in controlling the arthritic symptoms and the fever. Believing that the use of the salicyl compounds, when begun at the onset of acute articular rheumatism, affords a limited protection to the heart, a larger number of cases than are yet at his disposal are necessary to permit an expression of opinion in regard to a greater efficiency of the *mixed* treatment in averting cardiac complications.

Dr. Beverley Robinson treats the cases of rheumatism which come into his hands as follows: If the bowels are not freely open, the patient is first given a mild mercurial purge, such as calomel gr. x, with sod. bicarb. gr. x. After this has operated, if the disease is acute, ol. gaultheriæ gtt. xv, q. 2 h., ten doses daily, is prescribed; the diet is usually restricted to milk and farinaceous food. If necessary, a small dose of morphine is given to relieve the pain.

If the patient has been suffering for some weeks before coming under observation, and the disease has become subacute, sodii salicylat. gr. xx, s. q. 6 h., is prescribed; and if anæmia also exist, iron is given. In these cases the diet is usually not restricted.

In chronic cases, especially those in which only one joint is affected, and the disease is not of gonorrhœal origin, the salicylate of lithium, in doses of gr. x–xv, repeated three times daily, together with tonics, and a nourishing diet, seems to give the best results. Many chronic cases are also benefited by fixing the joint for several weeks by means of plaster bandages, and after these have been removed, by daily applications of faradism to the joint. In all cases where there has been much thickening of the parts in and about the joint, repeated blisters have been found of great service.

In the cases of gonorrhœal rheumatism which have been under his observation, quinine and potassium iodide, with tonics, have yielded good results. The local treatment of the affected parts was the same as described above—*i. e.*, fixation and, later, faradization.

Ingenious Method of Extracting a Cockle-Bur from the Larynx.

Dr. D. B. Crawley, of King, Mississippi, writes us that recently a negro boy, aged nine, was brought to him with a cockle-bur lodged in his larynx. His voice was almost gone, and respiration was much interfered with. With his finger introduced well down the throat, Dr. Crawley could feel the bur. Having no instruments at hand, he wrapped some cotton around the end of his right index finger, which he then passed down to the bur, and by a rotary motion he sought to entangle in the cotton the prickles of the bur, and thus withdraw it. After several attempts he succeeded in extracting the bur by this ingenious method.

MEDICAL PROGRESS.

Therapeutic Uses of the Hot Bath.—Dr. W. J. Notley writes as follows in the *Lancet* of Nov. 13, 1886:

Some time ago an opportunity was afforded me of making some observations on the effect of the hot bath in removing some morbid conditions of the system. A man of middle life, in temperament nervous-sanguine, spare, and somewhat below the average height and weight, complained of languor, debility, want of energy, and lowness of spirits. On examination it was found that his heart and arteries were sound, though his circulation was rather weak. His alimentary system was fairly good, though the quantity of food taken was below the average. His skin was somewhat dry, and a few spots of psoriasis were found on the extensor aspects of the legs, arms, and trunk. His urine was clouded with phosphates, and below the average in quantity. As the Turkish bath was not in this case available, he was advised to take a water bath at a temperature of 105° F., and directions were given him how to proceed in case of faintness. The day after taking the bath, his condition was wonderfully improved. His circulation was stronger, his urine was clear, and he now felt cheerful and well. This improved state of matters continued for about twelve days, when all the unpleasant symptoms reappeared, and he began to feel as ill and dejected as ever. The most natural proceeding was, of course, to order him another bath, and this he took with the same happy result as before. Since that time he has had the hot bath about once a fortnight, and by this means has managed to keep himself in very tolerable health and spirits.

It would be interesting to know the exact means by which the hot bath produces this powerful and beneficial effect on the system. It must, in the first place, be carefully borne in mind that the warm bath at a temperature below 100° F. has no influence that can be compared with the results to be obtained from the hot bath. The hot bath stimulates the whole system, and the effect of this stimulation appears to last for some

time, for the patient above referred to remained well for about a fortnight after taking the bath. Having ascertained that his diet was as nearly uniform as possible, the quantity of urea excreted on three successive days immediately before and after the bath was estimated by Russell and West's method, with the following result:

Average quantity of urine in 24 hours for 3 days *before* the bath	916.67 c.c.
Average weight of urea in 24 hours for 3 days *before* the bath	22.8 grms.
Average quantity of urine in 24 hours for 3 days *after* the bath	1040 c.c.
Average weight of urea in 24 hours for 3 days *after* the bath	26.25 grms.

From this it appears that the quantity of urine and the weight of urea excreted were below what are usually stated to be the averages for a healthy man, but that both were very perceptibly increased by the hot bath. If we may assume that the other secretions and excretions were proportionately increased, then we have clear evidence as to the proximate cause of the improvement brought about in the general condition of the body.

As in most other remedies, so in the case of the hot bath, the time and manner of application are of some importance. Like all other baths, the hot bath should be taken before the principal meal of the day, and if this meal be taken early, the good results will be more certain than if it be taken late. The duration of the bath should be about fifteen minutes, and the temperature should be about 105° F. If faintness should come on while in the bath, the whole head should be immersed in the hot water, and kept there for a few seconds, when the faintness will disappear. The usual directions given in public baths are to get out of the bath as soon as drowsiness or faintness begins, and to ring for the attendant; but anyone who attempts to do this will most certainly aggravate his danger. As pointed out some time ago by Mr. Benham, and subsequently by myself, the application of heat to the head is a most potent means of averting syncope. From time to time we hear of deaths in the warm bath; and I am convinced that many of these might have been prevented by the adoption of the simple method referred to, instead of the deadly and often impossible means commonly recommended.

Chromatic Asymmetry of the Iris a Symptom of Neurosis.—Ch. Féré classifies eyes as brown, blue, green, and gray; in the first can be distinguished red, orange, and yellow; in the second blue and indigo: in the third no pure color, but portions which appear bluish; the fourth are not a mixture of black and white, but often blue, violet, and green, the gray eye is that in which the color is undecided.

Varieties of color are due to varied refraction of light caused by different dispositions of the anatomical elements of the retina, and not by a particular pigment.

Varieties of tone are very numerous; they are three in each color, dark, intermediate, and light. They are probably dependent upon refraction, some have thought them caused by the varying thickness of iris pigment.

The iris presents three concentric zones for observation—external, middle, internal; of which the middle is generally light, the inner dark; the degree of dilatation of the pupil affects the color of the iris; it follows that eyes should be observed equally well dilated and from the same distance.

In addition to changes in eye colors caused by light, age, and race, there are differences which are symptoms of pathological conditions. The examination of 600 subjects, healthy, insane, idiotic, epileptic, and hysterical, showed that those diseased possessed a larger proportion of light eyes than the healthy; this was especially evident with the hysterical.

Asymmetry of color, when not dependent on morbid local conditions, is very rare; in over 600 subjects only seven were found in which such asymmetry was present, and these patients were imbecile, hysterical, or epileptic.

Asymmetry of tone is not rare, especially among the neurotic; in 75 cases in 100 of facial hemiatrophy or hemiparesis, with or without epilepsy, the iris of the side affected was darker in tone than the other.

In epileptics 26.7 per cent. had this symptom, 62 out of 76 hysterical patients; in choreic patients, those with obstinate facial neuralgia and with sciatica, chromatic asymmetry was observed.

Chromatic asymmetry the author considers a valuable symptom in neurosis tending to become unilateral; with deviation of the pupil it points to congenital lesion.

Chromatic asymmetry, when present with unequal pupils, may aid in diagnosticating hysteria and asymmetric degenerations from locomotor ataxia and general paralysis.

When observed in the children of the hysterical it is a sign of neurotic tendencies, calling for prophylactic treatment.—*Le Progrès Médicale*, September 25, 1886.

Styptic paper, much used abroad, though but little known here, is a new modification of medicated organic matter. It is made by mixing with the paper pulp (during the process of manufacture of this material) some solution of ferric chloride, and carefully drying the product, or, in place of the iron solution, another variety is made with tannic acid. The proportions needed are about one part of iron solution to an equivalent of pulp that will yield four parts of dry product, or, if tannic acid be used, one part of the acid to make eight parts of finished product. When made on the small scale, white absorbent (or blotting) paper may be used and made into a pulp, to which the astringents are added, and then carefully dried. It forms an excellent means of stopping bleeding by simply binding on a small quantity of the prepared paper.—*Pharmaceutical Record.*

Citrate of Iron Hypodermatically.—In anæmia occurring during pregnancy, caused by metrorrhagia, and from other causes, Chiara found that ten centigrammes of ferric citrate in one gramme of water might, with advantage, be injected deeply, twice daily, in the gluteal region in cases where the stomach had refused to tolerate iron.

Microscopic examination of the blood showed the red corpuscles greatly increased, and rapid cures followed. —*L'Abeille Médicale*, October 11, 1886.

Horseflesh and other Meats as Public Food.—Experiments made by Decroix have shown that horseflesh is a wholesome and available food; that in time

of need the flesh of animals perishing from non-infectious causes may be safely eaten; that, of course, infectious disease makes flesh unfit for food, while the author thinks medicaments have no bad influence. The author thinks that a single meal of the flesh of animals which died of glanders or rabies (as would happen accidentally) would be without injury; the efficient means of destroying most poison is thorough cooking. The author's conclusions are based on the observation of the extensive use of horseflesh in France, and on thorough experiments with diseased meats on the human subject. —*Fortschritte der Medicin*, November 1, 1886.

Hebra's Lotion for Eczema.—

Phenic acid	4 parts.
Glycerine	15 "
Sulphuric ether	15 "
Alcohol	90 "

A mixture to be applied to dry and scaly eczema occurring in plaques, and which gives good results in obstinate cases. Tincture of iodine, applied with a brush, often gives equally good results.—*L'Union Médicale*, November 6, 1886.

Syphilitic Albuminuria.—Horteloup, in an extended article, reaches the following conclusions:

1. Syphilis, in the first months of its appearance, can occasion albuminuria, which is easily curable by antisyphilitic treatment, and leaves no trace.

2. This albuminuria must be distinguished from that which occurs in the second and third years of syphilis, whose prognosis is very grave, for it may be considered the point of departure for chronic nephritis, generally recognized long afterward.

3. A person having syphilis, from the depression the disease always produces, becomes more susceptible to cold, and more predisposed to nephritis resulting from cold.—*Annales de Dermatologie et de Syphiligraphie*, October 25, 1886.

Intrapulmonary Injections.—At the meeting of the Manchester Medical Society on Nov. 3, 1886, Dr. A. Ransome gave the details of one case of gangrene of the lung, and four of phthisis, in which iodoform dissolved in ether, in olive oil, or in oil o eucalyptus, had been employed, the latter vehicle being preferred. The case of gangrene of the lungs was restored to health, the treatment having been very thoroughly carried out. In the phthisical cases, only from two to eight injections had been used in each case, and temporary benefit was obtained in two of them. In one of he others, symptoms of iodoform poisoning had followed an injection, and, in the remaining case, temporary pneumothorax was produced. Hemorrhage from the lung followed one of the injections, in the case of gangrene, but without any bad results.

Tests for Sugar.—Penzoldt describes the two following reactions which are applicable to cane-sugar, to glucose, milk sugar, levulose, maltose, carbohydrates, and to glucosides which yield glucose when treated by sulphuric acid. These tests are applicable neither to inosite, mannite, or quercite.

Treat one-half to two cubic centimetres of the suspected liquid with two drops of an alcoholic solution 15 to 20 to 100 parts alpha naphthol and shake the mixture. A slight cloudiness will result owing to the precipitation of a small quantity of naphthol; add double the volume of sulphuric acid and shake well. If sugar be present an intense violet color appears; on adding water a violet-bluish precipitate appears; this precipitate, soluble in alcohol and ether, colors these solvents yellow, caustic potash dissolves the yellow color.

This test must be made exactly as described; it shows a very minute trace of sugar, and the reaction never results except with sugar, vanilline, anethol, salicylate of methyl, and some other similar products. Substances other than sugar are colored by sulphuric acid alone, while the violet precipitate which results from the dilution of the liquid with water differs entirely from that which results in liquids containing sugar.

If the alpha naphthol in the preceding test be replaced by a solution of thymol of similar strength, the performance of the test remaining the same, a dark red color becoming crimson and carmine results.

The dilution of the liquid gives a carmine tint, a flocculent precipitate is deposited after a little which colors alcohol, ether, and caustic potash a pale yellow as it dissolves, and with ammonia gives a clear yellow. This test is as delicate as that with naphthol.

The urine of healthy persons diluted from 100 to 200 times reacts with this test, but not in greater dilution.

Urea, creatine xanthine, uric acid, allantoin, hippuric acid, succinic acid, phenol, pyrocatechine, and indican do not respond to these tests.—*Annales des Maladies des Organes Génito-Urinaires*, October, 1886.

A Novel Treatment of Phthisis.—Dr. Bergeon, of Lyons, recommends a method of treating phthisis which has, at any rate, the merit of novelty. His plan is to utilize the effects of sulphuretted hydrogen, and this he proposes to do by injecting carbonic acid gas, saturated with sulphuretted hydrogen, into the intestines. If care be taken to secure the absence of atmospheric air, no inconvenience, it is said, results from the injection even of large quantities of the mixture; absorption into the venous system and elimination by the lungs taking place very rapidly. It is claimed for this procedure that, by its means, the use of sulphuretted hydrogen is unattended with any toxic effects, and exerts its influence directly on the lungs themselves. It has been employed in a number of cases at the hospitals of Lyons, Bordeaux, and Paris with great benefit to the patients, even in very advanced cases, and, latterly, similar observations have been made in the consumption hospitals of London, the results of which have not yet been made known. The method has been very much simplified by the introduction of an ingenious but simple apparatus whereby the carbonic acid gas is generated, and saturated with sulphuretted hydrogen, ready for use.—*Brit. Med. Journ.*, November 27, 1886.

Mollin is the name of a potassium soap described by Kirsten, containing a large proportion of fat and glycerine. It is very bland, and takes its name from sapo mollis. Combined with equal parts of ung. hydrargyrum, it is easily and quickly used for inunction. In combination with styrax it is useful in scabies, and is useful as a vehicle for many drugs.—*Centralblatt für die gesammte Therapie*, November, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, DECEMBER 11, 1886.

THE TREATMENT OF PNEUMONIA.

In this country pneumonia is unquestionably the most serious and the most fatal of the acute diseases. In mortality tables it follows consumption, and causes a larger number of deaths than any one of the eruptive fevers. The statistics of the disease have been elaborately studied, and as Dickson observes, the most remarkable fact they show is "the wonderful equality of proportional mortality—in peace and all comfort; in hospitals of wealthy communities; in the field of destructive war, and in hospitals and barracks, the emphatic seats of destitution, privation, exposure, and neglect." The rate of mortality in the large general hospitals of this country is rarely below—more often above—twenty-five per cent., which represents about the average death-rate from this disease in the Northern and Southern armies during the civil war. In this country extensive statistics of pneumonia in private practice are not available; but in the recent returns of the Collective Investigation Committee of the British Medical Association the mortality was eighteen per cent. We have referred to these figures as indicating the terribly destructive character of this disease, and they may serve to correct an impression which still seems to prevail in some quarters that it is not a very fatal malady.

The treatment of pneumonia has always been influenced by the prevalent notions regarding its pathology, and we are now in an interesting period of transition. So long as the disease was regarded as a local inflammation, antiphlogistic measures were in vogue, of which bleeding and antimony were the most important. The courageous experiments of Skoda and Deitl, in Vienna, and of Bennett, in Edinburgh, taught us the natural history of the disease, and laid the foundation of an expectant, or, better, a rational method of treatment which does not profess to control the course of the malady, but meets indications as they arise and combats the tendencies to death. Of late, the opinion has gained ground that pneumonia is an acute specific fever dependent upon a microörganism, and various antiseptic plans of treatment have been suggested.

We propose to call attention to one or two practical points about which there is a wide difference of opinion among practitioners in this country. There is a tendency at present to revive venesection, and it is important to understand clearly the indications for its practice. Unquestionably prompt and free bleeding is called for in threatened death from asphyxia when the right heart is distended, cyanosis marked, and the pulse becoming small and rapid. The timely abstraction of sixteen to twenty ounces of blood will sometimes save life, though we must confess to some disappointment in the results, for, of five such cases observed, only one recovered. The practice of free bleeding at the onset, which is still employed by some practitioners, is not to be commended, except in rare cases.

In spite of the fact that the leading text-books on practice in this country, and many of the prominent teachers discourage the use of arterial sedatives in pneumonia, they are still most extensively employed. It is true that tartar emetic has lost favor, but aconite and veratrum viride are still favorite remedies, and there are practitioners who claim wonderful results from their use. We have never been able to satisfy ourselves that they have the slightest influence upon the duration of the disease, and, on the other hand, they tend to depress the heart, and may thus be directly injurious if continued for many days. The calomel treatment has been revived of late, but the careful reports from Botkin's clinic, in St. Petersburg, do not indicate that it has any value in controlling the severity of the disease.

Opium in the form of Dover's powder is a most valuable remedy in the early stage of the disease, and was much used in Edinburgh some years ago. It is contra-indicated if there is any tendency to accumulation in the bronchial tubes, but in the painful onset it is often of signal service in allaying the pain and restlessness. We doubt if it has had a sufficient trial in the hands of practitioners.

While many cases of pneumonia do well if carefully nursed and fed, there arise in others two indications demanding the most judicious treatment, viz., high fever and heart failure. So long as the temperature does not rise above 103°, the use of antipyretics is not necessary; but, with a temperature above this, quinine should be given in from twenty to twenty-five grain doses. Antipyrin is not so suit-

able, as it is decidedly more depressing than the quinine, and the same objection holds with thallin and kairin. Repeated cold sponging is a useful adjunct, and in the combination of high temperature with delirium and great restlessness the cold pack is indicated. In the heart failure of which so many pneumonic patients die there is as yet no substitute for alcohol, which, as in typhoid fever, is well borne. Camphor, as a cardiac stimulant, has valuable uses.

The antiseptic treatment of the acute specific fevers is not in a satisfactory state, and has not yet got beyond the tentative stage. Benzoate of soda, phenic acid, iodine, and salicylate of soda, have all been recommended. We have already referred (The Medical News, January 9, 1886) to the good results obtained by Lepine, who injects antiseptic solutions into the hepatized lung. He has again brought the subject to the attention of the profession, and recommends as an injecting solution a mixture of corrosive sublimate, 1 : 5000–50,000 ; salicylic acid and carbolic acid, 1 : 1000 ; hydrobromate of quinine and chloroform, 1 : 2000 ; and bromine, 1 : 10,000. The data are not yet available for a judgment upon this method.

A study of the history of the treatment of pneumonia makes one almost despair of the future of therapeutics, so impossible does it seem to arrive at reliable conclusions regarding the use of medicines. And yet our feelings of despair vanish when we compare the figures of to-day, bad as they appear, with those of the first quarter of this century ; for we then see that there has been in the treatment of pneumonia, as in that of fevers, a steady, progressive enlightenment. The heavy mortality is due largely to the fact that pneumonia attacks with special avidity the aged, the weak, and the dissipated. A study of a large number of autopsies in this disease will show a considerable percentage of persons with serious visceral lesions, particularly of the kidneys, and these circumstances we must take into account in estimating the value of treatment. This disease in drunkards swells enormously the bill of mortality in the city hospitals, while in private life it is in this climate the acute affection to which the aged succumb in large numbers.

A NEW INDICATION FOR LAPAROTOMY

Schultze, in a recent number of the *Deutsche medicinische Wochenshrift*, records a remarkable laparotomy done by himself for the purpose of removing the body of a uterus that was septically infected by the decomposition of a retained placenta. The woman, who had a uterus bicornis, had been delivered, without difficulty, of a fœtus at the seventh month of pregnancy, but the placenta was retained within the right division of the uterus ; after several attempts on the part of a midwife to extract the placenta, which only resulted in the detachment of the cord, a physician was summoned, who likewise failed to empty the uterus ; the patient was then taken to the hospital in Jena, where for five days repeated attempts to remove the placenta were unsuccessful. As by this time the woman had a high temperature, associated with chills and a fetid discharge from the vagina, it was determined to perform laparotomy in order to remove the source of infection, with the hope of averting a general septicæmia which otherwise seemed inevitable. The abdomen was accordingly opened, the body of the uterus was amputated, and the cervical stump fastened in the abdominal wound ; the temperature fell immediately, and the woman made a good recovery.

As Schultze himself remarks, the field for this operation must be a very limited one, for the conditions that would justify its performance would be the existence of the source of infection in the uterus alone, the impossibility of removing it *per vias naturales*, and the certainty that no infecting thrombi or emboli were producing metastatic abscesses in other parts of the body—a combination of circumstances that would not often be found.

The reason assigned by Schultze for not removing the decomposing placenta by the natural passage in his case was the tightly constricted internal os, which prevented ready access to the cavity of the uterus on the right side ; but no mention is made of an attempt to overcome this constriction by instrumental means, as, for instance, by bougies of gradually increasing size, in order to endeavor to strip the placenta from its attachment with the aid of a curette—a procedure, one would think, that should have been at least attempted before subjecting the woman to the danger of an abdominal section, and leaving her ever afterward in a mutilated condition.

SURGICAL MYXŒDEMA.

Total ablation of the thyroid gland is liable to be followed by a remarkable constitutional affection called surgical, or operative, myxœdema, in contradistinction to the disease of the same nature which occurs spontaneously. The surgeons in certain of the Swiss cantons in which bronchocele is endemic have had a large experience with this remarkable condition, and some months ago we referred to the conclusions of Kocher as well as to the artificial production of the disease in monkeys by Horsley.

At the recent Surgical Congress at Paris, Reverdin, of Geneva, presented a paper on the identity of the operative and spontaneous myxœdema. The earliest and most important of the symptoms of operative myxœdema is swelling of the face, hands, and neck ; not the puffy œdema of dropsy, but a firmer, more solid exudation. The tactile sensation

is slow, the special senses are dulled, and there are often unpleasant subjective sensations, particularly that of cold. The skin becomes dry and scaly, and the hair often falls; speech becomes slow and there is loss of memory. With these there are no visceral symptoms, though occasionally the urine is albuminous. In children from whom the gland has been removed, a condition of cretinism may be induced and there may be such an arrest of the physical and mental development that the child becomes an idiot. Bourneville and Bricon have observed myxœdema in idiotic children, and have determined the absence of the thyroid gland in these cases.

It is well to know that this condition does not invariably follow removal of the gland. Thus, of Kocher's thirty cases twenty-four became myxœdematous; of Reverdin's eleven, only five; on the other hand, Billroth, in a large number of operations, has not had a case, and Bottini has been equally fortunate. It would certainly seem as if in Switzerland, where goitre is endemic in certain regions, there are other conditions which render the patients more liable to this unfortunate event. The extirpation need not be total; Reverdin has seen a mild grade of the disease follow removal of only one lobe. There are many different grades of the affection and the milder forms are capable of amelioration and occasionally of cure.

THE ENUCLEATION OF NODULES OF STRUMA.

Since the publication of Kocher's observations on "Cachexia Strumipriva," or operative myxœdema, following the total excision of the thyroid body for neoplasms, surgeons have reached the conclusion that the operation should only be practised for malignant growths; and they have resorted to various methods of operating in ordinary cases with the view of obviating the condition first described by Kocher, and amply verified by other surgeons.

Among these modifications the most recent is that of Socin, of Basle, described by his assistant, Garré, in the *Centralblatt für Chirurgie*, No. 45, 1886. It consists in the intraglandular enucleation of the degenerated portions of the thyroid body, which portions, in the great majority of cases, exist as circumscribed nodules separated from the functionally active tissue by more or less thick capsules. If the nodules are superficial the surrounding layer of sound glandular tissue is very thin; should they, on the other hand, be embedded deeply, the overlying tissue varies in thickness from one fifth to four-fifths of an inch.

In either event the translucent, bluish, slightly vascular capsule having been reached, it is opened, and the tubers enucleated with the finger, a periosteotome, or any other suitable instrument. The hemorrhage is venous and not abundant, although profuse bleeding may occur in cutting through thick layers of the gland to reach the nodules, unless hemostatic forceps be first applied. The walls of the cavities are closed by catgut ligatures, spaces being left for drainage tubes, and the external wound is united and dressed on ordinary antiseptic principles.

The procedure, thus briefly described, has been resorted to in about fifty cases, with the best results. It is easily practised; unattended with danger; large vessels, as well as the recurrent laryngeal and other nerves, are secure from injury; and it has never been followed by surgical myxœdema. For these reasons, the operation deserves an extended trial.

LOCAL APPLICATIONS IN VAGINITIS.

Slocum has recently, in The Medical News, called attention to a communication upon the use of vaginal tampons of absorbent cotton "coated with boracic acid" in the treatment of profuse and offensive leucorrhœa, a method which he prefers to the use of boroglyceride cotton tampons, because the glycerine causes a copious watery discharge which, though at times beneficial, is not always desirable. At the Jefferson Medical College Hospital boric acid has been used in the treatment of vaginitis with very satisfactory results. A large cylindrical tampon with a string attached to it, is covered with glycerine and then thoroughly coated with boric acid sprinkled from an ordinary pepper-box. It is allowed to remain in the vagina for forty-eight hours.

Delineau, in the *Revue Médico-Chirurgicale des Maladies des Femmes* for October, advises, in vaginitis, the use of a powder composed of salicylic acid three parts, powder of poplar charcoal five parts, and powdered talc ten parts, applied by an insufflator to the entire vaginal surface.

We find in the same number of the *Revue* the following method of preparing salicylated cotton, which may also be used not only for uterine, but also for vaginal application. One hundred parts each of concentrated alcohol and of purified cotton, ten of salicylic acid, and one of glycerine are provided. The salicylic acid is dissolved in the alcohol, the glycerine added, and then the cotton is saturated in the mixture, the superfluous fluid squeezed out, and the cotton dried and kept in hermetically sealed flasks.

Surgeon-General Moore arrived at Washington from San Francisco on Tuesday, and at once assumed the duties of the office of Surgeon-General of the Army, to which he has just been appointed.

Dr. N. A. Randolph has been elected Professor of Hygiene in the University of Pennsylvania, to succeed the late Dr. Joseph G. Richardson.

The arrangements for the Centennial Celebration of the foundation of the College of Physicians of Philadelphia are being rapidly perfected. The ceremonies on January 3d, will include an address, at Association Hall, by the President, Dr. S. Weir Mitchell, followed by a Reception, in the College building, by the President and Fellows. On Tuesday, January 4th, at noon, a Centennial Meeting of the College will be held with appropriate exercises, and in the evening the Fellows will dine together.

It is anticipated that representatives from the leading medical societies of the country will be present and participate in the celebration.

M. Colin, the eminent professor in the Veterinary School at Alfort, read a paper last week before the Paris Academy of Sciences, showing that the average annual number of deaths from rabies in France is 26, and that since M. Pasteur began his course of treatment the same number of patients has died. According to official statistics the number of persons bitten by mad animals last year in France was 351, while M. Pasteur has treated 1700 patients. M. Colin concludes that the Pasteur system is of doubtful efficacy, and he is alarmed for the results of virulent inoculation.

The Medical Missionary Record is the title of a new medical journal, of which the first seven numbers have appeared. It is edited and published by Dr. George D. Dowkontt, Medical Superintendent of the New York Medical Missionary Society, among the managers of which we notice are Drs. Sabine, Markoe, Roosa, Loomis, and Thomson.

The first number has a list of all the medical missionaries throughout the world, numbering nearly 230. The reading matter is varied, interesting, and valuable, whether from the medical or the missionary aspect.

The Pennsylvania Hospital for the Insane has opened a dispensary service for cases of incipient mental disorders, at the out-patient department of the hospital, Ninth and Spruce Streets, which is intended to furnish advice and treatment to this class of cases among the poor. It is the purpose that only cases unable to pay for their medical advice are to be treated at this service.

A new *Centralblatt*, devoted to the subject of bacteriology and animal parasites, will shortly appear in Germany, under the editorship of Dr. Oscar Uhlworm, in Cassel. The coöperation of Drs. Baumler, Bollinger, Buchner, Doutrelpont, van Ermingen, von Etlinger, Flügge, Grassi, Heiberg, Hueppe. Kitasato, Klebs, Koch, Miller, Neisser, Oerley, Prazmowski, Watson Cheyne, Weichselbaum, Weigert, and Zopf has been secured.

There is also to be issued in Germany a new quarterly, entitled *Progress in the Chemistry of Food Stuffs and Condiments*, which will be under the editorial management of Hilger, Keyser, König, and Sell.

The New York Skin and Cancer Hospital, and its country branch at Fordham, Westchester County, N. Y., are now ready for the admission of patients from New York and other States. Applications should be directed to L. D. Bulkley, M.D., 4 East Thirty-seventh Street, New York, Secretary of the Medical Board.

REVIEWS.

A Treatise on the Principles and Practice of Medicine. By Austin Flint, M.D., late Professor of the Principles and Practice of Medicine and of Clinical Medicine in the Bellevue Hospital Medical College, New York. Sixth edition, revised and largely rewritten by the author, assisted by William H. Welch, M.D., Professor of Pathology in Johns Hopkins University, Baltimore, and Austin Flint, Jr., M.D., Professor of Physiology in the Bellevue Hospital Medical College, New York. 8vo. pp. 1160. Philadelphia: Lea Brothers & Co., 1886.

It was known at the time of Dr. Flint's death that he had, with the coöperation of Prof. Welch, completed the revision and partly rewritten a sixth edition of his *Practice of Medicine*. Dr. Welch and Dr. Flint, Jr., have carried the work through the press. The latter has written an interesting preface which adds not a little to the value of the work, as showing the untiring industry of the author and the care with which he collected materials during an unusually long and active professional life. The work is based, we are told, upon an unbroken series of clinical records begun in 1833, and continued for more than half a century and which embraces sixteen thousand nine hundred and twenty-two folio pages of manuscript written with the author's own hand! Dr. Flint was unquestionably one of the most careful clinical students which this country has produced, and he enjoyed exceptional facilities for the study of the diseases incident to all parts of the United States, as during the half century of professional duties he occupied chairs in Buffalo, Louisville, New Orleans, and New York. One characteristic of Dr. Flint's mind has contributed to make this work of special value. He never strained after that false consistency which makes so many teachers, as age creeps over them, cling all the closer to the views which they may have formed as young men. His mind was unusually receptive and he kept thoroughly abreast with the current medical opinions of the world.

Among the changes in this edition we notice many new articles of great value, such as the following: "Infectious Tumors," "Cerebral Syphilis," "Syphilitic Disease of the Lungs," "Spastic Cerebral Paralysis of Children," "Hereditary Ataxia," "Myxœdema," "Multiple Neuritis," "General Pathology of Fever," and "Milk Sickness." The pathological portions of the entire work have been revised and rewritten by Professor Welch with the greatest care.

No more fitting monument to the author could be desired than this great work, which has contributed more than any other text-book to inculcate in English-speaking physicians sound principles in the practice of medicine.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 2, 1886.

The President, A. Jacobi, M.D., in the Chair.

Dr. J. Blake White presented a

PHTHISICAL LUNG INJECTED WITH CARBOLIZED IODINE.

He said that the results which he had met with during the past year from injections into diseased lungs had greatly excited his enthusiasm. Intra-pulmonary medication theoretically seemed to be a very rational method of treatment, and practically it was found to be of much efficacy. Having referred to the success met with by Drs. Pepper, Robinson, and others, he mentioned a case of his own in which recovery took place, and the course of which was watched by three professional friends. The preparation which he prepared for injections was a mixture of carbolic acid and tincture of iodine, to which was added a small amount of morphia and atropia. In the cases in which he had employed it all the symptoms had been relieved; the cough being controlled, expectoration diminished, the sleep improved, and night-sweats checked.

The specimen presented was the left lung of a patient in whose case three injections were made with the effect of producing marked relief. The case was hopeless, however, as regards cure, at the time the first injection was made, and the patient died six weeks after the administration of the third. Dr. White gave the history of the case in detail.

The patient was a native of Ireland, a male, and forty-six years of age. He was a milkman by occupation. When first seen by Dr. White in his service at Charity Hospital, last summer, he was in the third stage of phthisis, with a large cavity in the upper part of the left lung, which was in a state of active suppuration. There were profuse expectoration, exhausting night-sweats, and all the ordinary symptoms of advanced pulmonary tuberculosis. On the 19th of July, 1886, the first injection of ten minims of carbolized iodine was made in the first intercostal space. It was followed by no reaction, and there was immediate and marked improvement in the patient's condition. The next week a second injection of the same character and quantity was given, and this also, without any reaction whatever; marked improvement in all the symptoms followed. The man felt so much better, indeed, that he was enabled to make an amount of physical exertion that before the treatment would have been imposisble.

On the 30th of August a third injection was made, this time twenty-five minims of the carbolized iodine being employed. It was attended by a brief paroxysm of coughing, but no bad results followed, and marked improvement was subsequently noted. Dr. White's term of service at the hospital now expired, and no more injections were made.

The patient died October 19th, and at the autopsy the left lung was found bound down everywhere by the most extensive pleuritic adhesions. The pericardium was also involved by adhesions to such an extent that it was a wonder to those present how the heart had been enabled to perform its functions for so long a time as it had. Much of the tissue of the left lung presented a cirrhotic appearance, and in the vicinity o the cavity in the apex, a considerable space was found to be tinged by the injections. The upper portions, where the injections had been made, presented a marked contrast to the lower portions, where the tissues were in a state of advanced disintegration. During life also the auscultating signs had indicated a dry condition of the upper parts very different from that met with in the lower. Very little pus was found in the cavity.

Dr. William P. Northrup read a paper on

LARYNGEAL DIPHTHERIA; INTUBATION, AND PATHOLOGICAL ANATOMY.

He alluded to the conflict in Paris, in 1858, between Bouchut and Trousseau, regarding intubation of the larynx, which ended in the official declaration by the Académie de Médecine that this procedure was impracticable. Nothing more was heard of intubation for nearly thirty years, when the practice was revived by Dr. Joseph O'Dwyer; in whose hands it had been attended with such marked success that the method had now attracted an amount of attention which had not been met or equalled in the profession since the advantages of Esmarch's tourniquet were made known.

He then proceeded to give a *résumé* of the statistics of all the cases of death from laryngeal diphtheria occurring during the last five years among the children under the care of the New York Foundling Asylum, who number almost 1800 per year; 1100 of these being intrusted to paid nurses, who look after the children in their own homes, and the rest being kept in the asylum buildings. During this period there were 87 deaths from the cause named; of which 50 were in females and 37 in males. The greatest mortality was noted in children between the ages of 3 and 4 years. In 56 of the 87 cases the membranes formed in the larynx either before or simultaneously with their appearance in the pharynx. In two cases, croup was the first symptom noticed, and death occurred within 20 hours. In 54 cases there was pneumonia, and broncho-pneumonia was very frequently met with. 27 children died from extension of the membranes into the bronchi, and in 29 the pneumonia alone was sufficiently severe to cause death. The highest temperature met with was, in 19, 104°; in 15, 105°; in 3, 106°; in 2, 103°; and in 1, 107°.

Having given the statistics of the extent of the membranous exudation, he said that in all but three of the 87 cases the membranes were very extensive. Interstitial emphysema occurred in 8 cases. There were 51 cases of primary diphtheria, and 31 in which the disease was nearly or remotely related to scarlet fever or measles.

Dr. Northrup exhibited a set of O'Dwyer's instruments for intubation, and explained the method of introducing and extracting the tube for the larynx. It is important, he said, that the child, wrapped in a blanket, should be held upright in the arms of the nurse, who, by grasping the elbows, secures a firm position without interfering with the movements of respiration. The gag is inserted in the left angle of the mouth, well back

between the teeth, and opened widely; and an assistant holds the head, thrown somewhat backward, while the operator inserts the index finger of the left hand to hook up the epiglottis, and direct the tube into the larynx. It is better to make several short attempts to introduce the tube than one prolonged effort, on account of the interference with respiration thus caused. The extraction of the tube is more difficult than its introduction, and Dr. Northrup, at the suggestion of Dr. O'Dwyer, recommended that physicians should practise both introduction and extraction on the cadaver. The procedure, however, is easier in the living child.

Those beginning to practise intubation, he said, are apt to use too small a tube, with the result that it is coughed up. This mistake, however, can easily be avoided by taking proper care to use the right sized tube for the age of the child, as indicated by the scale furnished with each set of instruments. There is, however, no danger of the tube slipping down into the trachea, as some seem to fear. In the first place, no case of such an accident is on record; and, secondly, it will be found that the head of the tube is always caught by the cricoid cartilage, which is situated at the narrowest point of the passage. Moreover, there is no danger of ulceration of the vocal cords being caused by the tube.

If the condition of the child appear favorable for forty-eight hours after the insertion of the tube, the prognosis is good; but it is entirely unsafe to give a favorable prognosis at any period before the expiration of the forty-eight hours. Not infrequently the greatest possible relief is afforded temporarily by intubation in cases which afterward terminate fatally by the extension of the membranes, or the occurrence of pneumonia. Dr. Northrup also spoke a word of caution in regard to withdrawing the tube too soon. Whether it is advisable to reintroduce the latter in any case will be shown by the examination of the chest. If, on auscultation, the vesicular murmur is normal, there is no cause for uneasiness; but if it is found that the air can not get into the lungs well, especially in the posterior portions, it is time to reintroduce the tube. The condition of the pulse also serves as a valuable guide. If the child is not very young, the tube can usually be removed in five or six days.

After mentioning to the kinds of food most useful and easily taken after intubation, he referred to the cases reported by Dr. Jennings, of Detroit, four in number, all of which terminated fatally. Dr. Jennings recommends tracheotomy in preference; stating that he has had ninety-five per cent. of cases of recovery in this operation. Dr. Northrup called attention to the fact, however, that his cases of intubation were of a very unfavorable character. Still, Dr. Jennings recommended intubation in children under fifteen months old, and in hopeless cases; believing that it was a supplement to, though not a substitute for tracheotomy.

Having mentioned that O'Dwyer's tubes are of great service in stenosis of the larynx in adults, and particularly when the condition is due to syphilis, Dr. Northrup gave his conclusions in regard to intubation as follows:

It relieves dyspnœa due to laryngeal stenosis. There are few objections to the method, and it is comparatively simple and free from danger. No anæsthetic is required. No trained assistant is required. There is no fresh wound to serve as a point for new impaction. If it proves inefficacious, tracheotomy can still be performed. It has one conspicuous fault, viz., that it embarrasses and sometimes interferes with deglutition.

There is also some danger connected with it. The tube may possibly push some of the tenacious membrane down before it, and thus cause a blocking up of the trachea below.

He then asked, Does it meet the requirements? and argued that the statistics show that it does. Waxham has had 96 cases, and O'Dwyer 48. In all, 165 cases have been reported. Dr. Northrup stated that 28½ per cent. of these had recovered.

It is to be remembered, too, that the operation is still new. Valuable experience has been gained, and it can scarcely be doubted that in the future the results will be even more favorable. The statistics of tracheotomy show no such satisfactory result as this, and he believed that if all the fatal cases of the operation were reported, the percentage of mortality would be considerably larger than it now appears.

Dr. Francis Huber said that he had performed intubation eleven times. The special symptoms for which he had resorted to it are aphonia, stridulous expiration and extreme recession of the chest-walls above and below the sternum. The first two cases were in very young children with extensive diphtheritic deposit, and both proved fatal. The third was in a child two years and three months old, and was followed by recovery. The fourth was in a child six years old, in whom croup occurred as a complication of measles. The fifth was a case of diphtheria, in which death resulted from double pneumonia. The sixth was in a girl three years old, suffering from croup and measles. The membranes became gangrenous, and the child died in uræmic convulsions. The seventh was in a child twenty-seven months old, suffering from diphtheria. The eighth was in a child with diphtheria, who had an old endocarditis. The tube was removed at the end of six days, but two days later he was called in and found that the stenosis had returned. The child had been carelessly exposed, and a new laryngitis had been set up. The tube was again introduced, and allowed to remain three days; after which the patient recovered. The ninth was a case of croup with measles, in which death occurred from pulmonary œdema. In the tenth case, in which intubation was practised the previous day, the child is still alive, but it is probable that death will soon occur from pneumonia. In the eleventh case, which was also intubated the same day, the child was moribund at the time, and died soon afterward.

Out of the eleven cases there were four recoveries, while one child was still wearing the tube. Ten had died, and one other would probably do so. These results are much better than he had obtained with tracheotomy. He had performed this twelve times, but had saved only two out of the twelve children. He stated, also, that in all his cases of intubation, the method was resorted to very late. In conclusion, he exhibited a modification of the O'Dwyer gag, devised by his friend, Dr. Emhard, who had also had several cases of intubation. Five of these were successful, and all of the eleven, like his own, were late cases.

Dr. Alexander S. Hunter said that he had prac-

tised intubation twice, both times in cases in which he was called in consultation. The first case was that of a child, six years of age, who had been suffering from membranous croup for two days. The stenosis was extreme, and pulmonary œdema was coming on. He introduced the tube with little difficulty, and the relief was immediate and most marked. After forty-eight hours, however, he saw the patient again, and found the respiration very rapid. He had great difficulty in swallowing, and he found that by giving it a large quantity of nourishment at a time it got along better than if the attempt was made to give it by the teaspoonful. The pulmonary trouble was now so great that it was evident that the child could live but a few hours longer. He therefore removed the tube, and it still breathed quite well; but died some hours afterward.

The second case was in a child, two and a half years old, with diphtheria, who had a temperature of 103½°. There was marked stenosis, and it was almost completely asphyxiated. The relief afforded by intubation was prompt, as in the other case. The next day the child coughed up the tube, and it was reintroduced by the attending physician; but death ensued in five or six hours. Dr. Hunter stated that he had practised intubation five or six times on the cadaver before he attempted it on the living subject.

Dr. E. L. Partridge said that Dr. Northrup had mentioned that the only danger from intubation was the possible detachment of portions of membrane which might act as a diaphragm in the trachea below the tube. The same objection held true, however, in regard to tracheotomy, and he referred to a case in which fatal obstruction occurred in this way.

Dr. A. G. Caille said that he had had one case, but intubation was resorted at so late a period that he thought it should not go on record. He believed that the introduction of the tube would be more easily effected if the special points about the anatomy of the parts are carefully borne in mind.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, November 22, 1886.

The President, James T. Whittaker, M.D., in the Chair.

Dr. T. A. Reamy read a paper on

ergot in labor and puerperal convalescence, with protests against the extent to which it is employed.

He said that the field of utility for ergot has faded from the rather extensive indications given by Stearns in 1807 to the canonical law of banishment by Barnes in 1885. Its dangers have been proclaimed ever since its introduction, and the long list of injury and death in the catalogue of recorded accidents is a solemn warning against its indiscriminate employment.

The character and extent of the evils of ergot are so well known that they need only be mentioned. Lacerations of the perineum, vagina, and cervix, retention of the placenta, the death of the child, acute toxic ergotism and gangrene, the rupture of the uterus and the death of the mother, all offer abundant evidence of the frightful energy of ergot and its consequent perils. Yet, notwithstanding this startling category of possible dangers, and these numerous lines and precepts of caution, ergot is to this day the most generally abused agent in obstetric practice.

We are perfectly well aware of the almost universal practice among midwives of administering this drug at any stage of labor when the progress is at all tardy, and when it is considered that in this city seventy per cent. of labors are attended by midwives, we must tremble at the perils to parturient women. Nor is this evil practice confined to midwives. It is within his personal knowledge that there are very many physicians, both in city and country practice, who employ this agent very extensively before the end of the second stage of labor.

He expressed his firm conviction that the cases are extremely rare where the exhibition of ergot prior to the termination of the second stage of labor is justifiable, and in these rare cases of ante-partum uterine inertia, which have resisted other means of securing contraction, the ergot should be given in small doses with caution. It will not be claimed that these restrictions are more radical than the rules given by almost every modern obstetric writer of reputation, as already cited in this paper. Nevertheless, it must be confessed that this teaching is too often disregarded. The practitioner does not discriminate. He knows that ergot certainly and powerfully increases uterine contractions, that contractions consummate delivery. He therefore gives ergot to shorten the duration of labor, and the evils follow.

The objections to the administration of ergot before the close of the third stage of labor are equally positive, though the dangers of rupture of the uterus, death of the child, laceration of the cervix or perineum are not now in the count. Closure of the uterus with incarceration of the placenta is no uncommon result from the practice, since it is a well-observed clinical fact, though difficult to explain, that the action of ergot tends expecially to close the os internum, the ring of contraction of Schröder, rather than to produce expulsive contraction of the upper portion of the uterus. Should the placenta not be retained, clots are retained in the uterine cavity rather than expelled, by virtue of the same faulty character of contraction. But a still greater evil is hidden in this question, so that it is not generally seen, namely: The rigid contraction secured by the ergot does not result in thickening of the uterine walls in the upper segment, the region of placental attachment, with corresponding thinning of the walls in the lower segment of the uterus. In other words, it does not promote and secure retraction, a condition essential, first, to permanent protection against hemorrhage; second, to the first steps in involution. This condition of perfect retraction is only secured by the intermittent contractions and relaxations which normally occur in execution of the physiological law governing the uterus at such a time. If from any cause these contractions are too feeble, they may be strengthened by friction upon the abdomen, gentle compression of the uterus through the abdominal wall, or, if need be, by suitable doses of ergot. But it is here that he wished to enter his emphatic protest against the practice so extensively adopted of administering a drachm of the fluid extract of ergot immediately upon delivery of the placenta. Not only does he protest against this single dose, but against the custom of continuing the exhibition of full doses three times a day for

several days, though he advises the use of small doses sufficient to maintain healthy uterine contraction in all cases where the natural muscular tonicity is inadequate.

It is proper that further reasons be given for these protests. Important objects of treatment during the puerperal period, must be to secure perfect involution, and provide against subinvolution, a disease whose prevalence and disasters are common knowledge, but whose causes are not always clear.

It is admitted, however, that proper uterine retraction is essential to involution. A clear conception of the processes by which retraction is reached, is of importance in this inquiry. By retraction is meant not only the gradual drawing up of the contraction ring of Schröder, by the shortening of the longitudinal fibres of the body and fundus in process of contraction, but also the general rearrangement of the muscular fibres of the whole organ, both during and subsequent to delivery. This rearrangement so disposes the fibres that those previously placed end to end now become situated side by side. Thus a general thickening of the uterine walls ensues, and consequently the vessels are both compressed and rendered more tortuous.

After-pains are nature's expression of the rhythmical attempts of the muscular fibres to rearrange themselves, and normal retraction is secured by rhythmical contractions which persist after labor. These contractions are not always painful, for they are frequently carried on, as is evinced by the alternate hardening and relaxation of the uterus, without the patient's knowledge—that is, without after-pains.

Involution is both a constructive and destructive process, and it really begins with the degenerative changes which are set up in the muscular fibres with the first pains of labor. These contractions gradually lead to the destruction of the muscular cells, in common with the rules of function in muscular cells everywhere. Rhythm of contraction is essential both to their function and to such gradual destruction as will insure their subsequent absorption as fatty detritus. Persistent tonic contraction defeats the proper performance of their function in the exhaustion or paralysis which follows. Exhaustion follows because they are no longer able to secure sufficient nutrition, during relaxation, to induce them to perform another contraction, a condition readily fostering hemorrhage.

Every careful obstetric clinician has observed cases in which, after delivery of the placenta (the speaker did not now refer to cases in which ergot had been given), the uterus presents by palpation through the abdominal wall, the condition of stony hardness which is in strong contrast with the condition of firmness, marking the state of retraction. This hardness of the uterus is due to powerful tonic contraction, and if it be observed to persist for several minutes, the experienced physician recognizes in it unerring evidence that within a short time muscular paralysis will occur, the uterus becoming flabby and hemorrhage ensuing. This paralysis is due to muscular exhaustion, consequent upon the persistent violence of the contraction.

It is claimed by Cazeaux that uterine contraction, secured by a full dose of ergot, is maintained for about one hour and a half. Dr. Reamy's observations show that the period is longer. However, one hour and a half of persistent contraction is sufficient to produce muscular paralysis. The stony hardness of the uterus under such contraction by ergot, is identical with that above spoken of. The wise practitioner will not leave the bedside of his patient until the above-named hardness of the uterus is replaced by the firm but softer state of retraction, which, as already indicated, can only be reached after alternate contractions and retraction have intervened.

The foregoing remarks touching the question of hemorrhage may furnish a clinical lesson worthy of consideration, but the object in presenting these facts is for the illustration of principles germane to the discussion of the relations of ergot to subinvolution of the uterus by its interference with rhythmical contraction. It is the disturbance of rhythm, however, in the degenerative processes which prepare the hypertrophied uterine elements for absorption, which is of most importance in this study.

Dr. M. Putnam Jacobi has called attention to the relations existing between the arterial and venous circulation in the gravid and puerperal uterus. "There is," she says, "a tendency to venous excess in the uterine tissues from the moment of conception to the end of pregnancy;" and we all know that venous hyperæmia is the condition most favorable to growth, and the uterine changes during the entire time are those of simple growth alone.

"When the first pains of labor begin, the venous excess is cut off by the clogging of the sinuses at the placental site with giant cells," and a relatively greater amount of arterial blood fills the uterus. This arterial blood, bearing the oxygen of nutrition, stimulates the large muscle cells into contraction—that is, into the first performance of the function for which the gestative growth has prepared them. These contractions compress the veins and thus further diminish the venous supply. This process ultimately expels the ovum and checks venous hemorrhage from the placental site by venous thrombosis.

After the ovum is expelled, an excess of arterial blood is still required intermittingly, not only to produce the retraction induced by the after-pains, but also to furnish the oxygen necessary to the gradual reduction of the now unnecessary elements into fatty detritus preparatory to absorption. The facility of absorption by veins and lymphatics depends upon the relative difference between the venous and arterial tension.

In order to secure rapid and successful involution, a certain relation must exist between the venous and arterial pressure. An excess of venous blood will check involution and conduce to subinvolution, both by checking fatty degeneration and disabling absorption. On the other hand, excessive rise of arterial pressure, and tonic contraction of the uterus, also interfere with the necessary degenerative changes, by delaying the constructive changes in the endometrium, which, since they are processes of growth, are best performed under low pressure—venous hyperæmia.

At the placental site, as well as in a less degree throughout the endometrium, after the separation of the placenta and decidua, an important process of repair must be speedily instituted. This is important as prophylaxis against sepsis and subinvolution. It is at this part of the organ that degeneration and growth must go hand in hand. By the degeneration of the lacerated

membrane and its voidance through the lochial discharge, and by the stimulation of the venous blood to growth, a new endometrium is formed. When the uterus is injected, the veins blue and the arteries red; soon after parturition it is seen that while there is excess of arterial vessels, this excess is less manifest the nearer the endometrium is approached, showing that there is relatively more venous blood in this situation than further out in the muscular walls.

Further corroboration of this condition is found in the fact that the endometrium is entirely reformed much earlier than the complete reduction of the remainder of the organ. In the deeper parts of the uterine walls both degeneration and growth must occur. The new uterus is chiefly formed from the development of the muscular nuclei, while the enormous fibres of the gravid state are reduced to fat and absorbed in the course of involution, this process being slower than that in the endometrium, as a result of the greater relative excess of the arterial blood. Thus the result of a nice balance, a proper relation between arterial and venous pressure in the process of uterine involution is apparent. It is, therefore, manifest that the disturbance of this essential relation by the stony tetanic contraction maintained by full doses of ergot will defeat proper and speedy involution, will prolong the puerperal period, and will indirectly foster subinvolution.

Again, the tonic contraction of the uterus for an hour and a half after the expulsion of the placenta, is an objection to the employment of a full dose of ergot at this time, in that it confined to the general circulation a considerable quantity of blood which is normally lost in the intervals of relaxation which should occur. A certain amount of hemorrhage at parturition is conservative. Instead of blood being required for the sustenance of two lives, there is now only one, and that one requires less than before, because it is no longer required to sustain the laborious functions of the hypertrophied uterus and vagina.

Moderate hemorrhage is likewise conservative in permitting the loss of blood from the uterus, surcharged with the effete products of its recent extreme activity.

He said that it must not be forgotten that he was speaking of the effect of full doses of the drug. H. C. Wood, and many others, are authority for the statement that small doses—a few minims of the fluid extract, or a single grain of the solid extract—will only increase the force of the uterine contractions, and not affect the periods of relaxation—in other words, will not disturb rhythm in action. His own experience confirms this view. With small doses, where proper indications exist, he makes no issue.

The following should be the rules governing the administration of the drug:

1. Ergot may properly be administered in small doses, say ten to twenty drops of Squibb's fluid extract, before delivery, in cases of uterine inertia which resist other means; and especially in women who are predisposed to hemorrhage.

2. It should be administered in full doses hypodermatically, or per os, or both, in cases of post-partum hemorrhage.

3. When an anæsthetic has been freely used during the second stage of labor, it to some degree predisposes to post-partum hemorrhage. Ergot is, therefore, indicated.

4. It should be administered in small doses, two or three times daily, during the period of puerperal convalescence, whenever a flabby uterus indicates it. In such cases there is no better combination than the pill recommended by Mundé: one grain ext. ergot, one grain of quinine, and one-fourth of a grain ext. nux vomica.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 8, 1886.

DR. C. MCBURNEY IN THE CHAIR.

DR. GEORGE A. PETERS reported two cases of

RADICAL CURE OF HERNIA.

Case I.—Michael McG., Irish, aged forty-one, admitted into St. Luke's Hospital May 4, 1885, with double inguinal hernia—that upon the left side being much the larger of the two. Twelve years ago, while lifting a child at arm's length, he "felt something give way;" there was but little pain although a "small lump" was observed in the left groin. A physician whom he consulted pronounced it to be a hernia, and directed him to wear a truss, which he did for about two years, after which time, as he experienced no pain or inconvenience and the tumor was very small, he discontinued its use. Three years ago, while lifting a heavy weight, the tumor immediately became much larger and was attended with sharp pain in the lumbar region, for which he remained in bed for a week or two. Since this time he has never been able to hold up the hernial swelling with any truss which he could procure.

Eight years ago he came violently in contact with a "sharp corner," and a small bubonocele appeared in the right groin. This gave him no trouble until he lifted the heavy weight three years ago, after which time both his herniæ became large and painful. For the year or two past he has grown very fleshy. Summing up, this is his condition on admission to the hospital, viz:

On the left side is a large, indirect inguinal hernia, easily reduced excepting a small knuckle of intestine apparently adherent to the sac. The pillars of the ring are readily defined and very much spread, easily admitting four fingers. On coughing or straining a large mass of intestine comes down measuring three by six inches. The inguinal ring upon the right side easily admits two fingers and the edges are sharply defined. On coughing only a small bubonocele comes down.

Family history and general condition good, except that he had been drinking freely of spirits for some time. As he suffered so much from the size of the tumor and the fact that he could not wear a truss, Dr. Peters determined, after consultation with his colleagues, to perform Banks's operation for the radical cure of the hernia in the left groin.

May 7th. Patient was put upon the table for operation, and with much delay brought under the influence of ether. During almost the entire time of the inhalation he vomited, coughed, and struggled so that it made the performance of the operation one of great difficulty. A free incision was made through the skin commencing just above the level of the external abdominal ring and the dissection carried carefully down, layer by layer,

until the sac was exposed and the pillars of the ring brought distinctly into view. The ring was very large and patulous (easily admitting four fingers). The hernia was now reduced by gentle taxis, leaving the collapsed sac in the wound. The cord was found behind and well out of the way. The sac was now opened and a knuckle of gut was found closely adherent to its wall just at a level with the ring. It was not deemed prudent to attempt its separation and it was left as found. The opening of the sac was now carefully and with much difficulty stitched to the pillars through and through with stout catgut and the ring closed.

Owing to the restlessness of the patient under ether and frequent attacks of vomiting, the bowels were forced down in a large mass and spread out upon the outside of the belly. The protruding bowel was carefully guarded with towels and sponges wet with hot water. This stage of the operation was exceedingly difficult and prolonged. It was, however, finally accomplished. A great portion of the sac was now dissected out, two bone drainage tubes introduced and the wound closed with carbolized catgut and an antiseptic dressing over all. During the escape of the bowel the pulse sank very low and he suffered much from shock, but was finally restored by brandy, ether, and digitalis hypodermatically administered. Patient suffered very much from nausea, pain, and tympanites for a few days after the operation, but these symptoms gradually subsided. The wound did not heal throughout its whole extent by first intention, but remained open at the two angles, gradually filling up with granulations until June 17, 1885, when he was discharged cured.

Case II.—Alice S., Irish, aged fifty, married, was admitted into St. Luke's Hospital January 22, 1886. Six years ago, after lifting a heavy weight, she noticed a "small lump" in the right groin; finding that it did not disappear after a few days, she entered Roosevelt Hospital, where she was treated for a short time, but no operation was performed. Ever since that time she has "felt a weakness" in the right groin, and, on exertion, a reducible tumor would appear. Has never worn a truss. Ten days ago, after a severe strain, the tumor appeared; was painful, and increased in size; the bowels were constipated, and she suffered somewhat from nausea. On admission, examination revealed a tumor in the right groin, below the inner third of Poupart's ligament, globular in shape, about one inch in diameter, elastic to the touch, slightly painful on pressure, and dull on percussion. A portion resembling a pedicle extends down toward the femoral canal. Before admission, attempts had been made to reduce it by taxis, but without success. The attempt was renewed after admission, with no result except to occasion local inflammation and considerable pain. She was ordered strict decubitus, and the cold coil was applied.

The tumor was considered to be an incarcerated femoral hernia, contents chiefly omentum, and, after consultation, Dr. Peters determined to perform Banks's operation, hoping to make a radical cure.

February 5th, she was put upon the table, ether was administered, and she was quickly brought under its influence. The integument of the groin and neighborhood was shaved, scrubbed, and rendered aseptic. An incision about two inches long was made over the convexity of the tumor, and the dissection was carefully made down toward the sac. The connective tissues in this neighborhood were matted together, thickened, and extensively adherent to the sac itself. These adhesions were carefully dissected away, and the sac opened, allowing the escape of some yellowish fluid. When brought into view, the contents of the hernial sac were found to be a sheet of omentum enveloping about three inches of the vermiform appendix, the distal portion of which was doubled upon itself, allowing the knuckle thus formed to project above the omentum, resembling a gland, for which it was indeed mistaken until the unravelling of the tissues determined its true character. The contents were adherent to this sac, but were dissected free, and the vermiform appendix and omentum were separated down to the ring, where each was separately ligated with stout catgut, and cut off. The portion of the appendix vermiformis removed was two and a half inches long, and about the size of a goose-quill. The sac was now tied off, and with the stump which was left just at the femoral ring was stitched through and through with catgut. A rubber drainage tube was now inserted to the bottom of the wound, and the skin closed over with fine catgut suture. During the operation the wound was frequently irrigated with solut. hydrarg. bichlor., 1 to 1000. The dressing was iodoform gauze and spica bandage. The first dressing was not disturbed until February 10th, when the drainage tube was removed, there being perfect union except where the tube emerged. During the progress of the cure a small collection of pus occurred, which somewhat delayed the healing. Discharged cured March 9, 1886.

On presenting these two cases of operation for the radical cure of hernia, he desired to call attention to complications occurring in both of them. In the case of McGowan, who took ether badly, on opening the sac a large mass of intestines was forced by his efforts to vomit, through the distended and flabby ring, and was the source of much embarrassment and considerable danger until they were returned. The principal assistant should guard very carefully the open ring, and check the first attempt at escape. The danger from shock will be much lessened if the truant gut be kept carefully protected by hot, wet sponges.

In the case of femoral hernia, a complication presented, namely, the appendix vermiformis, which he did not remember to have seen in any hernial sac which he had opened. In this case it was, when first seen, supposed to be a gland, but as the mass was unrolled its identity was established. As the hernial mass was adherent to the neck of the sac, it was determined to ligate the entire protrusion, so that it might act as a plug. On examining the appendix after its removal, it was found to be pervious down to the very tip, but contained no fecal matter. The wound of operation healed kindly, and the presence of the divided appendix seemed in no way to retard the cure.

Of all the methods which have been adopted for the radical cure of hernia, the one described above, and introduced to the notice of the profession by Banks, of Liverpool, is the most rational to the student, and captivating to the surgeon. The experience which most of us have had with the operations of Heaton by injection, and with the needle and wire, has not, he ventured to say, been so satisfactory as to convince us that nothing better can be devised.

The methods of procedure adopted vary according to the theories or experience of different surgeons. Some use the silver wire, others aseptic silken thread, and others carbolized catgut. The result of my experience and observation inclines me to advocate the catgut properly prepared, so that it will not dissolve too readily. Union by first intention in the wound is not so desirable as might at first seem. A sufficient amount of inflammation to produce a dense thickened mass of tissue, provided this be the result of suppuration and granulation about the ring and canal, is to be preferred. That the operation is a reasonably safe one is, he thinks, proven by the results already obtained. When the cases are properly selected, and the operation done with all modern precautions, the percentage of recoveries is large, as in the cases reported by Banks and others abroad. Even when such precautions are not observed, the statistics show a death-rate of only one in eight.

In cases where the hernia is large, and subjects its owner to much pain and discomfort, where it cannot be entirely returned, or, if returned, cannot be kept in place with a truss, this operation is indicated. Even if it should not result in a perfect cure, the patient will be so much improved as to be able to wear a truss with comfort, and become again a bread-winner.

Dr. Gerster remarked that, in regard to the name given to the operation by Dr. Peters, a very similar operation was first performed by Prof. Czerny, of Heidelberg, and he thought the precedence belonged to him. As regards the use of ether in herniotomy causing vomiting, he would mention the case of a very fat man who was admitted to the German Hospital, suffering from a massive scrotal hernia. The inguinal opening was large enough to put in the fist. The patient bore ether very badly—that is, coughed and choked so incessantly as to render operating impossible—and he changed to chloroform, and immediately the respiration became quiet, cyanosis disappeared, and the operation could be completed without interruption. Ether was borne very badly, although a hypodermatic injection of morphine had been administered previous to anæsthesia.

Dr. Lange asked if any one had any experience in McEwen's (Edinburgh) operation for hernia, in which the sac is pushed back into the properitoneal space, and the pillars of the ring closed in such a manner as to make a valvular closure? Dr. Lange had performed the same operation three times, but could give no definite statement as to its value.

Dr. Weir remarked that he had performed the operation a few days previously.

Dr. Stimson asked what sutures were used.

Dr. Lange replied he had used silk once, silkworm gut once, and catgut once.

Dr. Peters asked if the gut did not give way.

Dr. Lange replied that the cases were only very recent, although the wound was healed; that this was the third week after the operation, and there had been no trouble, but even at the time he used the catgut against his better judgment, as he had nothing else on hand.

Dr. Weir remarked that he used catgut, as he thought it was best, as the wound would heal without any trouble. With the use of the silver wire a sinus was frequently kept up until the suture was discharged or removed. In his hands the wound only exceptionally closed over the wire. Silk had a similar objection to it.

Dr. Lange said he had not used silver wire; he thought the silkworm gut was best.

Dr. Weir stated he had tested the use of catgut, and found it would last nearly two weeks.

Dr. Abbe said that he had used silver wire in three cases, and it had caused ulceration, although he had used great care. In one case, although suppuration occurred, it granulated over the wire. He had operated for hernia over forty times. The use of silver wire, advocated by Banks, is his only modification of the German method.

Dr. Wyeth asked Dr. Abbe how many of his cases had been really cured? how many had been able to go without a truss?

Dr. Abbe thought about one-third or one-fourth have a recurrence of the hernia at about the end of two years, the majority going from one to two years. He thought, with a light truss, they would be able to attend to their duties for many years. He thought a very important point was that the femoral hernias are almost invariably cured, while the inguinal are more difficult to cure. He thought it was those cases (the femoral) which often can go without a truss after the operation.

Dr. Weir remarked, as to this point of recurrence, he thought the method of leaving the wound open, filling it with iodoform gauze, and allowing it to heal from the bottom, would give better results. It had given satisfactory results in his cases for the past two years, and he was led the more to place reliance on this procedure. Since then it had also recently been advocated by Nussbaum, who treated the wound openly after a free employment of the actual cautery.

Dr. Wyeth said that, out of the number of cases in which he had operated for the radical cure of hernia—some strangulated and some not—in all about twenty cases—he really could not state positively that more than two had been cured.

(*From our Special Correspondent.*)

Ligature of both Superior Thyroid Arteries for Difficult Respiration in Goitre.—At a recent meeting of the Imperial Royal Society of Physicians of Vienna, Prof. Weinlechner exhibited a woman with goitre, in whom he had ligatured both superior thyroid arteries on account of great difficulty of respiration, and the operation afforded marked relief.

The patient, aged thirty-three, was affected with goitre since her childhood, at last the tumor increased in size. On the eighth of October she came into Prof. Weinlechner's clinic, exhibiting a livid color with great difficulty of respiration, which increased on the slightest movement. On the right side, the goitre was the size of a fist; on the left, it was somewhat smaller. On the upper part of each half of the tumor the superior thyroid artery appeared much distended; her voice has been since childhood somewhat hoarse, but there was no affection of the larynx. As there was much difficulty of respiration, Prof. Weinlechner was anxious to perform a total or a partial extirpation of the tumor, and

for this reason ligatured, after the method of Wölfler, both superior thyroid arteries. As both arteries could be well felt on both sides, the operation was not difficult. Prof. Weinlechner remarked that the patient felt better immediately after the operation, the trouble of respiration diminished, and the goitre has since shown a decrease of seven centimetres in size. He said he would, perhaps, later, ligature also the right inferior artery. What was remarkable in this case was the fact that, soon after the operation, the patient had a series of spasmodic attacks, which disappeared after the lapse of some days. There was, however, no question of tetany, as during the attack there were also present clonic cramps, and the face showed great congestion.

PARIS.

(From our Special Correspondent.)

Transmission of Symptoms of Hysteria under the Influence of a Magnet.—M. Babinsky, in a paper read at the Paris Biological Society, stated that, under the influence of a magnet, certain hysterical symptoms may be transferred from one person to another, even should these persons be placed at some distance from each other. In a first series of experiments, practised upon two hystero-epileptic patients capable of being hypnotized, the hemianæsthesia from which they suffered was transmitted from one to the other, as well as other symptoms produced in one of the patients by suggestion; different forms of paralysis, brachial or crural monoplegia, hemiplegia, paraplegia, coxalgia, dumbness, etc. In a second series of experiments, one of the above mentioned patients was placed in communication with patients suffering from different forms of hysterical spontaneous paralysis. These symptoms were transmitted to the hypnotized patient, but continued in the patients who exhibited them. After two consecutive experiments an improvement was observed in one case of spontaneous paralysis. In a case of hemiplegia following an hysterical attack, M. Babinsky succeeded in causing the disappearance of paralysis after four consecutive experiments, such as above described. A method of treatment is thus determined. The author has proved by other experiments that hysterical symptoms are not the only ones capable of transmission. He succeeded in transmitting other symptoms, such as paralysis, tremor, etc., combined with organic changes of the nervous system. In these experiments, made in Dr. Charcot's ward at the Salpêtrière, suggestion or simulation was carefully avoided.

Fire at the University of Virginia.—The anatomical hall belonging to the medical department of the University of Virginia was destroyed by fire on the 20th of November. The loss is estimated at $8000, a portion of which is covered by insurance. The medical course will not be interrupted in consequence of the loss sustained.

The Baltimore Academy of Medicine has conferred its annual prize this year upon Dr. Frank Donaldson, Jr., and Dr. A. B. Arnold. These two gentlemen have submitted to the Academy papers of equal merit. Dr. Donaldson's paper was on "Diaphragmatic Pleurisy," and Dr. Arnold's on "Circumcision."

A Chair of Orthopedics in Naples.—The Italian Minister of Public Instruction has officially established a chair of orthopædic surgery at the University of Naples, designating Professor D'Ambrosio for the first incumbent.

A Curious Sewage Case was decided in a Detroit court, the other day, involving the right of a citizen to use a sewer constructed by private subscription in which he had refused to join. The Polish residents of a suburb since included within the city limits, had built the sewer, and asserted the right to exclude the non-paying neighbor from its benefits. In making his connection with the sewer, this person was assaulted by the Poles, and called in the police, by whom he was protected in the operation, and several of the Polish defenders of what they supposed to be their property were arrested. They sued for trespass and false imprisonment, and were nonsuited.

Jaccoud's Dictionary.—The fortieth and concluding volume of the *Dictionary of Practical Medicine and Surgery*, which has been brought out by Dr. Jaccoud, Professor of Clinical Medicine in the Faculty of Medicine of Paris, has just appeared. The complete work, the production of which has occupied many years, contains 33,000 pages and 3600 illustrations.

English Beri-beri Commission.—Drs. Pekelhäring and Winkler, of Utrecht University, have been commissioned by the Colonial Minister of Holland to proceed to the East Indies for the purpose of investigating the causes of Beri-beri.

Death under Chloroform.—An inquest was recently held at the Manchester Workhouse, Crumpsall, on the body of a man who died while under the influence of chloroform, administered for the performance of an operation. The jury returned a verdict of "Death from misadventure," and were of opinion that the drug had been skilfully and properly administered.

Charges for Disinfecting in Berlin.—A public disinfecting station has been established by the Berlin civic authorities, where as far as possible high-pressure steam is employed. For such articles—leather goods, for example—as would be injured by this process, chemicals are substituted. The charge is one dollar for each cubic metre of space occupied in the disinfecting chamber, while the articles requiring chemical treatment are charged at the rate of 80 pfennings, or less than twenty-five cents each per hour of treatment.

Pass and Pluck in Prussia.—During the past *annus medicus* in Prussia, of 434 candidates for the State examination for practitioners, the "one portal" to the profession, 175 were rejected, while 259 passed, 16 of them with the distinction "very good." Of 220 candidates for the pharmaceutical license, 190 passed, 30 being rejected.

Cremation.—On November 11th, the tenth cremation took place at the crematorium belonging to the Cremation Society of England, at St. John's Woking. The remains were those of a lady, aged forty-one, and

they were brought from the residence of the deceased in Leicestershire. The ashes weighed 3 lbs. 15½ ounces. It has been stated that the crematory is offensive during incineration of a body, but this is utterly untrue. Even to anyone standing on the crematory platform there is an entire absence of smell from even the burning wood, and no one could tell whether a cremation was taking place or not, so far as the sense of smell goes. This statement is but due to the founders of the Society, who chose the best system extant, a system which has been approved by the Paris authorities for erection at l'ère la Chaise.

A Fungus Developed in Human Saliva.—M. Galippe, having filtered saliva by means of Pasteur's apparatus, the filtered saliva remaining undisturbed, saw appear at the lower end of the filter, not in contact with the saliva, a mushroom made up of tubes of mycelium and of spores. By the advice of Prof. Max Cornu, M. Galippe has cultivated this fungus in Van Tieghem cells, and has been able to prove that it was neither an aspergillus nor a penicillium. This fungus, which has neither been described, nor drawn heretofore, belongs to the monilia family. M. Galippe proposes to give it the name of Monilia sputicola.

Women as Sanitarians.—The ladies of Beekman Hill and vicinity in New York City, have been organized into a Ladies' Health Protective Association since December, 1884. The Society now numbers 150 paying members. Their work met with a quick reward, and, for a time, nuisances were scarce. This success, possibly, made them less active, but now several nuisances have required new activity. They have attacked the slaughter-house nuisances, manure storage grounds, and the removal of all cows from the city. They will also undertake to better the condition of the tenement houses by compelling landlords to light halls by night and to keep them clean.

Typhoid from a Single Dose.—M. Dujardin-Beaumetz has forwarded to the Paris Academy of Sciences a communication on the Pierrefonds typhoid cases last summer. M. Fernet, who occupies a high post at the Ministry of Public Instruction, his wife and family, hired a house at Pierrefonds, a fashionable resort near Compiégne, contiguous to two others. After they had rented it for the season they were told to beware of the water in the well. On this account they drank exclusively mineral water until the last day, when the stock was out, and the servants were too busy preparing to return to Paris to go to fetch some bottles from the chemist. Madame Fernet said, "For once surely there can be no harm in drinking the well-water." They drank it. Six out of the nine persons have since died, including one of the servants. The cook, two of the four children, and Madame Fernet had had typhoid fever before, and though attacked again by it after their return from Pierrefonds, have got through the illness. The well has been examined and is reported to contain the bacilli which are believed to be associated with typhoid fever. This is a common danger to which visitors to so-called health resorts, both on the continent and at home, are frequently subjected. The facility with which well-water is infected is hidden from the population by the impunity with which filthy well-water may often be drunk by resident families who have become acclimatized, especially when that water is for the moment infected only by non-poisonous fecal matter, and this fancied immunity often leads to habits of carelessness, for which not only themselves, but their visitors have to suffer.

Obituary Record. — Dr. Cridland Crocker Field died suddenly at his home in Easton on November 26. He was born in 1817, and began the study of medicine as a private pupil of Dr. W. E. Horner, and was graduated with honors from the University of Pennsylvania in 1837. Both his father and grandfather were physicians, as are also his sons, Benjamin Rush Field and G. B. Wood Field. The operations through which he was best known were the removal of a cervical tumor, with ligation and excision of a considerable part of the jugular vein; excision of the entire femur; excision of the entire radius; extirpation of the parotid gland, which difficult operation he had performed several times. These operations placed him in the front rank of modern surgeons. His favorite region for operating was the neck, from which he frequently removed tumors which had entirely encompassed the carotid artery.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 30 to December 6, 1886.

Caldwell, Daniel G., *Major and Surgeon.*—Granted twenty days' extension of his leave of absence.—*S. O. 278, A. G. O.*, Dec. 1, 1886.

Ainsworth, F. C., *Captain and Assistant Surgeon.*—Will repair to this city and report in person to the Secretary of War, and, on completion of the duty which may be required of him, will return to his station (New York City).—*S. O. 280, A. G. O.*, Dec. 3, 1886.

Brown, P. R., *Captain and Assistant Surgeon.*—Leave of absence for seven days, granted by post orders, is extended twenty-three days.—*S. O. 124, Department of Arizona*, Nov. 24, 1886.

Fesson, Louis S., *Captain and Assistant Surgeon.*—Granted leave of absence for four months, to date from November 13, 1886. *S. O. 278, A. G. O.*, Dec. 1, 1886.

Clendennin, Paul, *First Lieutenant and Assistant Surgeon.*—Assigned to duty at Fort Davis, Texas.—*S. O. 166, Department of Texas*, Nov. 29, 1886.

Anderson, C. L. G. (recently appointed), *First Lieutenant and Assistant Surgeon.*—Ordered for assignment in Department of Arizona.—*S. O. 277, A. G. O.*, Nov. 30, 1886.

Ball, Robert R., *First Lieutenant and Assistant Surgeon* (recently appointed).—Ordered for duty in Department of the Missouri.—*S. O. 278, A. G. O.*, Dec. 1, 1886.

Woodhull, A. A., *Major and Surgeon.*—Ordered for duty at the post of Fort Leavenworth, Kansas.—*S. O. 138, Department of Missouri*, Dec. 3, 1886.

Carter, Edward C., *Captain and Assistant Surgeon.*—Leave of absence extended six months.—*S. O. 281, A. G. O.*, Dec. 4, 1886.

Official List of Changes in the Medical Corps of the U. S. Navy for the Week Ending December 4, 1886.

Farwell, Wm. G., *Surgeon.*—Detached from the "Kearsage," proceed home and await orders.

Gatewood, P. A., *Passed Assistant Surgeon.*—Detached from the "Kearsage," proceed home and await orders.

ORIGINAL LECTURES.

CLINICAL ELECTRO-THERAPEUTICS: SOME PRACTICAL POINTS IN THE TREATMENT OF DISEASES BY THE VARIOUS MODES OF THE ELECTRICAL FORCE.

Being a Clinical Lecture delivered at the Jefferson Medical College Hospital.

BY ROBERTS BARTHOLOW, M.D., LL.D.,

PROFESSOR OF THERAPEUTICS AND MATERIA MEDICA IN THE COLLEGE.

GENTLEMEN: It is my purpose to-day to utilize some of the cases we now have here, and which have also happened under my observation elsewhere, to set forth some practical points in respect to the uses of electricity as a remedy for certain morbid states. I am the more inclined to the discussion of this subject, because, as must be evident to every observant physician, an "electrical revival" is now in progress. Whilst we should not be inattentive to such professional movements, we should guard against that illogical enthusiasm which takes no note of objections, but hurries on to one-sided conclusions. My position is that electricity is a most admirable remedy when used in appropriate conditions, and that its utility has the same kind of limitations as those which belong to any other therapeutical agent. The actual value of electricity is still a *vexata questio*. In the medical profession, as in the other spheres of human thought and action, there are always two opposing parties—the optimists and the pessimists, the orthodox believers and the nihilists. The former accept everything unhesitatingly; the latter deny everything and ask for proofs, but they do not apply the Socratic method further, for, when the proofs are forthcoming, they continue to deny. A position of mere negation settles nothing. The Scriptural injunction to try all things and hold fast to that which is good, is the true position for us to assume.

One of the most significant facts of the electrical revival is the use of galvanism to remove inflammatory deposits so situated as to be within the immediate influence of the poles. The terms "catalytic" and "cataphoric" are now used to explain this action, but it must be confessed the notions associated with them are rather hazy. There seems to be an impression amongst the new advocates of the use of galvanism to cause the disappearance of exudates, that this phrase, catalytic, is new, and hence that the conception embodied in it is also new. This is an error, for if anyone will take the trouble to look over the work of Dr. Robert Remak, of Berlin—the apostle of the modern galvanic dispensation—he will find not only the word "catalytic," but, for the most part, a very true conception of the nature of the action.

We have here various cases that illustrate the utility of galvanism, and I have had many in my private practice. Amongst those seen here are cases of recent deposits about the joints the result of rheumatic inflammation, cases of exudations about enlarged and inflamed lymphatic glands, and a case, in especial, in which subacute pleuritis with extensive exudation set up changes in the lungs characteristic of that form of phthisis. I must call your attention to this example of the success of electrical treatment. This young man, the son of one of the College janitors, is now employed here, and you see him every day. He is now in robust health and seems to have recovered, but when he was put on the electrical treatment he was thin, weak, had a severe cough, night-sweats, diarrhœa—indeed, all the symptoms of consumption, and the physical corresponded with the rational signs. Every day for a long time the intercostal spaces were acted on by a strength of current sufficient to cause contraction of the muscles. The diarrhœa was arrested by phosphate of sodium; his general condition slowly improved, the chest troubles subsided, and you see the result in the robust young man before you.

We have here during the winter, many cases of rheumatism, in which effusion about the joints, weakness of the member, and constant pain and soreness, remain after acute attacks. In such cases we get the best results by a combination of electrical methods; by the use of galvanism to the joints and to the cervical sympathetic faradization, of the weakened muscles, and also general faradization. We make the galvanic applications to the joints in two modes: by the polar, and by labile movements of the pole. You are doubtless aware that the fluid about the joint, in a state of rheumatic inflammation, is strongly acid in reaction. It is now supposed that the rheumatic trouble is due to the presence of a form of lactic acid; it is known that the gouty paroxysm is caused by uric acid and urate of soda deposits. Now for the explanation. According to the laws of electrolysis, or decomposition by electricity, the acids appear at the positive pole and the alkalies at the negative. It follows, therefore, that if the negative electrode be placed over the affected joint, the alkali—potassa and soda—will be diverted thither. Hence the utility of the negative pole kept in contact with the joint for a time (stabile application). There are, however, other elements in this therapeutical problem.

We know that a galvanic current can act on the vessels of a part, and improve its nutrition by increasing the blood supply. Please consider this point with care. Onimus affirms that a descending galvanic current causes increased action—the vermicular motion—of the vessels, and in this way promotes the circulation in a part. Now this is true to a certain extent, although not generally accepted. It is true of mild currents of five to ten, possibly, fifteen milliampères, but it ceases to be true when a strong current of thirty to sixty milliampères is passed. The strong current throws the vessels into a tetanic state, and thus produces an exsanguine condition of the part acted on. I have ascer-

tained this lately by careful comparative examinations, and can, therefore, announce it as a fact.

How apply this important fact to the treatment of a joint in which a rheumatic inflammation has occurred? The vessels are left in an enlarged and relaxed state; their contractility impaired. To relieve this condition mild descending labile applications are required. In other words, the positive pole or anode is placed above, over the course of the principal arterial vessels, whilst the cathode or negative pole is slowly brushed over the affected joint. In this way applied, a mild galvanic current (five to fifteen miliampères) restores the tonicity of the vessels and promotes absorption of effusions.

Besides the local applications intended to accomplish the purposes just indicated, it is useful to act on the cervical apparatus. The positive pole placed in the fossa behind the angle of the jaw, and the negative on the epigastrium, we bring within the circuit the sympathetic ganglia, the accelerator and inhibiting nerves of the heart. We frequently hear of adverse criticism of this procedure, which we also owe to the genius of Remak, but I believe those who criticise have not really considered the question properly. This mode of application brings into action the great central apparatus of the circulation, and the effect is to increase the tone of the vascular system throughout. By this method Meyer, of Berlin, asserts that he has caused the disappearance of rheumatic nodosities of joints. Although optimist as I am said to be, I cannot quite accept such a statement.

Beside the galvanic treatment in the cases of rheumatic joints, it is our custom to faradize the muscles that have been weakened and wasted by the persistent rheumatic inflammation and by the consequent disuse of the limb. Just that strength of current required to cause muscular action is the strength used; but, as you have observed, we do not act on the muscles until the joint troubles have subsided.

Now, gentlemen, I wish to put before you some very striking facts showing the power of the galvanic current to effect the removal of inflammatory exudations. I refer to the results of pelvic inflammations in women. As I am not a gynecologist I do not see the large number of cases of pelvic inflammations that occur to the specialists, but it does happen me, comparatively often, to have patients suffering with nervous conditions in large part the outcome of such local diseases, and partly also of the means used to combat them. For the last three years current medical literature in this country, and especially in Germany, has contained many papers with illustrative cases showing that by the persistent use of galvanism exudations in the pelvic cavity, chronic metritis, uterine fibroids, and subinvolution of the womb are cured. Whilst the treatment is going on a simultaneous improvement in the general condition of these patients is also noted, and nervous phenomena of considerable severity disappear.

You will wish to know, of course, how to proceed in the electrical treatment of these cases. I need hardly observe that galvanism is used, and that the strength of the current, and the position of the electrodes are determined by the morbid conditions to be removed. To pass from the simple to the complex I refer first to the cases of subinvolution of the uterus, that state of the organ sometimes succeeding to delivery, in which from various causes involution does not take place, the womb remains voluminous, its vessels dilated and atonic, its mucous membrane the seat of a catarrh. When in this condition, partly because of its great weight, and partly because of the state of its annexed and associated organs, the uterus is apt to become misplaced. Obviously here, two objects are to be accomplished: to induce firmer contractions of the muscular tissue; and to restore the tone of the vascular apparatus. One electrode—the negative—is introduced into the vagina in contact with the uterus; the other—the positive—is put on the abdomen. The vaginal electrode should be perfectly insulated up to the metallic button or cylinder in which it terminates. If currents of great intensity are to be used, the metallic terminal of the electrode should be covered with absorbent cotton well moistened. The external electrode should be a large, well-moistened sponge. The negative is the vaginal electrode, because at this the alkalies appear, and it is therefore less irritating and at the same time more resolvent in its action. When the intention is merely to act on the organic muscular fibres sufficiently to increase the contractile action of the uterine elements and the vermicular movement of the vessels, a mild current—five to fifteen milliampères—suffices; but if on the other hand decided electrolytic effects are desired, and congestion is to be removed, much stronger currents are required—thirty to forty milliampères. I have already stated this, but the facts are important enough to warrant their repetition. In the condition of subinvolution the stronger currents are needed to remove the congestion.

In the cases of chronic metritis, of pelvic exudations, and of fibroids, our purpose is to increase the nutritive activities of the diseased parts, and this we effect by persistent and uniform applications of currents of moderate intensity.

In this connection, gentlemen, I must not fail to call your attention to a very important application of electrolysis. I refer to the electrolytic treatment of urethral stricture—a point of practice which we owe chiefly to Dr. Robert Newman, of New York. My own experience has been rather slender, and hence I must avail myself of the experience of others. This method has evoked much unfriendly criticism. Practical surgeons are, as a rule, intolerant of those procedures which seek to cure surgical maladies on other lines than regularly orthodox principles. In some instances discredit has fallen on the method by the failure of physicians who attempted to cure stricture of the urethra by electricity, without a suitable equipment of apparatus, and of knowledge of the essential details. In a brochure lately published, Dr. Newman has exhibited the cause of the failures in a series of extracts from the letters of correspondents. If I had not frequently received such letters, I should have found it difficult to credit the existence of such impossible ignorance. What can be expected of a man who attempts the electrolytic treatment of stricture, with an old magneto-electric machine turned by a crank, the urethral electrode being a *rubber catheter!* And yet it is such self-satisfied ignorance that we find criticising electrical methods, and saying, with an air of judicial severity, "I have tried electricity, there is nothing in it." Truly there is nothing in it to such incompetents.

Attention to certain details is necessary to success. One

of the small portable batteries, zinc-carbon, of twenty elements, suffices. The urethral electrode must be an insulated sound with an ovoid bulb of metal, and having a short rather than a large curve, A current of three to five milliampères, Dr. Newman says, is strong enough, but when the patient is not impressionable, five to ten may be used. The rules I have already formulated, based on physiological data, indicate that in such a condition, the weaker rather than the stronger current must be employed. The applications must not be made often, especially not if any irritation be produced, for absorption can go on no faster than the natural powers can effect it. As to the results, Dr. Newman states that failures are the exception, and in the past year many cases have been reported confirming this view. My own experience, very limited, it is true, has been favorable, and I was informed the other day by Dr. Wolff of a highly successful case treated by him. It must be a bold and uncompromising pessimist, indeed, who can deny in the face of all this evidence.

A case of sciatica, which we have been treating here to-day, reminds me that galvanism is one of the most precious remedies we have in that affection. Of course, we do not cure all cases, any more than we accomplish the same impossible task with any other single remedy. Cases of sciatica may be arranged in several groups, and our remedies must be selected accordingly. The largest group contains those cases caused by some diathesis—the rheumatic, the syphilitic, the plumbic, etc.; the next consists of those produced by some sudden and considerable exhaustion of the nervous system, as sexual excess in the newly married; and the third group is made up of all the conditions inducing neuritis, especially mechanical injury to the nerve. These several causes of the nerve-pain must be removed, if a complete and permanent success is to be obtained.

But I will not stray off into these subjects: my purpose is to say something of the electrical treatment. I wish to emphasize the fact that for severe and protracted cases of sciatica the strongest current that can be borne is the most effective. This is a truth not generally appreciated at its real importance. Indeed, I supposed myself to be almost the only one who really had a true conception of it, but about two years ago, Dr. Gibney, of New York, published a paper advocating the same doctrine. The severest example of sciatica that has ever come into my hands, was cured in two weeks by a current strength which caused intense burning pain, and could be endured but a few minutes at a time. The patient himself, who could only get about by the aid of crutches, soon saw how much more relief was to be obtained by the strongest applications that he could endure, and hence he bore, without protest, a degree of burning that otherwise he would hardly have been willing to experience. The cases of sciatica due to recent neuritis, as yet involving no actual changes of structure, need also sufficiently strong applications to cause contractions of the vessels of the parts in a state of congestion. The electrodes should be thoroughly moistened, the metal disks or carbons well covered, and labile applications made, and also stabile, the latter predominating. Old cases, in which exudations have occurred in and about the nerve, and trophic changes, consisting in more or less wasting of the limb, and in which lesions of sensibility and motility have also taken place, are best treated by the milder stabile applications long continued, both as to the duration of each *séance*, and as to the time occupied in the whole treatment.

I must also insist on another fact, that longer individual applications are required than those now enjoined on the operator. Sessions of five, ten, and fifteen minutes are usually recommended, when much better results would be obtained from them if twice or three times as long. The care with which the shorter sittings are prescribed, seems to be intended for the benefit of the doctor, by saving time, rather than the improvement of the patient's malady. A little reflection will make the truth of this clear. It can hardly be doubted that when a decided change in the nutritive condition of parts long the seat of inflammatory deposits is to be made, there must be considerable time required. The resistance to be overcome to reach the seat of disease, the modifications to be made in the dynamical and physical condition of exudations, and the process of absorption and excretion after the materials are prepared for it, all need a certain space of time and a certain amount of power to accomplish. Now, power also needs time for its development.

This reminds me that it has been suggested to obviate the resistance opposed by the tissues overlying the affected nerve, by introducing more or less deeply as may be necessary, acupuncture needles, insulated up to near their points. Besides the pain caused by inserting the needles, very considerable burning pain is excited by the current. I have made use of this plan a few times, but I do not find that it has any advantages over simple acupuncture. So much pain is induced by the current that I have not succeeded in using more than three milliampères.

A case of infantile paralysis, so-called, present here to-day, and of which we have many examples from time to time, induces me to make some observations on the use of electricity in this affection, which is so interesting from the point of view of the electrician. A proper diagnosis of this malady cannot be made without the aid of galvanism and faradism. Do not misapprehend me by supposing that I mean no diagnosis can be made—only that an entirely correct diagnosis is not possible without the use of certain electrical appliances. That you have seen here from time to time, as in the cases now under treatment before you. The therapeutical diagnosis must be made before we can use the remedy intelligently. I mean by that, we must ascertain the condition of the paralyzed muscles as to their response to galvanic and faradic excitation, before we can decide on the form of electricity to be employed. If, now, I apply a faradic current to the paralyzed muscles of this child, and get no contractions, and yet, when I send a mild galvanic current through them, there are brisk contractions, I conclude that the muscles are in the condition known as "reaction of degeneration." It is the peculiarity of some cases of paralysis, in which the lesion is in the anterior cornua of the spinal cord, that with the loss of power there occur wasting of the muscles, and in these we find the reaction of degeneration most characteristic. In these cases, also, the good effects of electricity are most conspicuous, but before promising how much to accomplish, be very sure that you have correctly ascertained the real state of the paralyzed parts.

When a child, having one or several members paralyzed in consequence of an anterior poliomyelitis, is brought to you for treatment, you may promise much if the muscles react to the faradic current, however feebly; but be reserved when they react only to the galvanic, and be responsible for nothing when neither current causes the least movement. If, however, the muscles are much wasted, and only galvanism moves them, but the joints are intact and no contractures or deformities have been brought about, you may speak hopefully of the results of persistent electrical treatment. If the muscles yet react to faradic stimulation, that is the current to use, but only strong enough to give the muscles some motion, and thus exercise them gently for fifteen minutes every day. Do not make the mistake of those electrical enthusiasts who use the current so vigorously as to tire the muscles. Furthermore, the character of the interrupter with which your machine is fitted is an important element in the success of the faradic treatment. You observe that the faradic instruments in use here have an arrangement that permits slow or rapid interruptions. The machines of Flemming and of the Galvano-faradic Company of New York, are the only ones that I know of which have a satisfactory interrupting hammer. When arranged to run slowly, you observe at each break in the circuit there is a distinct muscular contraction followed by an interval of complete relaxation. The Neef's hammer arrangement vibrates so rapidly that the muscle is tetanized for the time being, and hence is more quickly fatigued, because the contraction is not a physiological one.

Beside the local treatment of the paralyzed muscles, it is very necessary to act on the spinal cord, the real seat of the lesions. As the condition of the cells of the anterior cornua is one of impaired nutrition, the descending stabile current—not too strong, from ten to twenty milliampères—is that which brings about the best results. The positive pole should be placed over the cervical vertebra, the negative on the sacrum, the sponges well moistened and kept in position (stabile), and the current made to pass for ten to fifteen minutes.

You are no doubt aware, gentlemen, that a similar disease to that called infantile paralysis, occurs, also, in adults, but it is not often encountered here, and at present we have no example of it. We do have, however, cases of neuritis which resemble in respect to their merely objective symptoms those paralyses due to disease of the multipolar ganglion cells of the anterior cornua. The reason for this similarity is found in the fact that when motor-nerve bundles are changed by an inflammation, the muscles innervated by them undergo the alterations of structure manifested by the "reactions of degeneration." Late experiences have proved that neuritis is a common cause of certain sensory and motor disorders—cramp, paralyses, neuralgia, and anæsthesia. One of the practical experiences of the new developments regarding neuritis, is the curative effect of rightly applied electrical treatment. As I have just had something to say on this topic, there is no need to occupy further time with it, the more especially as I wish to make some practical observations on a nervous state very common in these days, called by the general public "nervous prostration," and by the medical profession *neurasthenia*. Having had no inconsiderable experience with this malady, I have formed some opinions in regard to its therapeutical management which I wish to put before you so far as the electrical part of it is concerned. I may, however, so far diverge from this, as to give a definition of neurasthenia as a basis for the treatment.

From my point of view neurasthenia consists essentially in an exaggerated susceptibility to bodily impressions and false reasoning thereon.

I will not stop to explain or defend this view. Some of the reasons for it may appear during the course of the exposition of the electrical treatment; but for the present I have merely to speak of the kind of electrical applications most effective. Since the advent of statical electricity, that mode of the force has occupied the first place in the estimation of the French school of neurologists; but in Germany the various forms of electrical baths have got to be the fashion in the treatment of neurasthenia. It is quite apparent, indeed, that the best results have been obtained from those forms of electrical treatment most complicated and imposing, or, in other words, that most appeal to the wonder-sense of the patient. It might be assumed from this that any treatment will be successful if it make a sufficiently profound impression on the morbid consciousness of the patient. Not so. Although the "faith cure," the "mind cure," and other similar psychical agencies have had some successes, they have not been so numerous and unequivocal as to justify the belief in their individual sufficiency. That such an influence will change the mental state from one of depressed self-esteem and of illusions of sense perceptions to one of hope in which everything seems possible, is surely a clear indication of the mode in which the electrical applications help to bring about a normal state.

The two methods of electrical treatment best adapted to cure neurasthenia and allied states are general faradization and central galvanization, and they should be used in alternation; but the former is applied for a longer time than the latter. General faradization, first proposed by the late Dr. Beard, of New York, consists in applying the electric brush excited by a moderate current of faradism to the whole surface of the body. One electrode—a moistened sponge—can be placed on the neck, and the other electrode, holding a wire brush, is passed over every part of the body, or the feet may rest on a metallic plate covered with felt, or be placed in a vessel of warm salt solution. Beard's method has not been popular in this country, partly because of prejudice against the author of it, and partly because regarded as unscientific. The criticisms have not been just. In Germany Beard's method has been practised by some of the most eminent neurologists, who have not failed, also, to point out that general faradization and the dipolar electric bath are almost identical. In the latter, however, the current reaches all parts of the body in nearly the same moment of time, and this constitutes the only difference. It is doubtful whether this be an advantage.

In using general faradization only such a current strength is advisable as affects the sensations agreeably. One of the real objects of the method is to change the morbid perceptions of peripheral impressions. It is not wise to effect this by an action of a painful kind. Daily *séances* of fifteen to twenty minutes are best.

Central galvanization, which we also owe to Beard,

consists in the application of the electrodes so as to bring within the circuit the cervical sympathetic, the pneumogastric, the phrenic, the cervical portion of the cord with its bundles of nerves, and the dorsal portion of the cord with its connecting nerves. The first step consists, as you often see here, in applying the positive pole to the fossa behind the angle of the jaw, and the negative to the epigastrium. The negative continuing in the same position, the positive pole is next moved to the nape of the neck, where it is permitted to remain for a time, and afterward moved down the spine to a point opposite the negative electrode. By this manœuvre, it is supposed that the great solar plexus is acted on as well as the parts already mentioned.

Within the past few years, it has been quite the fashion, I know, to decry Remak's method called "galvanization of the sympathetic;" and the claims put forth by this great electrician and his followers may not be tenable, but it will be hard to convince any practical electrician familiar with the effects of this procedure that it is not a distinctly useful practice. I may make the same remark respecting Beard's central galvanization. It may not consist in excitation of the parts I have named as brought within the circuit, but it is an effective means of accomplishing certain objects, and of these especially the increase in the vital activity of the great organs of vegetative life. In cases of neurasthenia this central galvanization is the more necessary, in that in most cases the first morbid sensations of the patient, which awaken that illusory self-consciousness that plays so important a part in this nervous state, have their origin in the abdominal organs.

The effects of central galvanization are well shown in exophthalmic goitre. This malady is a functional derangement of the cervical sympathetic, and, in consequence, the action of the heart is greatly increased, the vessels of the neck and head much dilated, the thyroid gland enlarged, and the eyes protruding. When a stabile galvanic current is passed through the sympathetic ganglia of the neck under these circumstances, the pulsations of the heart are lessened in number, the vessels contract, the thyroid shrinks, and the eyes become less prominent. It is true when the current ceases to pass, the effects disappear in large part, but if the applications be continued, finally the functional derangement disappears, and the normal condition is resumed again. As I have in various instances witnessed, exophthalmic goitre is curable by galvanism alone. Now, if the results which we can see take place under galvanic stimulation, is there any reason to discredit those which are said to be produced in neurasthenia by central galvanization? I hope you have distinctly realized the principle which governs the practice under these circumstances.

Let me repeat it with emphasis. When our object is to secure contraction of the vessels, we use strong galvanic currents occasionally interrupted; when we desire to improve the activity of the circulation, and promote nutrition, we use milder currents and stabile applications of sufficient duration. The latter is the method required in neurasthenia, for the most part; the former in exophthalmic goitre.

Many other tempting subjects are suggested by the cases in attendance, but my time having now expired, I must defer the consideration of them to another day.

A SUCCESSFUL NEPHROLITHOTOMY.

BY SAMUEL W. GROSS, A.M., M.D., LL.D.,

PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

JOHN R., a coal miner, æt. thirty-three, was admitted into the Jefferson Medical College Hospital on October 1, 1885, having been sent to me for an operation by Dr. D. T. Jones, of Plymouth, Pa., who had diagnosticated the existence of a stone in the left kidney. Repeated examinations of the urine, made by Dr. Jones during the preceding two months, disclosed a small quantity of albumen, a few tube casts, numerous mucous casts, crystals of oxalate of lime, and a few pus and red blood corpuscles. The patient, during the entire period of Dr. Jones's attendance, suffered from malarial fever, accompanied by vomiting, which induced intense pain in the left loin, and after which the urine was smoky. During the past two months he has lost twenty-three pounds, which he attributes to the chills and fever.

Palpation of the loin and abdomen failed to detect any fulness or hardness, and forcible pressure was unattended with tenderness. There had never been an attack of renal colic, and the urine was passed, on an average, only three times during the twenty-four hours. Daily examinations of the urine during the interval which elapsed from the date of his admission to that of the operation disclosed that the fluid was acid, of sp. gr. 1.022–1.024, and that it contained a trace of albumen, some red blood disks, strings of mucus, epithelium similar to that lining the pelvis of the kidney, and an abundance of crystals of oxalate of lime, with some fragments of the same nature.

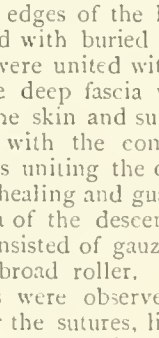
Until four years ago the patient had enjoyed good health, when he was seized with a dull, heavy pain in the left loin, which extended toward the median line of the abdomen, between the umbilicus and the pubes. This pain remained constant for two years, was relieved by recumbency, but set in again as soon as he got on his feet; and was occasionally sharp, and felt about the crest of the ilium. During the past two years it was not experienced daily. Throughout the entire time the pain was greatly increased by work, by rapid exercise, by railway travel, and by coughing, and on the day following such exacerbations he passed bloody urine once or twice. On one occasion, five months ago, after an attempt to work, he had an attack of retention of bloody urine, which was occasioned by five clots, each of which was about an inch long, and of the diameter of a large straw. Since the date of the appearance of the first symptoms he has been incapacitated from earning his living, every effort at work being followed by a paroxysm of severe suffering and hæmaturia.

Although frequency of micturition was conspicuous by its absence, and there was no swelling or tumor of the loin, nor tenderness on rough manipulation, nor renal colic, the almost constant pains, which were greatly aggravated by motion,

and the acts of vomiting and coughing, and the hæmaturia, along with the presence of strings of mucus, epithelial cells similar to those lining the pelvis of the kidney, and crystals and fragments of oxalate of lime, left little room for doubt as to the existence of an oxalate of lime calculus in the renal pelvis.

On October 13th, the patient having been placed under the influence of ether, and resting on his right side with a pillow under the abdomen and loin, an incision, four inches and a half long, and beginning at the edge of the erector spinæ muscle, was made parallel with the last rib, and three-quarters of an inch below it, and carried through the successive layers of muscles and aponeuroses, until the perirenal fatty tissue was reached. During this stage of the procedure two arteries in the latissimus dorsi and internal oblique muscles were secured with catgut ligatures. The circumrenal fat having next been torn through with forceps, the index finger, passed over the posterior surface of the kidney, came in contact with a hard substance at the site of the central infundibulum of the organ, which, on the insertion of a long needle, proved to be a stone. The overlying renal tissue was then scratched through with the finger-nail, and extraction attempted with a small lithotomy forceps. This failing, the anterior wall of the belly having been pressed backward by an assistant, the object was accomplished by the combined use of the finger and scoop, and the slight hemorrhage was arrested by pressure with a sponge wrung out of hot water. A drainage tube, with a lumen of nearly five-sixteenths of an inch in diameter, having been inserted close up to the opening in the kidney, the edges of the lumbar aponeurosis were approximated with buried catgut sutures, the divided muscles were united with two tiers of the same material, the deep fascia was secured with a single row, and the skin and superficial fascia were brought together with the continued silk suture. The objects in thus uniting the divided tissues were to facilitate rapid healing and guard against the occurrence of hernia of the descending colon. The outer dressings consisted of gauze and jute, secured in position by a broad roller. The strictest antiseptic precautions were observed throughout, the materials used for the sutures, ligatures, and dressings having been prepared with the usual solution of corrosive sublimate, and the instruments having been thoroughly scrubbed and soaked in a three per cent. solution of carbolic acid.

The stone weighed fifty-eight grains, was composed of oxalate of lime, and, as is shown in the



woodcut, was heart-shaped, rough on its exterior, and seven-eighths of an inch long, six-eighths of an inch broad, and a quarter of an inch thick. The kidney appeared to be perfectly normal in size, contour, and consistence, and there was not the slightest evidence that it contained pus.

For the first twenty-four hours the patient suffered from pain and slight shock. The pulse was 120, the temperature 98°, and he vomited frequently during the night. These symptoms were allayed by the hypodermatic use of atropia and morphia, and iced dry champagne. The catheter drew off twenty-seven ounces of clear urine. At the expiration of thirty hours the dressings were changed, when they were slightly stained by bloody urine. At this time the urine passed by the patient was tinged with blood, and it continued to be of this nature for twenty-four hours.

From this time until his discharge the patient did admirably. On the fourth, thirtieth, and thirty-eighth days, he suffered from chills, during which the temperature ran up to 103°, but which readily yielded to thirty grain suppositories of quinine. For the first two weeks the daily quantity of urine passed by the urethra varied between eighteen and thirty ounces; during the third week between twenty-nine and forty-seven ounces; during the fourth week between fifty-four and seventy-five ounces; and after this period, on several occasions, considerable quantities of urine passed from the sinus, when there was a corresponding diminution in the quantity passed by the urethra.

The entire wound, with the exception of the point of emergence of the drainage tube, healed by the first intention, and the continued suture was removed on the twelfth day. The dressings were changed as often as occasion demanded. The drainage tube was shortened and replaced by others of smaller calibre from time to time, but it was not finally dispensed with until November 29th, when the patient left his bed. The sinus had closed on December 5th. The man was sent home on December 9th. He had gained much in flesh, was perfectly free from suffering, and in every respect comfortable.

Remarks.—The case now narrated is another illustration of the debt which surgery owes to Mr. Henry Morris, who was the first, in 1880, to remove a stone from the otherwise healthy kidney, that is to say, a kidney not distended by pus or urine. By an early resort to nephrolithotomy the functions of the kidney are not only preserved, but suppurative destruction of the organ is prevented. The procedure is, moreover, comparatively safe, more successful, indeed, than lateral lithotomy in the adult. Thus, of 34 cases of which I have a record, 3, or 8.8 per cent., perished, 1 from the effects of morphia, 1 from blocking of the opposite ureter by a calculus, and 1 from pyæmia. If these results be compared with those following the removal of a stone from a disorganized kidney, the contrast will be seen to be most striking, since, of 33 cases of nephrotomy for calculous pyelitis or pyonephrosis, which I have collated, not less than 11, or 33 per cent., died.

In the majority of examples of nephrolithotomy the stone was small. In four instances, however, it weighed respectively four hundred and seventy-three grains, five hundred and fifty-six grains, two ounces, and two ounces and a quarter; and it is noteworthy

that these cases recovered. The most remarkable case on record is that of Clement Lucas, in which, on account of suppression of urine for one hundred and two hours, a calculus was removed from the left kidney of a patient whose right kidney had been extirpated, three months and a half previously, on account of calculous hydronephrosis. This case shows that there is little fear of the operation seriously interfering with the secretion of the urine; and, taken in connection with the fatal case from blocking of the opposite ureter by a concretion, it demonstrates that the trouble was symmetrical in 2 of the 34 examples in which the operation has been performed. It may also be mentioned that all of the recoveries were perfect, except the first case of Morris, in which a sinus persisted five years subsequently.

Under no circumstances should an otherwise healthy kidney be extirpated on account of a stone. The symptoms of renal calculus being present, the organ should be cut down upon and explored with the finger and needle, and by incision, if the other methods fail to detect it. Such a procedure has thus far proved to be perfectly safe, as is shown by 29 cases in which a stone was not found, and which I have collated. All recovered, and in four the organ was cut into. Hence, of 63 examples of attempted or accomplished nephrolithotomy, only 3, or 4.76 per cent., perished, a measure of success which is seldom attained in any other capital operation.

NOTES ON THREE CASES OF TROPICAL BERI-BERI, AND ON SOME ANALOGOUS INDIGENOUS CASES OF MULTIPLE NEURITIS.[1]

By E. C. SEGUIN, M.D.,
OF NEW YORK.

Having been courteously invited to participate in this evening's symposium on neuritis, I bring my mite of contribution in the shape of the relation of three cases of beri-beri, which, coming from tropical parts, have been under my care. That this disease is rarely seen in our latitudes, though very common in South and Central America and in the islands of the Gulf, I infer from the fact that it has not, to my knowledge, been discussed in medical societies or in private relations in New York during the past ten or fifteen years.

My apology for relating the following cases is that they well illustrate the prominence of neural symptoms in beri-beri, and that they justify the opinion expressed by a number of observers (Dr. B. Scheube and others) that beri-beri, or kak-ke, as the affection is called in Japan, is essentially a multiple, poly- or pan-neuritis, occurring as an endemic infectious (?) disease in many countries of the globe in both hemispheres. That beri-beri, or kak-ke, is nothing more than a multiple neuritis I am not prepared to say, and, indeed, my experience is so extremely limited that I can only use my cases to illustrate the probable neural origin of many of the symptoms of the disease.

In looking for notes of cases of multiple neuritis occurring in my local practice I found several. One, very typical, was recorded under the title of alcoholic polyneuritis; others were included in my essays on poliomyelitis anterior,[1] as examples of that disease. These three cases were marked by the ordinary symptoms of multiple neuritis—numbness, and partial anæsthesia, irregularly distributed atrophic paralysis, with degenerative reactions; and, besides, by œdema of the extremities. I was struck by the resemblance of these cases, thus symptomatized, to mild cases of the mixed form of beri-beri. There is quite a resemblance, if not a similarity, between Cases I. and II. of the category of beri-beri and Case I. of the category of indigenous neuritis.

Another aspect in which a study of beri-beri is of interest to us, is that the disease may take root and acquire considerable development in the United States. It appears that the affection has prevailed in Para, Brazil, for only a few years, perhaps only since 1878, having been brought there from Southern Brazil and Paraguay; and, as it is not uncommon in Cuba (at least the so-called wet form), it may very well show itself in the Gulf States.

With this brief preface, I pass on to the cases themselves.

First Category: Cases of Beri-beri.

Case I.—A Cuban lawyer, aged twenty-six, consulted me September 9, 1885, with letters from Drs. Landeta and Desvernines, of Havana, of which the following is an abstract: Married man of good constitution. Never had syphilis, scrofula, or paludism: never seriously ill. In summer and autumn of 1884, dyspeptic symptoms.

Symptoms of present illness: (1) Early in November (1884) pains in lower third of both legs. (2) In a few days these parts were slightly œdematous, while the malleoli and feet remained free from swelling. (3) Simultaneously, cardiac palpitations; rapid pulse, from 110 to 120. (4) Some muscular weakness was noticed in legs; walk difficult and done on tip-toe, or on fo ward part of foot. (6) Toward end of November the pulse was steadily 120 or more beats; large objective palpitations and souffles were noticed over cardiac area. (7) Œdema appeared in the face, invaded the whole of the legs, thighs, feet, and genitals. (8) The muscles of the thighs and legs became soft and painful to touch: there seemed to be intramuscular œdema. Toward the end of the month patient was unable to leave the bed; the palpitation was intense, and there was great dyspnœa. The thenar and hypothenar eminences became soft; the patient could no longer write, or use fork, spoon, etc. Later the weakness became such that the legs could not be lifted from the bed: face was nearly twice its normal size. The patellar reflex was abolished. Some muscles showed loss of contractility under electricity (*vide infra*).

As a summary of symptoms in the fourth and fifth weeks of the disease, it may be said that there

[1] Read by invitation before the Philadelphia Neurological Society, November 22, 1886.

[1] Myelitis of the Anterior Horns; or, Spinal Paralysis of the Adult and Child. New York, 1877. (Private edition, 1874.)

were anasarca, paralysis with electrical changes in certain muscular groups, cardiac bruits, with pulse up to 140 beats per minute, dyspnœa. At no time was there fever, and no albumen or sugar was ever found in urine.

Under the use of infusion of digitalis, cinchona, and nutritious food, these symptoms abated, and there was decided improvement by the end of December (eighth week). Under electrical treatment and sulphur baths the motor paralysis gradually passed off, and the patient was able to stand in March: steady improvement thereafter continued, the cardiac symptoms had about ceased by the end of December.

Dr. Desvernine's letter refers more particularly to the state of the heart, and to the electrical reactions. At the height of the disease the heart was enlarged, more especially the left ventricle, and the murmur heard was a mitral regurgitant one. These signs were due, Dr. Desvernines believes, to myocardial lesions; the endocardium being unaffected. This view is borne out by the disappearance of the symptoms.

There was an apparent pseudo-hypertrophy of all muscles of the body (œdema). A piece of muscle removed by Duchenne's trocar showed simple atrophy of its muscular fibrillæ with intramuscular œdema and proliferation of the connective tissue. The electrical reactions were not taken during the acute period of the disease, but afterward were very fully studied, and there were found with both currents the "reactions of degeneration characteristic of perverted nutrition in nerve and muscle."

The diagnosis made by Drs. Landeta and Desvernines was beri-beri or kak-ke, of the mixed form, and Dr. Desvernines recognized in the case the grounds for the views advanced by Scheube and Balz (from studies of the disease in Japan), that it is essentially a multiple neuritis. It is interesting to add that, while the wet form (anæmic œdematous type) is well known to the physicians of Cuba and Havana, not one of several who saw this case with Dr. Landeta had seen an example of the mixed form.

When I examined Señor M. about ten months after the beginning of the attack, he presented no objective symptoms except a degree of abnormal flushing of the face. Excepting a slight quantitative reduction in contractility of the calf muscles, I noticed no abnormality in the faradic and galvanic reactions of nerve, trunk, and muscles. The pulse was slow, from 57 to 63, and the heart normal in size and sound. The patient complained of occasional vertigo, and want of power of mental concentration. He was well about October 10th.

Case II.—Mr. J. G., a married man, thirty-eight years of age, a native and resident of Panama, was brought to me, for consultation, by Dr. Pio Rengifo, of New York, on November 17, 1885. Is a tall, strongly built man, who has enjoyed good health, except that sixteen years ago he had a single chancre with suppurating buboes, but no secondary symptoms. Had a year's treatment with Dupuytren's pills and iodide of potassium. A healthy child has been the result of marriage. In the past eight years occasional palpitations, supposed to be due to gastric disorder. Is temperate in use of stimulants. About two months ago noticed numbness in toes and fingers. This has continued as a constant symptom, affecting tips of fingers, toes, and forward part of soles; on lying down, however, there has been a certain sense of numbness in the legs and forearms. Pains appeared later, of two kinds: first, aching pains in the calves, which were hard and tender; second, sharp pains in spots in fingers, legs, and feet; not, however, repeated pains in spots, with cutaneous hyperalgesia (not fulgurating pains). Knees were weak, and toes seemed cramped. Had sensation of band around toes Had no vesical paresis, loss of sexual power, or spinal pains; no abnormal reflexes in legs, no diplopia. In last three weeks distinct œdema of feet and legs; has noticed that the calves measure two or three centimetres more in the evening than in the morning. During the past fortnight there has been marked improvement in power of legs, and in the paræsthesiæ.

Examination.—No objective symptoms about eyes or face. Grasp: right side, 38 and 32 degrees; left, 31 and 22 degrees; decidedly weak for a man of patient's muscular development and size. Sensibility is not positively diminished in fingers, but there is some confusion in estimating number of points applied; distinguishes texture of cloths well. No analgesia. Fingers are skilful; handwriting unchanged.

Lower extremities: no patellar reflex; walks a little awkwardly, with slapping of the feet; but, strictly speaking, there is no ataxia. Staggers when standing with eyes closed and feet together, but with eyes open stands fairly well, even on one foot. Sensibility to æsthesiometer is dull, but he localizes impressions well; no analgesia. Those movements of toes which are controlled by interossei are limited. There is yet a trace of œdema over the tibiæ. No electrical examination.

I concurred in Dr. Rengifo's diagnosis of beriberi or multiple neuritis, and the same opinion was expressed by Professor Charcot, who saw Mr. G. shortly after. I recently learned that entire recovery took place in a few months. It may be of interest to add that Mr. G. presesented complete transposition of the viscera, his heart (the sounds of which were normal) being distinctly on the right of the sternum, and his liver on the left side; he was, however, right-handed originally.

Case III.—Señor J., aged fifty, a native and resident of Para, in Brazil, was referred to me by my friend, Dr. Charles E. Simmons, on November 11th, and is now under observation. Former health good; never had beri beri or severe malarial fever. Subject to "bilious attacks." In August of present year had bleeding hemorrhoids for three weeks, followed by weakness of legs. This was soon followed by tingling, numbness, and pains in the legs, and lastly by œdema, not affecting feet. By advice of physicians, Mr. J. sailed from Para, October 27th, but instead of immediately improving, he grew worse. Soon noticed numbness and awkwardness of hands; the weakness and œdema of legs increased. In the last six days the long extensors and the long flexors of

the right thumb have shown paresis, and in the last four days the same muscles on the left side have been affected. No dypsnœa, vertigo, or mental symptoms. No fever observed; urine high colored. The pains were never severe.

Examination.—Stout, well-built man; complexion pale, muddy, and tanned. No motor or sensory symptoms in eyes or face. Heart normal; no effusion in pleura. Upper extremities: all voluntary movements present except extension and flexion of phalanges of both thumbs; the two long extensors on both sides are completely paralyzed, and the long flexors partially so. The thumbs hang as do fingers in certain cases of lead paralysis. The left extensor indicis is weak. The abductor pollicis longus, and the small hand muscles are normal on both sides. Opposition well done. Supinators strong. No ataxia. Grasp: right and left, each 25 degrees on dynamometer. Sensibility is normal to æsthesiometer on finger-tips; but, by pricking, a limited area of analgesia (incomplete) is found over the left metacarpus, in the ulnar territory. Temperature well perceived. Lower extremities: the walk is somewhat feeble, but not pathological in type; can stand upon his toes, and equilibrium with eyes open or closed is nearly perfect. No ataxia. Patellar reflex subnormal on both sides. Both legs present a soft œdema in their inferior half; the calves are large but flabby. No swelling distal of ankle-joints. All voluntary movements of legs, feet, and toes can be performed; though extension and flexion of toes are done feebly. The great toes are not as much affected as are the thumbs. Sensibility is slightly dull to touch (a numb feeling) as high as the umbilicus; but the only zone of actual analgesia is on outer (fibular) side of left leg in its lower third. Temperature well perceived. Urine is dense, deposits urates; without albumen; a few small hyaline casts. Summary of electrical examination: Arms, no faradic or galvanic nerve reaction in extensor primi et secundi internodii pollicis on either side. These muscles do not respond to faradism, while galvanism yields a slow contraction, with marked tendency to tetanus: CaCC=AnCC or CaCC<AnCC. In flexor longus pollicis (both sides) there is no nerve reaction, and only a faint oscillatory C, with a strong faradic current applied directly to muscle. Galvanism gives a slow contraction: CaCC=AnCC, and the latter tending to tetanus. The long extensors of fingers on both sides yield reduced faradic contractility, and rather sluggish galvanic contraction, through CaCC>AnCC. Legs: Quantitative reduction to faradism and galvanism in calves: CaCC =AnCC. Extensor longus pollicis and extensor longus digit. have almost no faradic contractility, and to galvanism yield slow C, with CaCC=AnCC, the latter almost tetanic. Through external popliteal nerve better contractions (both by faradism and galvanism) are obtained in these muscles. Tibialis anticus and small muscles of feet, normal reactions. In other words, we have in this case a well-marked DeR, limited to the nervo-muscular apparatus of both thumbs; partial DeR in long extensors of fingers, and in extensors (and flexors) of toes.

Second Category: Analogous Indigenous Cases.

Case I.—Mrs. X., aged forty years, seen in consultation with Dr. Carreau, of New York, in November, 1885. There is a clear history of excessive drinking and sexual indulgence for many years. Patient is still drinking brandy steadily. For more than two years has suffered from gastric catarrh and failing memory. Early in past summer felt burning sensations in feet, pains in feet and legs; occasional numbness in feet and hands. At end of July marked increase in gastric symptoms, diffused swelling of hands and feet, with prickling, numbness, and a hyperalgesic state of same parts. Was unable to walk. No arthritis. Hands have also been weak. No bladder symptoms. Pains have ceased, but hands and feet are in state of painful formication; dreads to be touched. There is frequent vomiting of food and mucus. Partial dementia, with a few delusions. Urine examined several times; no sign of renal disease. *Examination:* Tongue tremulous and foul. No motor or sensory symptoms in eyes and face. The grasp is feeble, but long extensors and flexors all act. Opposition of thumb is impossible: marked atrophy of radial side of thenar eminences. Examination shows marked reduction in tactile sensibility in tips of all fingers. The hands are œdematous, with dorsum tense. No arthritis. Lower extremities examined seated: feet puffy and tense, but not red; no arthritis. All movements of feet and toes are possible, though feebly done. State of sensibility cannot be well studied, owing to patient's absurd fear of all instruments and manipulations. This also prevents any electrical tests. Patellar reflex abolished (?). Spine not tender. Diagnosis: alcoholic multiple neuritis. Treatment by reduction of brandy, injections of strychnia, galvanism, and message begun. Carlsbad sprudelsalz for gastric catarrh. A note received from Dr. Carreau, a few days ago, states that faradism did not produce contraction at first, and galvanism was used alone until March, when both currents were employed. In March began to walk, and has steadily improved. Now well, except feebleness of memory, and some numbness.

It is interesting to consider that this and other alcoholic cases bear a certain etiological relation to tropical beri-beri. In both cases we have subjects living upon a relative or actual excess of carbonaceous food, alcohol or rice, as predisposing, if not efficient causes of neuritis.

The two following cases were published in my essay on "Myelitis of the Anterior Horns" (1874 and 1877) as examples of that affection. Reading them in the light of recent advances in nerve pathology, they now appear to have been cases of multiple neuritis, with dropsical symptoms, making them strongly resemble beri-beri or kak-ke. I give them merely in epitome, referring to the original for details.

Case II. (Case XVIII. of essay).—Male, aged forty years, seen in January, 1874. In September severe "cold," with bronchitis, temporary suppression of urine, swelling of face and feet, lasting

three to four weeks. Some stiffness and subjective coldness in feet. Relieved by strychnia. October 16th, feet heavy and cold, hands awkward and fingers numb. Increasing loss of power in legs. Physician stated positively that neither this nor the former attack was due to Bright's disease. In November marked anæsthesia and nearly complete paralysis of both legs; thigh muscles remained active; no rectal or vesical symptoms. Median distribution in both hands, anæsthetic; the hands and forearms rapidly wasted. No bedsore or cincture feeling. No cerebral symptoms. Improvement from end of December, when movement appeared in toes.

When examined by me he presented an atrophic paralysis of both hands, with partial anæsthesia (mostly tactile) of finger-ends. Toes (except great toes), feet, and legs, can be pretty well moved in bed; legs much atrophied, especially in anterior tibial group of muscles. Feet are partly anæsthetic, but present (as do the legs) marked hyperalgesia. No faradic reaction can be had in both extensor pollicis, and only feeble contraction in thenar eminences. These muscles contract well, however, to galvanism (DeR). Complete recovery occurred by end of summer.

Case III. (Case XIX. of essay).—Male, aged forty-seven years, seen in March, 1884. Large, healthy man. Severe "cold" in October, 1883, with bronchitis, slowly followed by numbness and paresis of limbs. The numbness appeared at about the same time in the ends of the upper and lower extremities. November 10th, walking was possible only with the assistance of a stick or a person, but he could still dress himself. Swelling of the feet, with glossy skin, was marked; by November 14th, subjective coldness of feet. A few days later was unable to sit up in bed; much formication up to the knees, and halfway up the forearms; some anæsthesia (?) of the feet. No head or eye symptoms; bladder and rectum normal. In the middle of January, 1884, intense formication ushered in recovery; gradual improvement in power of legs and hands. Feet remained a little swollen. Some wasting of legs. In January noticed numbness in distribution of left superior maxillary nerve on face. Can now walk with help of cane and crutch.

Examination.—No facial symptoms. Movements of arms and hands good, except that extension of the right fingers is incomplete, and is very feeble on left side, especially for the thumb and index-finger. Palmar muscles emaciated, but not atrophied. Sensibility good. Grasp: right, 26 degrees; left, 16 degrees. Coordinates well. In lower extremities the only paralysis is below the knees. The left foot is but slightly movable; the right, a little more. Toes are somewhat contracted in flexion. Sensibility to contact is good down to ankle, dull below that, very dull in toes. Toes are numb. No œdema of feet or legs. Urine is dense, but free from any signs of renal disease. Electrical examination shows very great loss of faradic contractility in palsied muscles, almost complete in left extensor indicis, and in extensors of toes and flexors of feet (anterior tibial groups); feeble reaction in calves. All these muscles, however, react well to galvanism (DeR).

These three indigenous cases of multiple neuritis—one clearly of alcoholic origin, the others of unknown etiology—I submit with but little comment. They were characterized by a combination of paræsthesiæ and anæsthesia, by paralysis with atrophy and DeR, of irregular peripheral distribution, and by œdema of the extremities, without signs of renal disease. Bronchitis occurred a short time before the nervous symptoms appeared in the two non-alcoholic cases. Cardiac and respiratory symptoms, indicating neuritis of the vagi and the phrenic nerves, were the only ones wanting to produce a symptom-group almost exactly like that of severe beri-beri or kak-ke.

Consult B. Scheube, Die Japanische Kak-ke (beriberi), *Deutsches Archiv für klin. Medicin*, xxi. p. 141; xxii. p. 83 (1882–83).

SOME POINTS IN MINOR SURGERY AT THE PENNSYLVANIA HOSPITAL.

By THOMAS S. K. MORTON, M.D.,
SENIOR RESIDENT SURGEON.

Shock is combated usually by warmth and stimulants. The former is applied by means of hot baths or water bags, generally the latter. The patient is surrounded by rubber bags filled with hot water. These we have had made for the purpose. They are round, from one and a half to two and a half feet long, from four to six inches in diameter, and have a filling-hole with a screw cap at one end, and a handle at the other. Atropia is freely used. Whiskey, ether, digitalis, aromatic spirits of ammonia, or, in desperate cases, aqua ammonia itself, are given. The injection of pure ammonia is, of course, always followed by local sloughing. Mustard, hot fomentations, large enemas, and drinks of warm fluids do good service. Previously warmed blankets are a great comfort as well as of benefit.

Ether is our standard anæsthetic, although the A.-C.-E. mixture is often employed; chloroform very seldom. A small amount of the latter is found useful to relax the muscular spasm which often remains in drunkards, even when ether is fully pushed. A few drops will often permanently stop it, when the ether can be continued. A.-C.-E. has given rise to no alarming symptoms in at least two hundred administrations from my hands, and I know of no untoward circumstance attending its use here. All general anæsthetics are administered from small, square-folded, very absorbent towels. Cone or apparatus are not used. The "rapid" and rectal methods have long since been abandoned as dangerous. The patent ink-bottle stopper is found convenient to pour ether from the bottle.

During the local anæsthetic action of cocaine, we have performed many minor amputations, circumcisions, and other small operations; but with us, at least, the field of the drug in this direction is becoming quite limited. Most eye operations, however, are performed under its influence.

Divided or torn muscles, tendons, and nerves, if their ends can be seen, are sutured with catgut. If not visible, they are freely cut for, and likewise

sutured. Good function is the almost invariable result.

Subcutaneous operations, such as tenotomy, aspiration, and even exploration by needle, are performed with as much antiseptic precaution as if a large wound were made, for death has been known to occur from wound complication following each of these procedures. Therefore, knowing that there is *some* risk, no matter how trivial, it becomes one's duty to avoid it.

In the amputation of fingers and toes below the metacarpo- or tarso-phalangeal joints, rubber umbrella rings are used as tourniquets. The flaps are closely stitched, and, if there be any bleeding when the ring is taken off, a deep lateral stitch back of the line of incision on one or both sides will always effectually control it. We never put a ligature upon these arteries, finding the above method amply secure, and, so far as our last few hundred such amputations show, unattended with disadvantage.

In exarticulations at the metarcarpo or tarso-phalangeal joints ligatures are applied if possible, but if the bleeding is obstinate, a deep stitch into the palm or sole can be made to control the appropriate vessel. These operations receive the usual house dressing and a palmar splint. They are, as a rule, not dressed for from ten days to two weeks, when solid and complete union is expected and usually found.

Catgut sutures are passed through finger- and toe-nails, without fear, if by so doing crushed or cut parts can better be brought into shape, and also in operations for ingrowing nails.

We have saved many fingers, ears, and noses, which came in hanging by mere shreds of tissue, by promptly sewing them in place, and treating antiseptically. No opportunity has occurred by which to test the saving of those parts when entirely severed from the body.

Abrasions and brush burns are carefully cleansed and treated with either boracic acid ointment, or the standard house dressing.

The latter consists of: protective; Lister gauze, wrung out of 1 : 1000 $HgCl_2$ solution, and its skin surface thickly dusted with iodoform; a pad of dry 1 : 1000 cotton, and moist 1 : 1000 gauze bandages over all. We have found that Lister's boracic acid ointment makes up better if wax be substituted for the paraffine of his formula. Our receipt is: boracic acid and yellow wax, each 1 part, cosmoline 4 parts.

Ligatures are never applied except in the largest operative and accidental wounds.

Sutures run under or through the bleeding points effectually control them. No trouble is experienced in tying catgut sutures or ligatures, when the first tie of the knot is made as for a surgeon's knot. Catgut is invariably used for these purposes. In treating some hundreds of scalp wounds, no matter how extensive, I have never applied a ligature, always finding that carefully placed sutures will stop all hemorrhage.

Stitches are placed very close together in all wounds; this presupposes proper drainage if it is necessary. If so, it is secured by a few strands of finest catgut, placed along the bottom, and brought out at one end of the wound.

Small or superficial wounds as rarely require drainage as ligature. Scalp wounds are not drained unless extensive. If the edges are much contused or torn, they are excised. Quite small wounds of the scalp or elsewhere, and sometimes larger ones, are, after antiseptic closure, covered in with a minute pad of bichloride cotton, and plastered down with either pure collodion or combinations of it with such drugs as evaporated tincture of benzoine (evap. fl. ℥ij tr. benz. comp. to fl. ʒij, and make to fl. ℥ij with collodion), iodoform (10 per cent.), salicylic acid, etc. Wounds too small for stitches are similarly treated. Large wounds, of course, receive the house dressing and possibly drainage.

Very tense hematomata are freely incised, the clot or fluid blood curetted out, any bleeding vessel stitched or tied if it can easily be found, and the whole sewn up with or without a drain, according to size, and dressed with some compression.

Slowly resolving hematomata or those in which suppuration is present or incipient, are manipulated in exactly the same way.

Punctured wounds are laid open, curetted, washed with 1 : 1000 $HgCl_2$ solution, and closed as above. If the bottom cannot be reached, a small drain should be carried as deep as possible, and the best hoped for.

Gunshot wounds are treated in much the same manner. If it can readily be done, the ball is extracted through the wound or by counter-opening. The entrance and exit (if there be one) wounds are excised, the track of the ball curetted thoroughly, a small gut drain carried all the way through, and the external wounds treated as simple incised ones.

Compound fractures, if the skin wound is small, are freely cut into, washed with 1 : 1000, curetted, accurately stitched, and, if extensive, drained with catgut.

Some of them are dressed more frequently than the actual wounds require in order that good position of the bones may be secured.

Wounds of joints are treated in precisely the same manner, save that, unless they are dirty, we are satisfied with thorough washing with 1 : 1000, and omit the curette. Cure in one dressing is here attempted and good function expected.

Poisoned wounds are also treated somewhat similarily, but the utmost care is taken to get to the bottom of the wound itself and into all ramifications and sinuses with the curette and strong antiseptic solution (1 : 500). If the wound is very bad and cellulitis present or threatening, continuous antiseptic irrigation (1 : 2000) is started as soon as the cleaning out is effected.

Large glass percolating jars, with glass stop-cocks, or other regulating device, suspended over the part give best satisfaction. Whilst thus employing irrigation any wounds should be well covered with protective, the whole part covered with lint, and the solution allowed to drip upon it.

Suppurating wounds might be classed as poison wounds, for the treatment is almost the same,

namely: curette and antiseptic solution (1 : 1000 or 1 : 500), excision of wound edges and, usually, accurate approximation, with or without a drain as circumstances indicate.

Punctured, gunshot, suppurating, poison, and compound bone and joint wounds when thus dealt with, as a rule heal by primary intention and under but one dressing.

Felons, buboes, simple and suppurating cysts, inflamed bursæ, and large, small, and diffused eradicable abscesses are treated by exactly the same method and usually with like result.

Ineradicable abscesses, such as the psoas, are treated by this method as far as it can be made to go, and are then drained into an antiseptic dressing by means of a rubber drainage tube; through which they are from time to time washed out with antiseptic solution. Care must be taken in so doing, however, whether it be these or other cavities, not to let any of the solution remain in. It should be displaced by a weaker solution or distilled water.

In cutting into abscesses, old hematomata, etc., a better result is secured by opening them from one side through sound tissue.

Simple cellulitis is treated like the complicated form as described above.

Burns, if small in area, or confined to an extremity, are treated by the regular antiseptic dressing. All easily removed, dead skin, etc., is taken away; the parts washed with 1 : 1000 bichloride solution, or iodoform sprinkled on (in part for its analgesic effect), then protective in narrow strips, and the dressing and cotton. Anæsthesia may be required to do this properly.

Extensive burns are covered in with boracic acid or oxide of zinc ointment, the surface of which is sprinkled with iodoform and, if there is much pain, smeared thinly with oleate of morphia. This dressing is covered in with cotton batting and a bandage or binder.

Just here it may be well to speak of sloughs, granulations, and skin-grafting, but what is said applies to all wounds as well as burns.

Under the antiseptic dressing sloughs are very slowly thrown off. It is our custom to excise them as soon as they become demarked. If properly done this causes scarcely any pain or bleeding and places the wound days, and, perhaps, weeks nearer closure. By picking up the edge of the slough with a pair of forceps, and cutting with knife or scissors through its readily apparent junction with healthy tissue, it is easily accomplished. By this same process I have successfully, and without pain or hemorrhage, amputated even fingers and toes which we had attempted to save.

All forms of exuberant granulations are usually shaved off with a sharp knife. The moist bichloride dressing, applied without the intervention of protective, is found to produce ample stimulation, if such is indicated.

If skin grafting becomes necessary, a patch of thin skin is selected and made aseptic, as is also the granulating surface, if it is not so already. Almost microscopic pieces of the cleansed skin are then cut out by means of a purified needle and a pair of scissors, and planted among the granulations. Narrow strips of protective are applied, and upon this is placed either the "house-dressing," or simply a pad of dry 1 : 1000 cotton. Any bichloride solution remaining about the parts should be washed off with distilled water before the grafts are cut and set, and strong solutions should not be used while the islets of epithelium are forming.

Leg ulcers, when small, are stimulated, if necessary, by scoring with a sharp knife, nitrate of silver stick, etc.; dusted with iodoform; accurately fitted with a piece of protective, and a gauze dressing put on with a firm roller. If they are large, and have callous edges, these latter are trimmed off, the sore curetted, perhaps straps applied after the iodoform and protective, and then the same dressing. By this method they can always be kept perfectly sweet and clean; the discharge is but slight, and the pain still less. If the ulcers are very irritable, and will not bear the gauze dressing, boracic acid ointment is substituted for it.

Those painful, non-ulcerative conditions of the legs so often met with behave excellently under one or the other of the above dressings.

In such regions where it is impossible to apply or retain a regular dressing, great pains are taken in the cleansing before and after an operation, and iodoform in conjunction with frequent corrosive sublimate irrigations is freely used afterward. Especially are these applications valuable about the genito-urinary organs and rectum. In females, after most operations thereabouts, the vagina is washed with 1 : 1000, and then *filled* with iodoform. Beyond an occasional irrigation of the external parts, nothing more need be done until the stitches—if they have not been of catgut—are ready for removal.

Chancroids heal wonderfully if kept buried in iodoform; sometimes they are previously brushed over with acid nitrate of mercury, etc. No treatment is directed to hard chancres unless complicated.

Body parasites are destroyed with 1 : 500 corrosive sublimate solution. No unpleasant effects have been known to follow even the freest use of the solution in this way. If the ear has been invaded, it is syringed with that solution, and then filled with oleate of morphia and a little wad of cotton put on top.

A CASE OF BACKWARD DISLOCATION OF THE FOOT WITHOUT FRACTURE.

By WILLIAM G. DAGGETT, M.D.,
of New Haven, Conn.

Cases of backward dislocation of the foot occurring without fracture of the tibia or fibula are of such extreme rarity that the following brief report is offered with the view of placing on record one which came under my care a few days ago.

J. D., aged fourteen, while wrestling with a schoolmate, fell in such a manner that his foot became fixed, and the weight of his opponent, who fell on top of him, was spent on the leg above the ankle. The resulting injury was a backward dislocation of the astragalus, together with the rest of the foot.

The dislocation was easily reduced. Repeated careful examinations by Dr. Francis Bacon and myself disclosed no fracture of tibia or fibula. There was no unusual injury to the soft parts.

22 College St., New Haven, Conn.
November 6, 1886.

HOSPITAL NOTES.

The Treatment of Rheumatism in the Boston Hospitals.

Massachusetts General Hospital.

Dr. Francis Minot usually employs in the treatment of acute articular rheumatism, ten grains of salicylic acid or fifteen grains of sodium salicycate, for an adult, every hour, or every two hours, until the pain and fever abate; after that, at longer intervals according to circumstances. If there be indications of endo- or pericardial complications, sinapisms are applied, followed by fomentations, and quinine is given in two grain doses, three or four times daily. In cases of suspected cerebral inflammation ice is applied to the head, with opium, chloral hydrate, aconite, etc., internally. The affected joints are simply wrapped in cotton wadding. Purging is avoided.

The diet during the acute stage consists chiefly of milk and farinaceous articles. Wine and other stimulants are ordered according to the degree of prostration. The patients are kept in bed at least a week after all pain and swelling have subsided, and the temperature and pulse have fallen to the normal standards.

In the more chronic forms of articular rheumatism, reliance is chiefly placed on quinine and iron. In all cases care is taken during convalescence to prevent fatigue, exposure to cold, and errors in diet.

Dr. F. C. Shattuck uses a combination of the salicyl and alkaline treatment, with a view to—first, relief of the articular pain and swelling; and, second, the prevention of cardiac complications, the results of which are far more serious than are those of the inflammation about and in the joints. He finds that under the use of the salicyl compounds the joint pains and the fever yield more promptly and fully than under any other medication. Relapses, are, however common; and it would seem that, though the patient is made much more comfortable, his stay in the hospital is but little if at all shortened. There are good authorities who maintain that this treatment tends directly to lessen the liability to cardiac complications; there are other equally good and more numerous authorities who maintain that it has no such direct action. That the full alkaline treatment has some effect in averting and curing these complications, rests on evidence strong enough to make us listen to it; and the stay in hospital under its use is, if the statistics quoted by Professor Howard in Pepper's *System of Medicine* are reliable, rather shorter than under the salicyl compounds.

MEDICAL PROGRESS.

Spartein Sulphate as a Medicament.—The following statements are based upon results obtained in the clinic of Nothnagel. In cases of deficient heart activity, whether in valvular disease or emphysema, pleuritis and icterus, the drug was given in powder in doses of one milligramme, easily taken. Syphygmograms showed the effects produced.

(1) In very small doses the heart's contraction was strengthened, the pulse was fuller and stronger, the arterial tension increased, the frequency slightly diminished.

(2) These effects followed from three-quarters of an hour to an hour after administration, endured often longer than twenty-four hours, and were increased by repetition of the dose. An intermission of several days is useful, after which the drug acts more powerfully; it may be given daily for more than a week without injury.

(3) Impaired rhythm at first noticed is in a few cases only again observed; in seven heart lesions the ventricular action is much improved, but not made that of health.

(4) Respiration at first becomes more frequent, is then slightly less frequent.

(5) Diuresis, as would follow increased heart action, is increased.

(6) A mild narcotic effect of the drug is often noticed, generally resulting in rest and sleep.

(7) Symptoms of intoxication, giddiness, headache, heart palpitation, and nausea follow the use of small doses (1 to 4 milligrammes) very rarely, soon disappear, are slight in character, and are generally not observed on repeating the dose.

Spartein resembles digitalis. Its effect is, however, too sudden, and does not remain at its maximum sufficiently long to relieve severe disorders of compensation, while repeated doses of spartein do not result as efficiently as the use of digitalis. Its fixed dose and harmlessness will make it very useful; it seems more useful than caffeine, adonis vernalis, or convallaria.

It may be given in valvular lesions when compensation fails and the pulse lacks strength; also to regulate and strengthen a disordered heart action; also in insufficiency of the heart muscle without valvular lesion; also in pericarditis, as an aid in diuresis, and to supplement digitalis.—*Centralblatt für die gesammte Therapie*, October, 1886.

A Case of Acute Articular Rheumatism and Typhoid Fever occurring Simultaneously.—Drs. Spillman and Ganzinatty report a case in a man aged thirty-six, and generally healthy. In reviewing the case they analyze it as follows:

1. Occurring simultaneously with a pseudo-rheumatism of typhoid nature and infectious, and in which the rheumatic element bears a secondary relationship to the typhoid infection, there can develop an association of acute articular rheumatism and typhoid fever.

2. The two diseases develop at the same time, the rheumatism preceding the typhoid fever, or following and outlasting it.

3. The rheumatic manifestations remain simply fluctuating; joint suppuration does not occur as in secondary and infectious joint swellings.

4. The rheumatic manifestations which are but little affected by sodium salicylate, yield to antipyrine, whose analgesic effect is, however, brief and intermittent.

5. The typhoid fever manifests its ordinary symptoms; its duration is the usual one, its fever curve is modified

by the rheumatic exacerbations, and by the administration of antipyrine.—*Revue de Médecine*, Oct. 10, 1886.

A Peculiar Form of Motor Disturbance of the Pupil.—Salgó describes a peculiar form of pupil, which consists essentially of an irregular contraction of the muscular tissue of the iris, by which its pupillary margin assumes many different shapes. The pupil generally appears triangular or poliangular, with the corners thickened and rounded out, resembling somewhat the slit-like pupil of the cat, or the irregular appearance caused by synechia. This kind of pupil reacts in a normal manner, but after each movement assumes a somewhat different form, so that the contracted pupil appears different from the same when dilated.

The great majority of cases so far observed have been associated with general paralysis of the insane, though it has been seen in chronic, progressive psychoses in which no paralysis could be detected. The author considers that it is much the most frequent pupillary symptom in general paralysis, and regards it as an expression of the varying intensity of innervation from the cortex. —*Chicago Medical Journal and Examiner*, Dec. 1886.

Thallin.—In a work on the effects of this drug, Maragliano, of Genoa, says that

1. A single dose of one-tenth of a gramme results in a fall of temperature whose minimum is 0.7°, whose maximum is 2°.

2. A dose of one-fourth of a gramme will depress temperature 3.1°; one-half of a gramme brings temperature down 3.3°; three-fourths of a gramme causes 3.6°, and one gramme will depress temperature 4.7°.

3. The antipyretic effect begins commonly one hour after taking, and reaches its maximum after two hours, while the depression of temperature is only one degree for the first hour, and becomes greater after three or four hours.

4. The effect of a dose of one-tenth of a gramme persists from two to four hours; one-fourth of a gramme from two to nine hours; one-half of a gramme from two to ten hours.

5. The intensity of the effect varies with the same dose, and is effected by the following circumstances: *a*. The initial temperature; the higher this is, the greater the drug's action. *b*. The hour of the day, for which no rule can be given. *c*. Susceptibility of the patient.

6. Cumulative effects are produced by successive doses.

In comparing thallin and antipyrin, we find one-fourth of a gramme of thallin acting as powerfully as one gramme of antipyrin, with no appreciable difference in the continuance of the effect; to depress temperature for a given time, two or three times as much antipyrin as thallin must be given. Thallin is, therefore, bulk for bulk, the most powerful of antipyretics; it may be given in powder by the mouth, or hypodermatically, and results well in enemeta.—*Medicinisch Chirurgisches Centralblatt*, November 5, 1886.

The Causation and Cure of Uric Acid Calculi. —Pfeiffer has made a series of experiments as to the effect of different mineral waters in dissolving uric acid. He differs from other experimenters in imitating the natural condition of things, by placing the calculi in the urine altered by drinking the various mineral waters. The urine of healthy people, using no minerals, had no uric acid solving property, but, on the contrary, rendered the uric acid masses heavier. Acting on this hint, he successfully produced calculi outside the body. The Kochbrunnen water (Wiesbaden), he found, had very slight dissolving properties; the Carlsbad was a far stronger solvent, but with this disadvantage, that after leaving off taking it the calculi increased with great rapidity. Lithium water, twenty times as strong as the strongest natural water, had very slight solvent powers. In powder, lithium had more effect, but the quantity required daily was far beyond that which could be taken of any natural lithium water, and the effect ceased as soon as the remedy was left off. But with the pure alkali waters of Fachingen the effect was quite different, the urine in this case acquiring very well-marked solvent properties, and these persisting for a considerable time after, without the use of the waters. Pfeiffer, therefore, recommends, for uric acid stones in kidney and bladder, the continued use of the Fachingen waters, for months or years, at the rate of one or two bottles per week. Lehmann (Oeynhausen) has remarked that the waters of Wildungen were also useful in dissolving calculi. Ziemssen (Wiesbaden) states that Wildungen owed its renown mainly to the successful lithotripsy of its surgeons.—*Manchester Medical Chronicle*, November, 1886.

A Successful Hysterectomy.—A most extraordinary injury, done by violence to the genital apparatus of a woman, is described in the *Centralblatt für Gynäkologie* of November 13th. A woman was brought one morning to the hospital in Hamburg by the police, who had found her lying in the street insensible, her clothing covered with mud and stained with blood. An examination showed a fleshy tumor protruding from the vulva, which proved to be the uterus torn loose from all its attachments except at the anterior vaginal vault; there was also a tear involving the whole recto-vaginal septum and opening above into the peritoneal cavity. The total extirpation of the uterus was completed in the hospital, and, strange to say, the woman made a perfect recovery. The recto-vaginal tear was then repaired by a plastic operation which was also successful. The subsequent judicial investigation elicited the fact that the woman had been drinking heavily, till after midnight, with two male companions, who, following her on her way home, had cohabited with her, not without her consent; she herself being intoxicated could not tell clearly what had taken place, but it was apparent, from the nature of the injury, that one of these men, in a drunken frenzy, had introduced his whole hand into the rectum and, rupturing its anterior wall, had endeavored to drag out the uterus entire. The woman had remained lying in the street, in midwinter, until the following morning, and when found showed evidence of having lost a large quantity of blood. Her recovery, under the circumstances, was remarkable, and, taken in connection with the rarity of the injury, if indeed it is not unique, makes the report of the case very interesting.

The Means of Preventing the Deterioration of Rubber Apparatus.—An inquiry has been carried out under the direction of the French Minister of War with the object of ascertaining the cause and the remedy for

the peculiar changes which articles made of India-rubber undergo when kept in stock, the annual loss to the government from the deterioration of this class of goods being very considerable. Experience shows that India-rubber, after a time, loses the very qualities which make it useful, for it becomes dry and brittle. Articles kept in boxes, such as Higginson's syringes, Esmarch's bandages and drainage tubes, are particularly liable to deteriorate, as are also the insufflation bulbs so largely used in connection with spray-producing apparatus and thermo-cauteries. Unfortunately, the results of a long and patient investigation are not by any means satisfactory, so far as the discovery of a means of prevention is concerned. Nevertheless, certain precautions are advised, both in the quality and storage of India-rubber goods, which, it is hoped, will do something to minimize the loss. The commissioners advise, for instance, that Esmarch's bandages should be taken out of the boxes at least once a month, unrolled, and manipulated. Drainage tubes should be hung up in a cool place, or soaked in a non-putrescible fluid. Finally, all objects made of rubber should be kept in a cool, damp place, at a constant temperature, and sheltered from light, heat, and frost. Seeing that, in many cases, these conditions cannot be complied with, it is recommended that the bandages should be made of pure leaf rubber, in lieu of the elastic tissue usually employed. The purer the rubber the less readily does it undergo these structural alterations, and the lighter it weighs: its weight is, therefore, a sure guide to its quality. In consequence of these inquiries, the minister has ordered that in future all rubber articles are to be made with pure rubber of the best quality, preferably with the leaf rubber. The quality of the articles will be gauged by their specific gravity in order to insure the purity of the material employed.

Muscular Rheumatism due to the Use of Tobacco.—Dr. Edward Anderson, of Rockville, Md., writes as follows to the *Maryland Medical Journal*, November 27, 1886:

I have met with a great many cases of muscular rheumatism due to the use of tobacco in some form, mostly in the shape of snuff placed under the tongue. All remedies were unavailing whilst the use of the weed was indulged in. Every practitioner, I think, on meeting with a case of the above disorder should inquire as to the tobacco habit, and correct it, if possible.

Intermittent Albuminuria in a Child.—Dr. Mareau observed the above-mentioned phenomenon in a healthy chi'd aged ten, whose father, a chemist, made most careful and patient analyses. The child had had croup, whooping-cough, bronchitis, typhoid fever, and measles, all very mildly, and had recovered to good health. It was before the last illness, and during its continuance, that albuminuria appeared. There was no history of scarlatina. The child, although physically and mentally impressionable, gave no evidence of Bright's disease except a slight malaise, and headache occasionally. 447 analyses were made before the patient contracted measles, and the result of these observations was—

1. The existence of an albuminuria of unknown nature, bu t compatible with health.

2. This albuminuria was intermittent, transitory, and rarely resulted in the loss of much albumen; it was greatest after a meal.

3. The slight albuminuria of early morning is doubtless caused by the meal of the night preceding. Measles neither increased nor diminished the albuminuria.

4. When the child was prevented by fever from eating, its greatest albuminuria was on waking; when enjoying full meals, it had albumen after meals.

5. Excepting the presence of albumen, chemical and microscopic examination revealed no abnormality.

6. Milk diet, absolutely and patiently enforced, lessened a considerable amount of albumen, but had no effect upon mere traces.—*Revue de Médecine*, October, 1886.

Vallez's Ointment for Hemorrhoids:

Unguent. simpl.	16 parts.
Extract of elder	4 "
Burnt alum	2 "

Used by inunction every two hours.—*Revue de Thérapeutique*, November 15, 1886.

Treatment of Blenorrhagic Cystitis.—Desnos has arrived at the following conclusions after trying different modes of treatment:

1. Blenorrhagic cystitis attacks the neck of the bladder; it is always connected with an inflammation of the deep portion of the urethra, but such urethritis alone cannot give rise to all the symptoms of cystitis.

2. The frequent micturition which occurs in the beginning of blenorrhœa is of too short duration to be mistaken for a positive symptom of cystitis, especially in the absence of other symptoms.

3. In chronic cases the differential diagnosis between blenorrhagic and tuberculous cystitis is generally impossible when the former follows an old blenorrhœa.

4. A number of cases known as cystalgia, or neuralgia of the neck of the bladder, are simply partly cured cases of blenorrhagic cystitis; a painful sensation commonly persists in such cases.

5. The treatment of acute cystitis by emollients is generally fruitless; the injection of solution of nitrate of silver (one in fifty to one in ten) produces a sharp reaction at first but rapid improvement follows.

6. In chronic cases irrigation of the bladder is of little benefit and can excite fresh inflammation; general treatment is useful, but local treatment applied to the neck of the bladder is indispensable.

7. Bichloride of mercury solution, one in two hundred and fifty to one in five hundred, gives sharp and prolonged pain, and its beneficial effects are less prompt than those of nitrate of silver.

8. Iodoform in oil, or in suspension in glycerine is not painful; its effects, although good, are slow and uncertain.

9. Hydrochlorate of cocaine relieves pain in the bladder for a very short time; applied to the neck of the bladder just before the introduction of a caustic, it lessens greatly the painful effects of cauterization.

10. Nitrate of silver, in solutions of one fiftieth to one tenth, in injections of from ten drops to twenty-five or thirty, the author considers the most efficient, safe, and rapid means of treatment.—*Bulletin Général de Thérapeutique*, November 15, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 18, 1886.

THE TREATMENT OF RHEUMATIC FEVER.

IN this and in the past two numbers of THE MEDICAL NEWS we have presented our readers with brief reports on the methods employed in the treatment of rheumatism in the chief hospitals of Philadelphia, New York, and Boston.

For a knowledge of the natural history of rheumatic fever uninfluenced by drugs we are indebted to the late Dr. Flint, who treated thirteen patients in Bellevue Hospital with infusion of quassia, and to Dr. Sutton, of London, who treated a large number of cases with mint water. The observations of the latter physician, in conjunction with Sir William Gull, deserve a more thoughtful consideration than has been afforded them by many clinicians, as they are of primary importance in enabling us to judge of the effect of medicines on the disease.

Since the introduction of salicylic acid in 1875, this remedy and its compounds have been universally employed in rheumatism, and about sufficient time has now elapsed to permit us to arrive at a safe judgment of its uses. On looking over the reports, we find that in some form or other it is still employed in every one of the hospitals represented, and we ask for no better guarantee of its merit than this one fact. As a rule, a decade plays sad havoc with a drug announced with the *éclat* which attended the introduction of salicylic acid, but the experience of many physicians the world over seems to have accorded it a safe place in the therapeutics of rheumatism. The early anticipations, however, that we had in it a specific have not been realized, and too rapid cures have been expected. The elaborate analysis by Palmer Howard in Pepper's *System of Medicine*, vol. ii., seems to indicate very surely that cases treated by this method do not get better any quicker than on the old alkaline plan; indeed, if statistics are worth anything, they show that the cases do not get well so soon. Cardiac complications are probably more frequent, though in the reports we have published Dr. Loomis alone suggests that the effects of the acid favor their occurrence. It is a very general opinion, also, that under the salicylate treatment relapses are more frequent. Unquestionably the most striking action of the drug is in the relief of the pain and the reduction of the temperature, so that the extreme suffering and the general misery of the patient are promptly relieved. Upon these manifestations of the disease it often acts "like a charm," and possibly relapses are in many cases brought on by careless exposure or errors in diet in patients whose acute symptoms have been rapidly removed while the *materies morbi*—whatever that may be—still remains in the system. A combination of the salicylates and alkalies has probably a more decided effect upon the disease than either remedy alone. Dr. Kinnicutt, as shown by the report from St. Luke's Hospital, New York, continues to have good results from the use of oil of wintergreen, which seems to act almost as promptly as salicylic acid, of which it is a methyl ether.

That rheumatic fever is essentially a self limited disease, and is not materially influenced in its *duration* by drugs, is an opinion fully justified by a comparison of the reports of Sutton with those of the various writers who have published the results of the alkaline and salicylate plans of treatment. We have been too ready to mistake the relief of symptoms for the cure of the disease.

The reports do not refer very fully to the use of antipyrin in this disease, which is spoken of by recent German writers as a specific. It would seem, like the salicylates, to reduce the fever and to relieve the pain, and so far it may be specific, but we require further evidence to show that it really limits the course of the malady. Fränkel, in *Deutsche medicinische Wochenschrift*, Nos. 43 and 44, speaks very highly of its value in thirty-four cases, but acknowledges that in certain cases it cannot replace the salicylates.

INJECTION OF ETHER AND IODOFORM INTO COLD ABSCESSES.

THE use of iodoform has been of such marked advantage in the treatment of wounds that it is not surprising to find its employment extended to the treatment of lesions beneath the surface, such as cold abscesses. Of the vehicles which have been used, glycerine has certain disadvantages, on account of its density and the difficulty of bringing it into intimate contact with the whole

of the abscess wall. Ether has the great advantage of being an admirable solvent, and so fluid that it can penetrate where glycerine cannot. Besides this, it is believed that its vaporization by the heat of the body causes a further penetration and serves to convey the iodoform into the deepest recesses and most intricate sinuses.

The injection of iodoform dissolved in ether into cold abscesses was first brought prominently to the notice of surgeons by Verneuil, at the Congress of French Surgeons in 1885, and since then it has been used to a considerable extent, in France especially. Recently Verchère, in the *Révue de Chirurgie*, has called attention again to its advantages, and given an account of its use in twenty-three cases, including abscesses connected with disease of the bones of the thorax, pelvis, and spinal column, of the humerus, of the femur, of the elbow, and of the carpal bones, and abscesses in the neck, and in the temporal fossa. In all of these cases, except one, the treatment was followed by prompt improvement, and by more or less complete recovery. In one case death followed from causes unconnected with the treatment, and this furnished an opportunity to demonstrate how thoroughly the iodoform had been deposited upon the entire wall of the abscess.

It appears from the report of Verchère that this method is of special value in the treatment of tubercular abscesses. The iodoform seems to have a specific action upon tubercular deposits, and may act constitutionally as well as locally, since there is abundant evidence that it is absorbed when injected into an abscess, and its internal administration appears to be beneficial in general tuberculosis.

The method of Verneuil consists in evacuating the whole or a part of the contents of an abscess by means of an aspirator—or of a hypodermatic syringe, if the abscess be very small—and in injecting through the same tube a suitable quantity of iodoform-ether. Two dangers accompany these injections: 1. That of too great distention from the expansion of the vaporized ether. 2. That of iodoform poisoning. Verchère saw a case in which the distention of an abscess in the front of the neck was so great that symptoms of suffocation, from compression of the trachea, appeared, and another in which the whole of the scalp was raised from the bone. In both of these cases prompt relief was afforded by introducing needles of hypodermatic syringes, which permitted the escape of the ether vapor. The danger of iodoform poisoning is to be avoided by using only moderate quantities of iodoform. Verchère considers a drachm to be the maximum quantity which can be used with safety. In large abscesses about one and a half fluid-ounces of a five per cent. solution may be injected; in small abscesses a ten per cent. solution, or even a saturated solution may be used. In the case of very small abscesses with thick contents, Verchère employs the following ingenious method. He introduces the needle of a hypodermatic syringe into one part of the abscess and leaves it in place, while at another point he evacuates the abscess through an aspirator and closes the aperture with collodion and gauze; when this is done, he injects the ether through the hypodermatic needle.

It is important, where it is possible, to prevent the escape of the ether vapor after the injection, and this is accomplished by closing the opening with collodion and gauze, as stated above. As the iodoform remains a long time in an abscess cavity before it is wholly absorbed, the injections should be repeated, if necessary, only after a considerable interval; Verchère advises once a month in cases of large abscesses in which the skin does not give way, until a cure is effected. This may require six or more months. When the skin does give way after the injection, the sac is eliminated as a sort of slough, and the cure is more rapid. The observation of this fact leads Verchère to suggest opening the sac as part of the treatment.

One of the greatest merits of this method consists in the fact that the patients do not have to go to bed, and can continue their usual occupations.

The results obtained by Verneuil and by Verchère are so brilliant that their example may well be followed in the treatment of tuberculous or glandular abscesses. It may be that a still better medicament may be discovered for injection into abscess cavities. Carbolic acid and corrosive sublimate have been used, but they are far from safe, and they are certainly no more efficient than iodoform. Iodine may be used in abscesses of moderate size, and, if diluted, in large abscesses. In the former, pure tincture of iodine is an admirable agent, and nothing could surpass the results obtainable by its injection into small cysts and broken-down gummata, or into the sloughing tissue of felons and palmar abscesses. The action of iodoform is probably due to the gradual release of iodine, and it may be that the use of iodine itself would secure a more prompt action of the remedy. How much of the success of Verneuil's method depends upon the action of the ether it would be hard to say. As ether, it must act upon the tissues, and the great distention which follows its vaporization reminds one of the method of hyperdistention suggested, and very successfully employed for a time, by the late Mr. Callender.

It should be stated that Mickulicz was the first to call attention, in 1881, to the good effects of iodoform in tuberculous abscess, he having employed it in connection with glycerine. In 1884 Fränkel reported twenty cases from Billroth's clinic, of which all save two were complete cures, and fifteen of

which were dependent upon diseased bone. We regret to say that neither Verneuil nor Verchère makes the slightest allusion to the experiences of those surgeons to whom the credit of using iodoform in cold abscesses is justly due.

INTRAUTERINE DISINFECTION.

Although the whole medical world has reason to thank Koch for the announcement of his discovery, in 1881, that a solution of bichloride of mercury, of the strength of 1 : 1000, was absolutely fatal to the hardiest forms of microbes and their spores, and while this antiseptic agent has given brilliant evidence of its efficiency in obstetrics, it has not, unfortunately, shown itself to be the ideal disinfectant, fatal to the infecting parasites, but innocuous to their host. It is now clearly proven that the danger of fatal poisoning after the use upon absorbent surfaces of a solution of the strength already mentioned is by no means slight.

Having employed it extensively, and seeing no bad consequences, Carl Braun, of Vienna, recommends that a solution of thymol, also 1 : 1000, be substituted for corrosive sublimate in intrauterine injections, not only directly after delivery, when the danger of absorption and poisoning is, of course, greatest, but also later in the puerperium in those cases in which there is decomposition of retained fragments of the placenta, or membranes. In such cases the uterine walls are scraped with a curette, the thymol solution is injected, and a bougie of iodoform is inserted into the cervical canal, this plan of treatment giving the most excellent results.

THE EQUINE ORIGIN OF TETANUS.

It is somewhat remarkable that so able a man as Verneuil has recently accepted one dubious theory—that of Pasteur in regard to hydrophobia—and has proposed another—that of the so-called equine origin of tetanus. This latter was first announced in the *Gazette Hebdomadaire de Médecine*, in 1886, and Verneuil has repeated it before the Congress of French Surgeons. The principal grounds upon which it rests are the assertions that: 1. Tetanus often occurs in men who have been in contact with horses. 2. Tetanus is most frequently caused by injuries received from horses. 3. Horsedealers, stablemen, and grooms are more liable than other men to tetanus. And 4. Wounds which have come in contact with earth contaminated with the excreta of horses are more frequently followed by tetanus than any others.

Verneuil's theory received the approval of a number of the French surgeons present at the Congress, and was not seriously opposed by any of them. This approval accords well with the reception which Pasteur's theory of hydrophobia received at the Paris Academy of Medicine, and, like that, indicates that patriotism rather than reason may sometimes rule in French councils. Of the theory of Pasteur we have already expressed an unfavorable opinion which is gaining more and more adherents as time passes. Of Verneuil's theory we are compelled to express an equally unfavorable opinion. It is proper to give a reason for this, although it would suffice to say simply that Verneuil and his supporters have not adduced evidence sufficient to establish their views. We may go further, and say that the evidence they do adduce is not to be accepted at all. In the first place, it is not true that tetanus results most frequently from injuries received from horses, or in persons who are in habitual contact with horses. The injuries which may be followed by tetanus are of the most various kinds, and no one of them can be selected as fixing the nature of the malady. The style of reasoning adopted by Verneuil might in this country be applied to the toy-pistol, which about the Fourth of July creates such ravages among the children of certain cities of the United States. But to do this would be to repeat Verneuil's error of generalizing from too scanty premises. One of Verneuil's supporters, Dr. Blanc, of Bombay, illustrates the dangers of this method of reasoning by stretching it so as to cover cholera as well as tetanus, and spoils his argument by attempting to prove too much.

We cannot help comparing the loose theorizing of Verneuil with the carefully worked-out opinions of Rosenbach, presented to the Fifteenth Congress of German Surgeons, to which we have referred in The Medical News, of August 7, 1886. These opinions were supported by reports of experiments which might be used to show that tetanus can be produced almost at will without the intervention of any equine influence whatever. We do not regard Rosenbach's theory as to the origin of tetanus as fully demonstrated, nor did he so regard it; but it is certainly far more probable than Verneuil's theory, and it is supported by a much better argument.

We call attention to this subject, because we have not yet seen any warning against the hasty acceptance of the theory of the equine origin of tetanus. We cannot say what the future may show, and it may not be amiss to take this theory into consideration, and to investigate its claims; but, as it now stands, it appears to us to be an example of very faulty reasoning, and to require very different confirmation from that which seems to have satisfied the Congress of French Surgeons.

That the endemic paraplegia, or Beri-beri, of Japan and of certain tropical countries has not yet

been described in this country, lends special interest to the communication of Dr. Seguin on this subject at the meeting of the Neurological Society of Philadelphia. The researches of Scheube and others in Japan have shown that the disease is a multiple neuritis, probably of infectious origin. Dr. Seguin's cases came from Cuba, Brazil, and the Isthmus, in which regions it would appear to be of pretty recent occurrence. It is quite possible that the disease may appear in the Gulf States or in California, as it prevails extensively among the Chinese in the Sandwich Islands. The analogous indigenous cases reported by Dr. Seguin certainly resemble beri-beri in essential features, though it is doubtful if they are etiologically of the same nature.

The Library of the College of Physicians contains 34,234 volumes, exclusive of duplicates, and 16,026 unbound pamphlets, an increase during the year of 2452 volumes and 2239 pamphlets; 325 current periodicals devoted to medicine and the collateral sciences are regularly received, of which 173 are published within the United States. With the single exception of the library of the Surgeon-General's Office, at Washington, the library of the College constitutes the largest and most valuable collection of medical books in the United States.

The principal medical libraries of the country are the following:

	Volumes.	Pamphlets.
Library of Surgeon-General's Office	76,700	106,600
Library of College of Physicians of Philadelphia	34,234	16,026
Library of New York Academy of Medicine	20,000	12,000
Boston Medical Library	16,374	13,364
Library of the New York Hospital	15,860	
" Pennsylvania Hospital	15,000	

At the annual meeting of the Board of Managers of the Utica State Lunatic Asylum, held last Tuesday, Dr. G. Adler Blumer was unanimously elected Superintendent, to fill the vacancy created by the death of Dr. John P. Gray.

Dr. Blumer is a native of Sunderland, England, and about thirty-seven years of age. He came to the United States when quite young, but returned to Europe to study in Great Britain, Germany, and France. He graduated in medicine at the University of Pennsylvania, in 1879. He was appointed fourth assistant physician in the Utica Asylum in June, 1880, and promoted to second assistant two years later, and became first assistant in 1884. He performed very acceptably the duties of Superintendent during the illness of Dr. Gray.

Diphtheria is now prevalent in St. Paul, Minnesota, and at the request of the Board of Health of that city the Common Council has passed an ordinance requiring all physicians to report to the Department of Health all cases of membranous croup in the same way that they now report diphtheria, scarlet fever, and other contagious diseases. The Board inclines to a belief in the identity of so-called membranous croup with diphtheritic croup.

SOCIETY PROCEEDINGS.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, November 22, 1886.

The Vice-President, Charles K. Mills, M.D., in the Chair.

Dr. E. C. Seguin, of New York, read by invitation

NOTES ON THREE CASES OF TROPICAL BERI-BERI, AND ON SOME SIMILAR AMERICAN CASES.

(See page 679.)

Dr. Charles K. Mills then made some remarks on

THE CONCURRENCE OF MULTIPLE NEURITIS WITH MYELITIS OR ENCEPHALITIS.

As one result of the interest which has been aroused in the subject of multiple neuritis, or polyneuritis, some cures have been effected which were before not considered possible; but it seemed to the speaker that, as in the case of other advances in medicine, some have been led to go too far in their conclusions, and have overlooked facts which are worthy of close attention. That multiple neuritis frequently occurs, can no longer be doubted; but that it occurs frequently as an absolutely isolated affection is, to say the least, doubful. His own experience was, that not infrequently either myelitis or encephalitis, or both, concur with this affection; that is, in not a few cases in which the diagnosis of multiple neuritis could be made by the strict rules applicable to the study of this affection—by a certain combination of motor and sensory symptoms, by their localization in distal parts of the limbs, and by tenderness of the nerve trunks, and of the muscles—positive evidences of the existence of the central disorders were also present.

If, as is generally believed, multiple neuritis is the result of a direct toxic influence on the nerve elements themselves, it was reasonable to suppose that this same influence would frequently be exercised upon the nerve elements of the brain and spinal cord.

Gowers, in his *Manual of Diseases of the Nervous System*, says, with reference to the cases of multiple neuritis which have been pathologically examined:

"The *spinal cord* has been found healthy in most cases. The ganglion cells, in some instances, have presented abnormal appearances, a vitreous appearance, or vacuolation, and this when the anterior nerve roots were not diseased. Now and then more considerable changes, usually those of chronic myelitis, have been found in the cord. They are probably merely coincident. Morbid appearances in other organs are common in the cases of alcoholic origin. The brain will present signs of chronic meningitis. The liver is frequently, and the kidneys are occasionally, found diseased."

Dr. Mills's conclusions were that we may have four classes of cases: 1. Cases of multiple neuritis, pure and

simple; such cases, however, were rare. 2. Cases in which the multiple neuritis was associated with myelitis. 3. Cases in which multiple neuritis was associated with encephalitis. 4. Cases in which multiple neuritis was associated with both myelitis and encephalitis. Instead of the association being just as is indicated by this classification, the combination might be of neuritis or perineuritis, with meningo-myelitis or meningo-encephalitis; or, finally, any modification of these combinations might be found.

Dr. Mills referred to a case which he had seen in consultation recently, in which the patient presented all the typical marks of multiple neuritis, the condition of her limbs being such as to call to mind the picture in Gowers's recent book of a case of multiple alcoholic neuritis, with palsy of extensors of wrist and flexors of ankle. This patient had also very positive evidences of cerebral involvement—mental confusion, with hallucinations and delusions both of sight and hearing. She had a clear history of abuse, not only of alcohol, but also of opium, chloral, and other narcotics. He believed that in this case there was a concurrence of multiple neuritis, with a similar pathological condition in the spinal cord and brain. He also referred to other cases, seen in consultation, and more particularly in the Philadelphia Hospital, where the majority of patients have been the victims of alcoholic excess—cases in which a confused picture of nerve, cord, and cerebral disease, probably inflammatory, was frequently presented. Cases of poisoning by lead, mercury, and particularly arsenic, were also discussed. Particular reference was made to the series of cases of poisoning by arsenic which he reported to the College of Physicians of Philadelphia in 1883.

A most interesting case, as bearing upon the views here presented, was one which he saw with Dr. O'Hara, of Philadelphia, to whom he was indebted for notes of the past history of the case, and also for suggestions as to the condition present at different stages. This patient, a professional man of originally good physique, and of remarkable intellectual attainments, had, eight years ago, an attack of rheumatism, which left him with a crippled heart, the damage to this organ, however, not seeming to have been of its valvular, but rather of its nervous structures. The patient was in the habit of using tobacco and alcohol, but not to excess, and sometimes did not use these agents at all for long periods. Two years after the first attack of rheumatism he began to have trouble with his vision. Sight in both eyes slowly failed until he scarcely had more than perception of light in both eyes. Careful ophthalmoscopic examinations were made with negative results; the media were clear, and no signs of retinitis or neuritis were discovered. In eighteen months he entirely recovered his sight from travel, rest, and the use, in the latter months, of strychnia hypodermatically injected. About a year after recovery of his sight he had another attack, rheumatic or rheumatoid gouty in character. In this attack he had insomnia and evidences of general nervous irritability. At this time the left upper extremity suffered from an undoubted attack of neuritis, affecting the most of the brachial nerves, but more markedly those of the median distribution.

About six months ago, he had what appeared to be an apoplectiform attack, his left side—face, arm, and leg—being temporarily paralyzed, but without unconsciousness. The attack passed off in a few hours.

About two months since he was engaged in work which called for both mental and physical effort, and considerable exposure. One day, when at a height of more than one hundred feet, he was suddenly stricken with incomplete paralysis of motion and sensation in the lower extremities, accompanied by great pain, but succeeded by his own efforts in getting again to the ground. This attack he attributed, probably correctly, to a stroke of air. On examination, he was found to have almost complete paralysis of the left leg from the knee downward, with blueness and coldness of the foot, and typical anæsthesia dolorosa as high as the ankle. He complained of excruciating pains, which he described as "jamming" in the sole of the foot. The right leg showed a similar condition, but much less marked, the paralysis of motion and sensation extending only half way to the knee, and not being nearly as complete as upon the other side. In two weeks, under the use of anodynes, local and general, with massage and weak currents of electricity, he recovered completely from these symptoms in his limbs. He then began again to use both head and limbs without rhyme or reason, and was attacked with loss of power and great pain, and perverted sensation in the right leg below the knee, with swelling of the dorsum of the foot and of the ankles. He also began to have lightning pains, here and there, in both lower extremities, and radiating from the spine upward, these being sometimes accompanied by retraction of the head. Still later he developed symptoms of cerebral excitement—total insomnia, refusal to take medicine, quasi-delusions, great loquacity, etc. He was without sleep for nine days and nights. Various remedies were vainly tried, but the first genuine relief which he obtained was from hypodermatic injections of morphia, repeated every twelve hours. This was followed by the administration of deodorized tincture of opium regularly every four hours, in doses of from ten to twenty minims, with twenty minims at bedtime. This treatment was continued, with digitalis, which he had been taking more or less for six or seven years, for about nine days. Mild alcoholic stimulus was also used, and nourishment was systematically administered. He has improved to such an extent that all the symptoms, neural, spinal, and cerebral, have greatly diminished, so that he is able to travel, but he cannot yet endure any great strain, either physical or mental.

Dr. H. C. Wood stated his belief that chronic multiple neuritis is one of the most frequent of the severe organic nerve diseases, and that in a large proportion of cases of serious nerve disease, the whole spinal axis and its accessories are affected. In general paralysis of the insane, four-fifths of the cases have some lateral or posterior spinal sclerosis, and a large proportion of these cases, no doubt, have multiple neuritis. He thinks that it is perfectly proven that locomotor ataxia may travel down the cord and produce peripheral neuritis, and that it is equally well proven that peripheral neuritis may travel upward, producing secondary lesions in the cord. With reference to electrical studies, it may be said that a large number of cases show that in the various forms of neuritis, every possible change in the electrical reactions can be found. Post-mortem examinations are sufficiently numerous to show that peripheral

neuritis is frequently not associated with other diseases, and that it frequently causes symptoms which simulate other affections. When we have peripheral neuritis, it is difficult to make out a spinal trouble back of it.

Dr. Osler thought that it was clear that we have the curious disease beri-beri in this country. It is probable that it exists in the Gulf States, as, a few months ago, he received some slides, which had been sent by a physician of Texas, and were said to contain the micro-organism of beri-beri. Anyone reading the descriptions of this disease must have been struck with the remarkable resemblance of some of the cases to acute ascending paralysis. His friend, Dr. Vineberg, now of New York, who formerly practised in the Sandwich Islands, gives a very accurate account of the suddenness of onset, the rapidity of the ascension of the paralysis, which, in some cases, ultimately involves the respiratory muscles, producing death in that way. He agreed with Dr. Wood that multiple neuritis must be an exceedingly common disease. The French journals of the current year contain a surprising amount of literature on the subject. He had been particularly interested in cases of neuritis occurring in connection with certain of the fevers. After typhoid fever it has been described a number of times, and also after phthisis. During the past year, he has had one interesting case of paralysis of the extensors of the left foot in connection with phthisis, unquestionably a case of neuritis. He suggested that possibly some of these cases of paræsthesia of the hands, with feelings of numbness and tingling, which Putnam has described so accurately, may be of the nature of a peripheral neuritis. A case recently presented itself at his service at the Infirmary for Nervous Diseases, in which these symptoms were very marked, and in which there apparently were some trophic changes. The skin was glossy, and the hands were somewhat swollen, and, indeed, they presented in a slight degree the appearances seen in myxœdema.

In connection with the diagnosis between acute ascending paralysis, anterior myelitis, and multiple neuritis, he would refer to an article by Francotte in the *Revue de Médecine*, to which attention was called in The Medical News, of July 3, 1886. He reports four cases, two of which were studied anatomically, and in which the cord was found to be absolutely normal. In these two cases the clinical picture was that of Landry's ascending paralysis.

Dr. Seguin said that he was much interested in the remarks of Dr. Mills as to the possible coëxistence of a central with a peripheral lesion. He had no doubt that this coëxistence is frequently a source of considerable difficulty in making up our minds whether a case is one of irregular poliomyelitis or of peripheral neuritis. It also seemed to him to be a matter of great practical importance as regards treatment that we should make up our mind whether we have a case of perineuritis or one of parenchymatous neuritis. The former disease, which is, he thinks, the more common, and perhaps present in some cases of so-called neuralgia, is essentially an inflammatory change in the connective tissue, perhaps penetrating into the interior of the nerve bundles, but not affecting the nutrition of the axis-cylinder or myelin and not capable of producing any distinct paralysis or atrophy. The diagnosis may be made clear by relying on this distinctive point, that in interstitial neuritis there must be anæsthesia, even if limited in area; and a true paralysis and atrophy, even if restricted to a few muscles. In perineuritis the symptoms are more diffused, milder, more subjective, and do not present a specific appearance. He thought that the true key-note had been struck in insisting on the importance of a careful study of the neural and muscular reactions. In true neuritis and interstitial neuritis, there must be degenerative reactions in some shape, distal from the point of disease, while in perineuritis and in some forms of myelitis the reactions are either irregular or simply a quantitative or nodal reduction.

The diagnosis is of great importance with respect to treatment. Perineuritis and meningitic conditions he treats with great energy with counter-irritation, with the actual cautery and blisters. Internally, he employs mostly tonic treatment and does not resort to mercury or iodide of potassium unless there is a special reason for their use. Rest is also an important element in the treatment of perineuritic conditions. In essential neuritis therapeutic measures can have but little effect, as we know that a natural repair takes place irrespective of artificial conditions. If we favor nutrition by our general remedies that is the most that we can do, although galvanism may serve to keep up a better nutrition in muscles pending nerve regeneration.

In regard to the relation between neuritis and beri-beri, he did not wish to be understood as stating positively that we have beri-beri among us, but he thought that it would not be out of place to call attention to the analogy between the symptoms of the two affections. He thought it well to have the attention of physicians in our Gulf States called to the features of the disease. As the disease has recently appeared in northern Brazil, it may appear in our Southern States.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 8, 1886.

The President, Charles McBurney, M.D., in the Chair.

Dr. George A. Peters reported the following case of

INFLAMMATION OF THE SUBMUCOUS TISSUE OF THE GLANS AND PREPUCE.

Early in May, 1883, a gentleman, Mr. S., sixty-five years of age, presented himself with a condition of the penis to which Dr. Peters had never seen a parallel. For more than two years past he had complained of pain in that organ, and changes in structure had taken place which occasioned him much mental worry, and had made him decidedly hypochrondriacal.

On examination Dr. Peters found the glans and body of the penis, for about one inch from the end, hard and unyielding to the touch. The prepuce was very hard, inelastic, and embraced the glans so closely that it could not be drawn back sufficiently to expose it. The portion of the glans penis which could be exposed had the same hard feel, and was mottled with two or three small red, smooth spots, not ulcerated. Pain, although not severe, had been a constant symptom. There was also much itching and burning.

His general health had been considerably affected, but apparently more from mental agitation than from actual disease. The organ was not increased in size. There was no syphilitic or glandular taint. Fearing that if left unaided it might degenerate into epithelioma, he determined to amputate the penis, which was done May 9, 1883.

The operation was done about one-quarter of the distance behind the corona glandis with a circular sweep of the knife; the urethra was then dissected out, drawn forward, and stitched with fine suture to the skin, in order to prevent retraction. The wound healed very kindly, and he returned to his home in the country May 22d, thirteen days after the operation.

The specimen was handed to Dr. Frank Ferguson, pathologist, who reported that "the meatus is small, admitting only a No. 15 French sound, and the tissues around it are anæmic and of a peculiar transparent color. The urethra behind the meatus bears the normal relation to a penis of this size.

"The mucous membrane covering the glans and inner surface of the prepuce is normal. There is a zone of inflammatory products in the submucous tissue of the prepuce and glans throughout their entire extent, and although generally at a considerable distance from the surface (in the glans, along the periphery of the corpus cavernosum), in places there extend from the inflamatory zone limited areas which reach the mucous surface. This zone is composed of small round cells (young cells); in places accumulations of considerable size are seen, as in the formation of abscesses, but nowhere is seen any tendency to break-down.

"Some of the bloodvessels in the neighborhood of this zone of young cells are filled with similar small round cells, while the vessels which pass up through the diseased parts to the mucous membrane are empty. The vessels of the corpora cavernosa are generally distended with blood.

"*Diagnosis:* Inflammation of the submucous tissue of the glans penis and prepuce.

"*Note 1st.* The inflammation is extensive, its products found at the time of incision in the amputation.

"*2d.* There are no epithelial cells found in the glans or prepuce, beneath the mucous membrane, nor anything indicating carcinoma or sarcoma.

"*3d.* There has been general pressure on the vessels and nerves by the inflammatory products."

This case is unique in Dr. Peters's experience. Dr. Ferguson also states that it is the first of the kind which has been brought to his notice. The operation, Dr. Peters thinks, is justified by the fact that Mr. S. is now in good health, and there has been no extension of the disease. The relief to his mental condition would in itself sanction the operation.

Stated Meeting, November 22, 1886.

DR. STIMSON presented a case of

TUMOR OF BOTH SUPERIOR MAXILLÆ

in a girl thirteen years of age. The disease was first noticed three and a half years ago, as a small swelling in the front wall of the left antrum which increased slowly for two years, and then more rapidly during the last eighteen months. An operation for its removal was undertaken two years ago, but abandoned because the tumor appeared to be solid bone; the growth now involves the whole of the left side and all the right side, except the floor and margin of the orbit; the nose is deviated to the right, and the line of the incisor teeth is an inch and a half in advance of that of the lower jaw. The mouth is constantly held partially open because of the growth. This appears bony, hard to the touch, does not yield to pressure, and the concavity of the roof of the mouth has given place to a convexity, most marked on the left side; but few teeth are left in the upper jaw; there are some three superficial ulcers on the roof of the mouth, the mucous membrane in front is injected and deeper in color than usual. The tumor had been growing three years and a half. Dr. Stimson then invited a careful examination of the case, and an opinion as to the nature of the growth and the advisability of an operation.

DR. HUTCHISON said that the growth appeared to be a bony tumor, malignant in character; and it was questionable whether it could be removed completely without too great risk of death from hemorrhage; and if it was not wholly removed it would probably speedily return and prove fatal.

DR. SANDS rather thought that the tumor was a mixture of bone and other tissues, probably sarcomatous. He thought an operation would be hazardous, but the case without an operation would be fatal, and as the skin was not involved he should try to remove the growth.

DR. WYETH thought it was an osteo-sarcoma, but would risk an operation.

DR. BRIDDON was inclined to think it an enchondroma; he would not hesitate to recommend an operation as anything was better than her present condition.

DR. LANGE thought it might not be a very malignant tumor, but a mixed sarcoma; the case indicated an operation, and it was a very favorable one; the only danger being loss of blood, which might be great: but he thought that with proper precaution, including temporary ligature of the carotids, the removal of the jaw would not only be feasible but would give comparatively good results. He pointed out that the tumor did not seem to have as much tendency to grow inward to the base of the skull as it did to grow outward. He did not think there would be much difficulty in regard to the ethmoidal bones and posterior nares.

THE PRESIDENT thought it could be operated on with success; he advised a careful preliminary tracheotomy before the operation. He believed that, with a thorough plugging of the whole pharynx, pressure upon the carotids, without ligation, would be sufficient to control the hemorrhage.

DR. LANGE advised ligation of both carotids and securing the artery by pressing it over a rubber tube, which can easily be done by applying just so much pressure as entirely or partially to interrupt the current.

DR. SANDS recalled but one case in which the blood-current had been shut off in both common carotids simultaneously, and in that case fatal head symptoms supervened almost immediately. Whether they would occur in this case or not he could not say, but thought there would be a risk in performing such an operation; moreover, in his opinion, hemorrhage would not be controlled to any great extent by such a procedure.

He mentioned a case in which he had removed a portion of the lower jaw, and in which secondary hemorrhage took place from the internal carotid artery. A ligature was immediately applied to the common carotid, but there was no diminution of the bleeding, and it was only when a ligature was applied above the bleeding point that hemorrhage ceased. He would prefer, in Dr. Stimson's case, to trust to other means of avoiding undue loss of blood.

DR. WYETH did not think that the danger of immediate death from cerebral anæmia was so very great, there being a number of cases recorded in which the patient survived the deligation of both common carotid arteries, there being a varying interval between the application.

DR. LANGE thought that the ligation should be done cautiously, passing the ligature around the vessel without tying it; as it is drawn tighter gradually, the current can at any moment be diminished at will. This he considered a much safer method, and the risk of mischief is avoided which would probably occur in digital compression during such an operation.

DR. STIMSON thought it would dangerously prolong the operation to perform tracheotomy and tie both common carotids previous to the main operation.

DR. LANGE thought that the operation of tying the carotids would not occupy more than ten or fifteen minutes.

DR. STIMSON thought that it would require half an hour or more.

DR. LANGE suggested that it was not necessary to tie both simultaneously; only three days ago he was compelled to tie the common carotid for hemorrhage from the mouth and tongue. He asked the patient the moment he ligated the artery (this operation being done under cocaine), if he had any sensation of pain, vertigo, etc. He replied he had not. There was no noticeable disturbance of brain function.

DR. LANGE then presented a case of

NEPHROTOMY FOR PYONEPHROSIS,

with the following history:

Mrs. H., thirty-three years of age, married; had for years painful sensations in her lumbar region. Since about eight weeks ago she suffered from severe fluor albus, most likely of gonorrhœal origin, her husband being under treatment for gonorrhœa at that time, and now. For several weeks she had had cystitis, and within the last fourteen days, severe pain in the left lumbar region supervening. On the 11th of March he saw the patient in consultation with Dr. L. Straap. She was feverish, and suffered severe pain in her left lumbar region, where a tumor about the size of a new-born child's head could be felt, in all its relations corresponding to an enlarged kidney. Probatory puncture revealed the presence of pus. On the 13th of March, nephrotomy was done by lumbar incision, and the following condition found: There existed a large, pretty smooth cavity covered with a thin mucous membrane. At the bottom of this cavity a roundish, fleshy elevation could be felt and seen, apparently the main portion of the kidney. This was fluctuating, and on incision by the actual cautery, discharged a moderate quantity of pus. The finger, when introduced, felt the characteristic edges and cavities of the dilated calices. The larger cavity was apparently not in free communication with this main part of the pelvis. By its great extension it seemed to be crowded over and overlapping the organ entirely. At its depth, also, some protruding edges of calices could be felt. Both cavities were thoroughly drained, and a weak solution of boracic acic used as a wash during the after-treatment.

A great feature of the case was the even recovery which took place within eight weeks after the operation, when cicatrization was complete. The discharge of pus and urine through the wound decreased very rapidly, probably on account of the communication through the urethra being reëstablished. The urine, also, soon showed a much better condition, and was quite clear three months after the operation, containing only traces of albumen. The kidney could then be felt much reduced in size, though somewhat enlarged; the patient, now present, being in excellent health. He thought it probable that the woman may have had a hydronephrosis for a longer time, and that, in consequence of gonorrhœal infection, suppuration may have supervened.

DR. LANGE then reported the following case of

NEPHRECTOMY:

S. Frank, Russian, aged thirty-eight years; male; peddler by occupation, being seven years in the United States. He was first seen by him on October 2, 1886. He then had a cachectic appearance, and stated that in the summer of 1880 he had been taken with a severe dysentery, from which he suffered many months, and never fully regained health. For the last two years, steadily increasing discomfort, pain, and tenderness in the right hypochondrium, extending from the hepatic and renal regions downward toward the iliac fossa, has been felt, being more severe at night. Rigors and severe chills, followed by fever and perspiration, were of frequent occurrence; bowels irregular; urine rather abundant, was sometimes clear, and again would show a thick white sediment; a specimen examined the following day showed a large amount of pus and some cylindrical epithelia.

On examination, Dr. Lange found the man greatly reduced in flesh and strength, heart and lungs normal, abdomen slightly distended, walls resistant, so that palpation was difficult. In the right hypochondriac and lumbar region, on bimanual palpation, a tumor could be felt immediately below the liver, of about the size of two fists, the intestine being in front. There was no fluctuation, resistance being quite firm. Probatory puncture from the lumbar region gave a thick, odorless pus, at about the depth of two inches. Urine contained much pus; sp. g. 1.018, acid; containing slight amount of albumen. Microscopically, nothing but pus and a few flat epithelial cells, no cylindrical cells appear. The left lumbar region offered no abnormality.

Operation performed October 19th: nephrotomy, with eventual extirpation of the organ following. The pyonephrotic sac at its lower circumference was incised with a thermocautery, and a great quantity of thick pus escaped. On digital examination it was found that the whole swelling consisted of narrow pus cavities, mostly from a half to two inches in diameter; that it extended pretty high up below the diaphragm, and that for the economy of the body as a urine-secreting organ, it could

not possibly have any value. In view of the advanced degeneration, and the quality and quantity of the urine, the conclusion seemed justified that the opposite kidney must be comparatively healthy, while the pus must mainly be delivered from the right side. Though the adhesions of the capsule were quite extensive they were not very difficult to separate, and he succeeded, in spite of the size of the kidney, in bringing it before the lumbar incision without adding any cross incision, as he had to do in former cases. It was difficult to secure the pedicle, which was thick, short, and unyielding, and overlapped by the mass of the organ; finally, a preliminary elastic ligature was applied, the kidney being then cut away in front of the ligature; in this way a free access to the insertion of the ureter and other vessels was secured. A double ligature was then applied behind the previous one by means of Thierstro's spindles, the first ligature being then removed, and then by scissors and forceps the superfluous portions removed from the pedicle, and the actual cautery applied; and iodoform dusted over the wound. No sutures were applied, the wound being loosely packed with iodoform gauze.

Recovery took place without any serious disturbance, so that on November 14th, five weeks after the operation, he was discharged with a healthy granulating wound. The urine was loaded with pus during the first thirty-six hours, apparently this was pressed down into the bladder by manipulations during the operation, and on account of its thick consistency, was only gradually evacuated by the bladder. It then almost abruptly changed to a more normal condition in quality and other respects, and has remained almost normal. The most interesting feature in the after-treatment was the fact that the pedicle did not slough off, and the coarse silk ligatures did not come away spontaneously.

It is sometimes not easy in nephrotomy to find the exact boundary line between the tunica propria of the kidney and the hard fibroid layer, into which, after protracted inflammation and suppuration, the capsula adiposa is changed. He proposed to carry the incision with the thermocautery through all the layers deep into the tissues of the kidney, and on the edges of this incision to analyze exactly the above boundary line. He considered it very important not to carry the operative manipulations beyond this limit, as he had once met with a serious disappointment in neglecting this rule: the peritoneum was torn without his seeing it in time, and the patient died from septic peritonitis. Eventually the removal of a very old pyonephritic sac might be extremely difficult, and sometimes impossible, of which he had satisfied himself at the autopsy of a lady who had suffered from pyonephrotic calculous kidney for years, with perforation outward and into the colon; so that, finally, fecal matter was discharged through the lumbar region. Both kidneys were affected, and the patient finally died from tuberculosis of the lungs. In this case an absolutely fixed, enormously thickened, cicatricial sac, containing stones, was all that was left of the kidney; and its removal during the autopsy was attended with the greatest difficulty.

The specimen shows a thickened capsule, the tissues of the organ itself apparently entirely gone; the inner surface of the pus cavity is irregular, almost papillary; its form corresponding with that of the calices. Microscopical examination made by Dr. F. Heppenheimer showed that those trabecular prominences represented the remainder of kidney tissue in an advanced state of inflammatory and fatty degeneration, and that a thin epithelial layer covered their free surface, which seemed to justify the conclusion that the mucous membrane of the calices is not entirely gone.

MEDICO-CHIRURGICAL SOCIETY OF MONTREAL.

Stated Meeting, December 3, 1886.

The President, James C. Cameron, M.D., in the Chair.

Dr. Shepherd exhibited a

CASE OF LEPROSY.

occurring in a man aged nineteen, a native of Trinidad. He had a well-marked tubercular eruption on the face and hands, and a copious macular eruption on the legs and buttocks. The maculæ were of the size of ten cent pieces, of a bronzed color, and showed some infiltration. The fingers of both hands were crooked and swollen, and patient could not use them. The claw-like appearance of the hands was very marked. Large bullæ were seen on the hands and wrists, which when evacuated left troublesome ulcers. The patient's face was very characteristic of leprosy, the thickened tissues, dull expression, and tubercular nodules, also loss of eyebrows, and injected conjunctiva, gave the individual an appearance *sui generis*. There were also a number of anæsthetic patches, viz., on the inside of each thigh with atrophy of the skin on right elbow, and on dorsal surface of fingers and toes. The anæsthetic patches have only appeared within the last year. The right ulnar nerve could be easily felt and was slightly enlarged. The mucous membranes were not affected. The patient had been in this country four years and had been treated for syphilis; he came to Canada by the advice of physicians who thought his disease would improve in a colder climate. He was affected with the disease two years before he left Trinidad; the eruption was then principally on the chest, and disappeared with the use of chaulmoogra oil internally and externally. He said the disease is common in Trinidad, and exists chiefly among the Portugese. There was no history of leprosy in his family. Dr. Wyatt Johnston had excised one of the tubercles on the nose and had obtained from it the bacilli of leprosy in abundance, a beautiful preparation of which was shown.

In reply to a question of Dr. A. L. Smith's as to the contagiousness of leprosy, Dr. Shepherd said that there was great diversity of opinion both as to the contagiousness and the heredity of leprosy. This diversity of opinion was well shown in the reports from various leper stations throughout the world, lately published by the Government of the Sandwich Islands. Many think it hereditary in the second generation, others that children of leprous parents are predisposed to the disease. Although the general impression is that leprosy is hereditary, still there are no very strong proofs supporting this opinion. Dr. Shepherd thought that the disease was no doubt communicable by sexual intercourse, and could be inoculated like syphilis—but is not contagious in the common meaning of the term.

SUCCESSFUL OVARIOTOMY IN A PREGNANT PHTHISICAL WOMAN.

Dr. Wm. Gardner reported the case of a lady who was the mother of two children, the youngest being ten years of age, and who had suffered for many years from cough, hemoptysis, and purulent expectoration. An ovarian tumor was diagnosticated five years previously by her family physician. When seen in March last, by Dr. Gardner, she was two months pregnant, and he decided that the best course was to remove the ovarian tumor, as she suffered much from nausea, vomiting, and orthopnœa. The operation was performed in the middle of May. The patient made a rapid recovery, and her breathing became easier, and cough and expectoration lessened. Since then she had been safely delivered of a fine healthy child, weighing over ten pounds. Dr. Gardner remarked that operative measures were much preferable and safer than the old treatment of tapping the tumor or bringing on premature labor.

Dr. Shepherd related the following case of

SECONDARY SUTURE OF THE ULNAR NERVE, WITH RAPID RETURN OF SENSATION.

John D., æt. fifty, was cut with an axe over the left elbow, between the olecranon process and the internal condyle. The wound healed rapidly, but the patient afterward found that he could not use his arm and that there was considerable pain in the elbow. He entered the Montreal General Hospital under Dr. Shepherd, June 23, 1885, some ten weeks after the injury. At that time the left arm was semi-flexed and fixed; on attempting to straighten it great pain was complained of in the elbow. The muscles on the ulnar side of the forearm were wasted, and the little and ring fingers bent and useless. No sensation felt in parts affected by ulnar nerve. On examining the elbow a scar two inches long was seen stretching across the space between the olecranon and internal condyle; this cicatrix was excessively tender on pressure. The diagnosis of division of the ulnar nerve was made, and next day (June 24th) an operation was performed for the purpose of uniting the divided ends. An incision was made in the line of the ulnar nerve and across the scar, and the nerve was soon reached. The upper end was bulbous, and lower atrophied; both were embedded in scar tissue. The ends were separated by an interval of half an inch. After dissecting out the nerve the divided ends were "freshened" and brought together by a continuous suture of fine catgut, and the wound closed and dressed with dry antiseptic dressing. Next day the man had fairly good sensation in his little and ring finger, and a tingling feeling as if the nerve were asleep. The wound was first dressed on the sixth day and drainage tube removed; by July 8th the wound was firmly united and patient was sent home. Sensation, both general heat and tactile, was good, but motion was deficient. He was heard from in January, 1886, and at that time he had gone back to his work (lumbering), and said he was fast recovering the use of his arm, the only complaint he had was a slight burning pain over the little finger. Since then he has not been heard from.

Dr. Shepherd remarked that in these cases, in order to get a good result, the wound should unite by first intention, and the newly united nerve should not be subject to any tension. As long as the freshened ends were kept in accurate apposition it did not matter much what the material was; he also stated it was only necessary to pare off the ends of the nerves, it was not necessary to excise the nerve till healthy nerve tissue was reached. The interesting point in this case was the rapid return of sensation after suture. Surmay reports a somewhat similar case. Motion often takes some time before it returns, even after sensation has been fully established.

Dr. Roddick reported a case of

SUTURE OF THE SCIATIC NERVE

eighteen months after its division, The operation was followed by the gradual return of sensation and motion to the foot and rapid healing of two large and troublesome ulcers on the outer border of the foot. The operation was performed May, 1884. The age of patient was twenty-six. At present he could walk without a stick. The interesting feature in this case was the rapid healing of the ulcers after the union of the nerve, showing that the nerves of nutrition had first resumed their functions, although sensation and motion were still in abeyance.

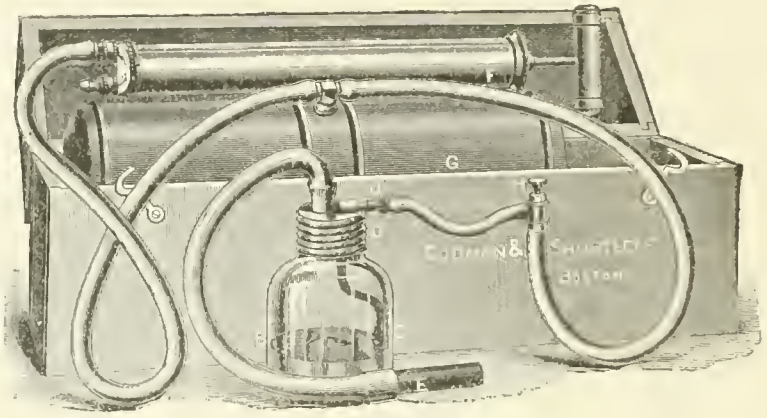
NEW INVENTIONS.

OLIVER'S ATOMIZER.

Depending upon the principle that a stream of water forced through a narrow tube against a firm resistance will become broken by the concussion into a coarser or finer spray, which remains for a short time suspended in the atmosphere, Auphan, at Euzet-les-Bains, in 1849, and, subsequently, Sales-Girons, Demarquay, Mathieu, Lewin, and others, constructed inhalation chambers, or portable apparatus for the inhalation of nebulized liquids. The apparatus of Bergson, constructed in 1862, after a suggestion of Nothanson, produces a spray by the impact of a current of air with a stream of liquid drawn by its suction power into a tube placed perpendicularly to the air-tube, the fineness of the spray being regulated by the size of the apertures in the tubes. The apparatus described twenty years ago by Dr. Henry K. Oliver, of Boston, combines these principles; the spray from a Bergson nebulizer being made to impinge upon the wall of the vessel containing the tubes and liquid, and thus becoming reduced into a state of still more minute subdivision. In the improved Oliver apparatus, the spray from the Bergson tubes first strikes upon an overhanging projection from the air-tube, and is thence deflected across the diameter and upon the wall of the glass container, being thus twice broken up, each time into finer particles; the nebula thus formed being conducted to the mouth of the patient by means of a rubber tube and mouthpiece of sufficient aperture. A separate mouthpiece should be used for each patient. The air for propulsion may be conveniently supplied by means of hand-bulbs, or, for office use, be drawn from a reservoir in connection with an air-pump; a very neat and complete apparatus, which will be found extremely satisfactory, is made at a very moderate price by Messrs. Codman & Shurtleff (see figure).

The very fine cloud produced by this instrument, remains suspended in the atmosphere for fully a minute, and, according to the observation of Dr. George A. Evans, the admixture of glycerine with the solution to be nebulized prolongs the period of suspension. This

persistent nebula can be drawn by the patient with the current of inspired air a much greater distance into the air-passages than is possible with the ordinary sprays from the simple Bergson or Richardson tubes, even though, in the latter case, the patient inhale merely the more distant particles lightly suspended in the atmosphere.



Oliver nebulizer, with reservoir and air-pump.

B, glass jar. C, Bergan tubes attached to D, metal cap. E, mouthpiece of hard rubber. F, pump. G, reservoir tested to 100 pounds. H, spring cut-off. J, metallic attachment of air-tube.

It is a fact, not generally appreciated, that when the ordinary spray-tube is placed within the mouth, the stream of spray strikes the hard palate, pharynx, or other structures, being there in part deposited as larger or smaller globules, and in part transformed into a nebula, as in Oliver's apparatus. A small portion of the nebula is inhaled, but most of it is lost by exhalation, forming the dense cloud which is seen to issue from the mouth. Oliver's apparatus, forming outside of the body the nebula which alone can pass the glottis, allows a much larger proportion of the fluid nebulized to reach the interior and deeper structures. It also avoids many of the objections which hold against the steam atomizer, such as the relaxing effect of the steam upon the mucous membranes. If it be considered advisable to warm the nebula, the vessel containing the medicament may be placed within another vessel containing hot water. By combining one of these instruments with an apparatus for the administration of inhalations of compressed air (Waldenburg's, or some of its modifications), the conditions are obtained which most highly favor the penetration of the vapor (into which, practically, the very fine spray becomes converted) into the ultimate air-cells.

Inhalation of nebulized liquids may be advantageously employed in most cases of inflammatory affections of the air-passages, whether acute or chronic, not only to modify local conditions, but, in certain cases, to secure constitutional effects by absorption of the drug through the respiratory mucous membrane. The drugs most generally useful are those which may be classed under the heads of astringents, sedatives, sorbefacients, antiseptics, and agents which promote secretion or liquefy its products. In acute laryngitis and laryngo-tracheitis, compound tincture of benzoin will be found highly useful, and may be combined with preparations, preferably of watery solutions, of opium, belladonna, stramonium, conium, cocaine, or other sedatives, if pain be a prominent symptom. In more sluggish inflammations of the upper air-tract, terebene,[1] eucalyptol, oil of pine, oil of fir, and other balsamics may be employed, properly diluted, with the addition, as recommended, of some light oil, as olive oil or oil of almonds. Creasote, properly diluted, and infusion of tar, are appropriate in the more chronic cases. Astringents, such as solutions of tannin, vegetable extracts containing tannin, solutions of alum, zinc sulphate or sulphocarbolate, zinc acetate, and the like, may be used in appropriate cases; the strength of the solution being regulated by the comparative recentness or chronicity of the case, stronger solutions being best borne in the more recent cases.

Solutions of ammonium chloride, sodium chloride, potassium chloride, ammonium iodide, sodium iodide, potassium iodide, tincture of iodine, ammonium carbonate, potassium carbonate, turpentine, terebene, tar, wine of ipecac, oleoresin of cubeb, and, perhaps, mineral or vegetable astringents, when expectoration is unduly profuse; cherry-laurel water, tincture of cimicifuga, sodium bromide, ammonium bromide, or the sedatives previously mentioned, when cough is unduly troublesome, are among the agents more or less useful, singly or in combination, in cases of bronchitis, acute, subacute, and chronic, the comparative freedom of expectoration, and the character of the material expectorated, being the principal guides in the selection. In fetid bronchitis, chronic broncho-pneumonitis, the collateral bronchitis of phthisis, and, perhaps, pulmonary gangrene, the same drugs may be used, with the addition of eucalyptol, creasote or carbolic acid, thymol, ethyl iodide, mercuric chloride, sodium borate, boric acid, salicylic acid, potassium permanganate, Labarraque's solution, solution of sulphurous acid or of hyposulphites, solution of hydrogen dioxide, and, in certain cases, with proper precautions as to dose and dilution, Fowler's solution. To restrain hæmoptysis, resort may be had to turpentine, ergot, hamamelis, gallic acid, tannic acid, sodium chloride, alum, tincture of chloride of iron, or Monsel's solution, according to indications.

[1] Among the agents mentioned in various connections are a number of volatile substances, which may also be employed without any apparatus, or with so simple a contrivance as a saucer or a piece of sponge for an evaporating surface.

In tonsillitis or pharyngitis, whether simple or diphtheritic, coarse sprays are more generally useful; and in croup, for obvious reasons, the steam atomizer is to be preferred.

In cases of syphilis, where the iodides are not well borne by the stomach, ethyl iodide, or solution of iodine, or of its salts, may be employed by inhalation with a view to the production of constitutional effects; and in all cases where it is desirable to minimize efforts of swallowing, and hypodermatic medication is to be avoided for any reason, the appropriate drug may be exhibited in this manner, with proper precautions. Opium, belladonna, and aconite are examples of agents readily absorbed by the respiratory mucous membrane. As a rule, the solutions should be of alkaline reaction. Instruments with metallic tubes or with hard rubber tubes, are furnished by the manufacturers. Notwithstanding the fact that in both cases the nozzles are of platinum, such saline solutions as will reduce metal (*e.g.*, ammonium chloride, mercuric chloride) should be used only with the rubber tubes; while benzoin and other agents that will dissolve rubber, must be used only with the metallic tubes, until such time as glass tubes, the preferable ones in all cases, are supplied by the manufacturers.

NEWS ITEMS.

PROFESSIONAL SECRECY.—We learn from the *Union Médicale* that a case was lately tried before a French court in which the secrecy imposed upon medical men by the law was pleaded by a physician as his justification for refusing to certify to the nature and duration of the last illness of a man who had insured his life in the sum of 10,000 francs. The life insurance company demanded the certificate as one of the conditions on which it would pay over the amount to the estate, and it appears that the heirs, for their part, united in absolving the physician from the obligation of secrecy. But the doctor held that it was not within the legal power of any representative or heir of the deceased to dissolve the obligation; that, he contended, was a function vested in the sick person up to the time of death, and one that could not pass into other hands after his death. He held also that he was not at liberty to use his own discretion in the matter, but was absolutely bound to secrecy. He laid the question before his professional brethren at Havre, the town in which the case was tried, and they sustained him. Furthermore, the court affirmed the validity of the position taken. It was laid down that, admitting that a patient might, in certain cases, relieve his medical adviser of the obligation of secrecy, that power was absolutely personal, and could not be transmitted to the heirs; also, that the physician must be the sole judge as to whether or not, in any given case, he had been consulted under the seal of secrecy.

CONSUMPTION OF TOBACCO IN EUROPE.—M. Paul Leroy-Beaulieu, in an interesting paper in the *Economiste Française*, gives the following figures showing the quantity of tobacco consumed in the different countries of Europe. The rate per 1000 inhabitants is, according to him, as follows: Spain, 110 pounds; Italy, 128 pounds; Great Britain, 138 pounds; Russia, 182 pounds; Hungary, 207 pounds; France, 210 pounds; Denmark, 224 pounds; Norway, 229 pounds; Austria, 273 pounds; Germany, 336 pounds; Holland, 448 pounds, and Belgium, 560 pounds. In other words, while in Spain little more than one pound per head is consumed, nearly double that quantity is consumed in France, three times as much in Germany, four times as much in Holland, and five times as much in Belgium.

COMPARATIVE PATHOLOGY.—At a recent meeting of the Biological Society, M. Raphael Blanchard showed a lizard which had a papilloma, probably of acarian origin, on its back.

RIGHTS AND LEFTS.—Dr. Louis Jobert has published a work on the cause and frequency of left-handedness. No purely left-handed race has ever been discovered, although there seems to be a difference in different tribes. Seventy per cent. of the inhabitants of the Pendjab use the left hand by preference, and the greater number of the Hottentots and Bushmen of South Africa also use the left hand in preference to the right. Dr. Marro, as a result of his study of criminals, has found that from fourteen to twenty-two per cent. of those who have been convicted of crime were left-handed, the highest ratio among people of all classes being only nine in the hundred.

THE CONTAGIOUSNESS OF LEPROSY has for a long time been a mooted question. The Royal College of Physicians, in order to obtain the best information on this subject, sent inquiries to physicians throughout the world, whose practice had brought them in contact with the disease, and whose opinions would, therefore, be of value. Thirteen of these have no doubt of its contagiousness, and thirty-four entertain no doubt of its non-contagiousness. Twelve regarded leprosy and syphilis as being intimately related; twenty-one believed there was no relation. Most of those to whom the inquiries were sent regard leprosy as hereditary, and also that it may originate spontaneously under suitable conditions.

THE ODOR OF BRANDY.—M. Ordonneau has lately made some investigations concerning the cause of the peculiar odor of brandy made from wine. That of brandy prepared from other materials such as maize, beets, and potatoes, is characterized by what is known to French experts as the "odeur de trois-six," which is not present in wine brandy. This odor has been traced by M. Ordonneau to the presence of isobutylic alcohol. In genuine cognac brandy, the predominating flavor is due to the presence of normal butylic alcohol, which is present to the extent of 218.60 grammes per hectolitre. The production of this alcohol appears to be due to the presence of *Saccharomyces ellipsoideus* in the grape juice, since it can be developed from the ordinary refinery liquid by fermenting it with the sediment of wine. The isobutylic alcohol, on the other hand, appears to be a secondary product of the fermentation with beer yeast. It might, therefore, be possible in future to obtain brandy of good flavor by fermenting malt liquor with the *Saccharomyces ellipsoideus*. The other flavoring product to which brandy owes its peculiar bouquet, appears to be a terpene boiling at 178° C., the products of the oxidation of which characterize old brandy. The author gives an analysis of cognac brandy, from which it ap-

pears that amylic and normal propylic alcohol and acetic ether form the principal ingredients, besides ethylic alcohol, although propionic, butyric, caproic and œnanthic ethers, and pyridin, are present in minute quantities.

ANCIENT IRISH MEDICAL JURISPRUDENCE. — The Brehon Code of Laws, the most ancient in Europe, dating from the fifth century, deals largely with medical affairs. They refer to surgeons who lived before the second century. They carefully provide for distress—that is, taxation—for the support of the son taken from his dead mother's breast, for the incurable, for the care of the sick as to food, bedding, nursing, and a house with the wind blowing in all quarters and with a stream close by. The medical man had power to keep from the house "fools and female scolds." The mode of distraint in case of a physician was, "Let his horsewhip and his probes be taken up. If he has not the proper number of such things, let a thread be tied about the finger next his little finger." The unqualified physician was to be fined if he operated without giving a guarantee against damages, or without giving notice that he was not qualified. The practitioner was to be quite exempt. An impartial physician was to be the judge of the mode of treatment and of the due recompense. The fees, always paid with oxen, the current coin, were most exactly proportioned to the rank of the patient. Cattle abounded, and as late as 1369 the value of a cow was only 3s. 4d.—DR. MAPOTHER, *in the Dublin Journal of Medical Science.*

SLEEPING IN THE WOODS.—In one of the German health-resorts, the *Allgemeine medicinische Central-Zeitung* states, the experiment was tried this summer of having the patients with pulmonary disorders sleep all night in the open air in the pine woods. The hammocks, used to rest in during the day, were provided with pillows and bed-clothing, and a party of five, two ladies and three gentlemen, spent their nights in the woods with no roof over their heads. The experiment was very successful, the patients slept better than they had been able to do in their rooms, and all declared themselves as feeling much more refreshed by their sleep than usual. It is proposed next summer to provide accommodation for a larger number of patients in the forest, so that the experiment may be tried on a large scale.

IODOFORM PREPARATIONS.—The dark color which iodoform salves and other solutions assume is said by Hebeler to depend on the presence of free iodine, and takes place the more quickly the more the preparations are exposed to the light. Solutions should, therefore, be kept in dark bottles, and ointments, especially those with a petroleum basis, be kept covered from the light.

CARLYLE ON THE MEDICAL PROFESSION.—In a letter written to Dr. Hutchinson Stirling in 1842, and but recently published, Carlyle said of the medical calling: "What profession is there equal in true nobleness to medicine? He that can abolish pain, relieve his fellow-mortal from sickness, he is indisputably usefullest of all men. Him savage and civilized will honor. He is in the right, be in the wrong who may. As a lord chancellor, under one's horse-hair wig, there might be misgivings; still more, perhaps, as a lord primate, under one's cauliflower; but if I could heal diseases I should say to all men and angels, without fear, 'En! ecce!'" Carlyle also gives some good advice on the subject of writing *versus* working. He counsels his correspondent, Dr. Stirling, then a young man, to "learn the indispensable significance of hard, stern, long-continued labor," and of silence. "Be in no haste to speak yourself," he says. "Why be *porous*—incontinent? Nothing can foment itself to clearness in a *colander*." Avoid literature, he continues, which, as a trade, is the "frightfullest, fatalest, and too generally despicablest of all trades now followed under the sun."

FATAL MISTAKE IN A POLICE LAZARET.—In a lazaret attached to a Moscow police-station an attendant recently administered by mistake a tablespoonful of a strong solution of carbolic acid to four patients, who at once complained of a burning sensation in the throat, and soon presented all the symptoms of carbolic acid poisoning. The surgeon managed to save all except one of the victims, who died next day.

PENNSYLVANIA HOSPITAL.—The second annual meeting of the Association of Ex-resident Physicians of the Pennsylvania Hospital was held in the library of the hospital, on Thursday evening, December 16, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 7 TO DECEMBER 13, 1886.

POPE, B. F., *Major and Surgeon.*—Relieved from duty in the office of the Surgeon-General of the Army, and will report in person to the President of the Army Medical Examining Board in New York City for duty as member and recorder of the Board. *S. O. 285, A. G. O.*, Dec. 9, 1886.

AINSWORTH, FRED. C., *Captain and Assistant Surgeon.*—Relieved from duty as Recorder of the Army Medical Examining Board, New York City, and ordered to report in person to the Surgeon-General of the Army for duty in his office.—*S. O. 282, A. G. O.*, Dec. 6, 1886.

TURRILL, H. S., *Captain and Assistant Surgeon.*—Ordered for duty as Post Surgeon at Fort Spokane, Washington Territory. —*S. O. 209, Department of Columbia*, Nov. 29, 1886.

BARROWS, CHARLES C., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for two months, to take effect when his services can be spared by his Post Commander.—*S. O. 285, A. G. O.*, Dec. 9, 1886.

WILSON, GEORGE F., *First Lieutenant and Assistant Surgeon.* —Granted leave of absence for one month, with permission to apply to headquarters, Department of the Missouri, for an extension of twenty days, to take effect about December 15.—*S. O. 125, Department of Dakota*, Dec. 1, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 11, 1886.

PERCY, H. P., *Passed Assistant Surgeon U. S. N.*—Ordered to Naval Academy at Annapolis, Md.

NORFLEET, ERNEST, *Passed Assistant Surgeon U. S. N.*—Granted three months' sick leave.

RECOVERY AFTER ABDOMINAL SECTION FOR PURULENT PERITONITIS.[1]

BY JOHN B. ROBERTS, M.D.,

PROFESSOR OF ANATOMY AND SURGERY IN THE PHILADELPHIA POLYCLINIC.

THE operative treatment of peritonitis is of sufficient importance to warrant the report of the following successful case:

A woman, aged forty-four years, came under my notice with the following history: About eight weeks ago she was seized with violent pain in the abdomen, which pain has been constant ever since, with occasional griping and colicky sensations. There has been no vomiting, but for three weeks past she has been restricted entirely to liquid food by her physician. There has been no chill. When first seen by me, she stated that some three weeks previously she had been seized with great pain in the abdomen during the night, and that about that time she had noticed in the left side of the belly a tumor. I could get from her no definite history of the tumor, or of any previous abdominal disease. Her health previous to the present illness had been good. At the time my attention was called to her by Dr. Arthur V. Meigs, she had a temperature of 102°, and a pulse of about 130. From the flushed face, the thighs flexed upon the pelvis, the considerable pain on palpation of the abdomen, and the adynamic condition, it was very evident that the woman was suffering from peritonitis, due in some way to this tumor.

Accurate examination was not practicable on account of the pain which it caused, and the woman was too weak to permit any extensive or elaborate means of diagnosis being instituted. The tumor was smooth in outline and apparently about the size of a fœtal head. A vaginal examination showed the uterus to be not much out of the normal position, although the fundus seemed to be tilted somewhat forward. My diagnosis, made in a provisional way, was a cyst of the left ovary, of perhaps several months' duration, which had ruptured, allowing the contents to escape into the abdominal cavity. It was possible, of course, that the peritonitis was due not to rupture of an ovarian cyst, but to some other form of tumor, or to disease of the Fallopian tubes.

Under the belief that removal of the tumor and cleansing the peritoneal cavity of the contents of the tumor which had been thrown into it would afford the best chance of recovery, I was induced to call a consultation as to the propriety of doing an abdominal section.

Accordingly, on the following day, with the consent of the other members of the surgical staff of the Pennsylvania Hospital who were present, I made an incision through the linea alba, extending almost from the umbilicus to the pubes, and at once came upon a smooth tumor containing fluid. Puncture of this with the trocar evacuated some five or six ounces of very offensive pus. The intestines and omentum were adherent to the surface of this sac, which was evidently the rounded mass felt through the abdominal wall. It was soon apparent that there had been a long-standing inflammation involving the structures contained within the abdominal cavity. It was impossible to enucleate this large sac or cyst because of the matting together of all the structures, and the large amount of new tissue which had formed as the result of the inflammatory process.

Although great care was taken, and a good deal of time consumed, I was unable, either by my hand or by means of a bougie introduced as an explorer, to determine the original site of the growth, or the reason for the beginning of the inflammation. There were a number of similar sacs or cysts containing pus, the walls of which were made up of adventitious tissue and the neighboring viscera. In fact, the whole contents of the left side of the pelvis were glued together by inflammatory adhesions and new tissue. As it was found impossible to remove all the new tissue or to tear up all the adhesions, I was contented with scraping out the most accessible portion of the sac wall, evacuating the pus from the numerous other cavities, and washing out the abdomen very thoroughly with a solution of bichloride of mercury containing one part of the salt to ten thousand parts of water. The abdominal wound, which was about five inches in length, was approximated by catgut sutures. Two rubber drainage tubes were inserted at the lower angle of the wound, and a dressing of iodoform and corrosive sublimate gauze applied.

The whole operation was done under the strictest antiseptic precautions, and the patient was then put to bed. For two days she received no food, liquid or solid, being allowed simply cracked ice, and an occasional small dose of morphia and brandy. Subsequently she was given small quantities of milk and such easily digested food. On and after the second day, a weak solution of corrosive sublimate of the same strength as that used at the time of the operation, namely, one to ten thousand, was used for washing out the abdominal cavity through the drainage tubes, but the upper portion of the wound dressing was not removed. The temperature gradually fell to normal, which point it had reached on the fourth day. At this time the upper portion of the dressing was removed for the first time, and a complete union of the upper part of the wound was found.

Three weeks after the operation, at her own

[1] Read before the Philadelphia Clinical Society, November 26, 1886.

request, she was discharged from the hospital, although she had not yet regained sufficient strength to be able to move about the room. In fact, we had kept her in bed up to that time, fearing that the exhaustion of getting up might be deleterious to her.

During the last week of her stay in the hospital, a portion of the incision reopened superficially. At the time of her discharge the opening into the abdominal cavity appeared closed, though there was still a small, superficial wound at the lower portion of the original incision.

This case of suppurative peritonitis due to an unknown cause, cured by operation, is a good illustration of the recent advances in abdominal surgery.

Although I did the operation under the impression that the origin of the trouble was an ovarian cyst, yet I should have been willing to do so had I known the exact condition of the disease, because in such a localized peritonitis as this, the symptoms present were almost certain to be followed by death. At least this is the reasonable conclusion when we consider the condition of the patient's temperature and pulse, and the fact that the peritonitis was so intense that her thighs were flexed upon her pelvis. I had, in fact, every reason to anticipate a speedy termination of the case.

Operations upon the abdomen have recently been performed for so many causes with such a high percentage of success, that it seems to me probable that many cases of peritonitis more or less resembling this one can be very successfully treated by abdominal incision and an evacuation of the purulent contents of the belly.

My experience in abdominal section and suture of the intestines, for stab wounds, and the experience of Bull, Hamilton, and others, in a similar treatment of gunshot injuries of the belly, together with my results in exploratory abdominal incisions, have convinced me that we are too ready to allow patients to die from intra-abdominal injuries. Rupture of the bladder, stab wounds of the intestines, gunshot wounds of the intestines, traumatic rupture of the intestines, perforating ulcers of the stomach, and even, perhaps, perforations due to typhoid fever should be treated in many cases by immediate opening of the belly and local surgical treatment.

This case is a contribution to the literature of the subject, to be added to the many cases similarly treated by gynecologists. General surgeons do not, I think, fully appreciate the advantages which are gained by imitating our gynecological brothers in the adoption of active surgical treatment for abdominal lesions.

A CASE OF CHRONIC DISCHARGE FROM THE MAMMA.

BY A. K. BOND, M.D.,
OF BALTIMORE.

ABSCESSES of the mamma, with consequent discharging sinuses, are familiar to every physician, and discharges of thin, sometimes bloody, fluid from the nipples are not infrequent in the course of mammary tumors. To the former class belongs the case which is the subject of the present article, differing from those commonly seen in several particulars which make it especially interesting.

The patient, a well-built colored woman, a washerwoman by trade, consulted me in the spring of 1883, in regard to a discharge from the right breast, giving, in answer to my questions, the following history. She was thirty-eight years of age, and as a girl had been strong and healthy. She was married in her eighteenth year, and bore four children in rapid succession, nursing them without any trouble, save a slight rawness of the nipples, which occurred at the beginning of each lactation, and was relieved quickly by the use of astringent lotions. One of her four children died of brain fever, and one is now consumptive. Since her twenty-fourth year she has not been pregnant.

About four years ago a goitre appeared on the right side of the neck, and increased to the size of a half orange, becoming especially large at the menstrual periods. This I succeeded in permanently reducing by hypodermatic injection of tincture of iodine.

One and a half years ago, without known cause, her right mamma increased in size, until it became as large as a nursing breast, and, upon the application of poultices, discharged a quantity of pus through the natural ducts of the nipple. After a time the flow of pus ceased, leaving a chronic discharge of colorless fluid, which had continued ever since, and of late had proved so troublesome that she applied to me for relief. The discharge was slight during the daytime, but at night, while she was in bed or asleep, it became so great as to drench her clothing even as far as the waist, thus disturbing her rest, and proving a drain upon her system.

I ordered the ointment of belladonna to be applied to the breast, and, for a few weeks, this lessened the discharge; but, on July 3, 1883, she returned, complaining that the flow had been on the foregoing night again very great.

Upon examination, the fluid expressed from the nipple—which was of a pale yellow color, slightly tinged with red, and of a neutral reaction to litmus—showed, under the microscope, pus cells and red blood-corpuscles scattered over the field. During the following night her menses appeared. On July 6th she reported a considerable flow of blood from the right nipple on the preceding night. Upon examination, I expressed from the nipple a quantity of fluid, which, standing in droplets, appeared blood red, but upon linen produced a pale yellow stain like that of thin pus.

The right mamma was at this time soft to the touch, and the parts about the nipple seemed somewhat infiltrated with clear fluid, but the breast did not otherwise differ in appearance from the left breast, which was normal for a non-pregnant woman. The openings through which the fluid passed out were on the upper side of the nipple, and pressure within an inch of the nipple caused an escape in jets, while pressure upon the surrounding part produced no result.

On July 13th I again examined the discharge, finding groups of granular cells like small colostrum

corpuscles, and but very few red blood-corpuscles in the field. Another examination, on July 19th, showed similar groups; red corpuscles here and there; a number of cells about the size of red corpuscles; but with edges digitate and not so deeply pigmented, some of them containing red granules, and a great number of active pus cells. On August 5th and September 5th, her menstrual periods, she had again bloody discharges from the nipple, and on December 6th, ten days after her menstrual flow, an abundant discharge of blood. The pale discharge remained uncured up to this time, although now and then lessened in quantity under the use of remedies.

As the patient was very much debilitated at the beginning of the treatment, I used, during the whole time she was under my care, general tonics, such as iron, arsenic, and cod-liver oil, with great benefit to her health. I also used internally for a time extract of belladonna and zinc oxide, but without any appreciable influence upon the mammary trouble.

The local treatment of the mamma was a subject of careful thought. Astringent lotions did no good. Belladonna ointment applied frequently to the breast was followed by considerable diminution in the flow, but after a few weeks ceased to have any influence upon it.

Strapping the breast with adhesive plaster, leaving the nipple free, lessened the discharge, and was of great comfort to the patient. Attacks of pain from irritation and over-distention, which occurred from time to time, were readily relieved by warm poultices over the breast.

In addition to the above methods, I devised still another which aided me greatly in the relief of the trouble. Wishing to reach directly the surface affected, and to apply the remedies immediately to it, and not feeling justified in laying it open by an incision, I thought of using the natural openings of the nipple for the purpose. Accordingly I had a hypodermatic needle filed blunt, and introducing this after the manner of a sound along one of the ducts from which the discharge escaped, found no difficulty in passing it in to the depth of an inch or more, and injecting, without injuring the parts, various solutions upon the mucus-secreting surfaces of the gland. Attaching the syringe, and holding the nipple firmly but gently against the needle, I threw in a small quantity—a half drachm or more—of fluid, until the parts were fully distended, and, after holding it in for a few seconds, permitted it again to escape. In this way I injected, at first water, then a solution of alum at intervals of a few days. After a fortnight, I exchanged this for liquor iodinii compositus diluted with water, continuing its use for several weeks, but without either checking the discharge or bringing about a healthy action of the secreting parts.

Again, on December 3d, three months after the failure of the iodine method, a degree of pain in the breast called for local anodynes, and I injected in the same way small quantities of morphia and atropia solution, or (when the pain was less) of a four grain solution of atropia, both of which injections seemed to diminish greatly the amount of the discharge.

Under these injections of atropia and of morphia, which were continued once or twice a week until the middle of February, 1884, the patient experienced great relief, the discharge ceasing altogether, although the secretion continued in a slight degree, the patient pressing out each morning a few drops of fluid from the nipple. An occasional attack of pain in the breast was readily relieved by the application of a poultice. My daily record ends April 11, 1884, two months after the latest injection, and up to this time there had been no recurrence of the discharge. The breast when last examined was soft to the touch, and showed no signs of induration. Pressure on the lacteal sinuses was painful, and caused the escape of a few drops of fluid.

A note added eight months later reports the patient in good health.

The peculiar points in the case above recorded are the occurrence of an abscess of the breast without known cause, in a woman who was neither pregnant nor nursing; the secretion of fluid in such large quantities, and the unusual manner of its discharge; the flow of blood from the nipple at the time at which the menstrual flow was taking place.

I cannot find any similar case noted in the books which I have at hand.

The direct method of application of drugs through sounding of the nipple ducts is worthy of recommendation in similar cases.

MARTIN'S OPERATION FOR PROLAPSUS UTERI, SLIGHTLY MODIFIED.

BY BARTON C. HIRST, M.D.,
PHYSICIAN TO THE MATERNITY HOSPITAL, PHILADELPHIA.

AT a time when an operation for prolapsus uteri so difficult of execution and often so unsatisfactory in its results as that proposed by Alexander, is seriously discussed, and when it is even suggested that abdominal section be performed in order to fasten the fundus of the uterus to the abdominal wall, a short account of an operation comparatively easy to do, absolutely safe, and which, its originator claims, has not yet failed to produce good results in his hands, may be of interest.

The operation described in the last edition of Martin's book *Pathologie und Therapie der Frauenkrankheiten*, was devised by him after a trial of the various methods proposed by Winkel, Neugebauer, Simon, Hegar, and Bischoff had convinced him that they were not to be relied upon to produce a permanent cure; it consists of a posterior and an anterior colporrhaphy and a circular amputation of the cervix. The posterior colporrhaphy resembles the operation proposed by Emmet for the cure of lacerations of the perineum; the denudation makes a figure that may be compared to a half-moon with two extensions from the plane surface, one on each side of the median line: these two extensions run up the posterior vaginal wall, one in each lateral sulcus, on both sides of the posterior column; when the stitches are introduced and the wounds are closed, the figure

is Y-shaped, the lateral arms being in the vagina on either side of the column, and the straight arm running through the perineum.

The anterior colporrhaphy is performed by excising an elliptical piece of mucous membrane from the anterior wall of the vagina, one pole of which should be at the junction of the external cervical with the vaginal mucous membrane, while the other should reach almost to the meatus urinarius; this should be the first step of the operation, and should be done while the uterus is in a condition of total prolapse. The mucous membrane should be dissected off in a single piece, the width of which at its widest part should about equal the width of the anterior wall of the vagina. The denuded surface will appear so extensive as to excite some apprehension that the wound cannot be closed, but this difficulty is obviated by the use of the continuous catgut "Etagennaht;" with a needle and a long catgut thread the central portions of the denuded surfaces are brought together, the needle passing with each stitch from the urethra toward the cervix; when the lowest point is reached, the same thread is carried up again toward the urethra, the relations of the parts being inverted by the prolapse, uniting still larger surfaces; and finally, if necessary, the same suture is again reversed, this time bringing together the edges of the mucous membrane that at first looked so far apart that their union seemed almost impossible. Thus the two sides of the denuded surface are brought into perfect apposition and without an excessive amount of tension.

Martin insists upon the amputation of the cervix as essential to the success of his operation, believing, as he does, that there is always present a hypertrophic elongation of the supravaginal portion of the cervix, but in this he is probably mistaken. Every one who is familiar with these cases must have noticed that after replacing a prolapsed uterus and confining the woman to bed for a few days, the measurement of the cavity will be little, if at all, above the normal, although before it may have been, perhaps, ten or fifteen centimetres. The so called hypertrophic elongation is therefore merely a temporary condition produced by mechanical causes, and by no means a true hypertrophy; if, then, the uterus can be retained in place the mutilation entailed by the amputation of the cervix is unnecessary.

I have lately had an opportunity of performing this operation, modified by the omission of the amputation of the cervix, with such a satisfactory result as to warrant me in calling the attention of those who have not had an opportunity of seeing Martin's book, to an operation which seems to promise the best results in a class of cases that have hitherto been only too apt to defy all treatment.

The case in which Martin's operation proved a success may be briefly described as follows: Mrs. C., aged fifty-seven, applied for treatment on September 10th, with the history that her womb had come down a year before; that since then she has had increasing difficulty in walking and in performing her housework, and that whenever she urinated she had first to lie down and replace her womb, but that even then urination was painful. An examination showed total prolapse of the uterus, a large cystocele, and extensive erosions of the cervix; the sound showed a length of ten centimetres. The womb was replaced, the woman confined to bed, and after the ordinary local treatment for five days the erosions were healed. The uterus measured seven centimetres. On September 15th, the operation was performed in exact accordance with the description already given, omitting, however, the amputation of the cervix. On the fourteenth day the stitches, shotted silkworm gut, were removed from the posterior vaginal wall and the perineum; the catgut sutures had been absorbed; the union was perfect. The highest temperature had been 99.5°, there had been no bleeding and no suppuration. To-day, November 4th, the uterus is in good position, the woman is actively engaged in her household duties, and considers herself cured.

MEDICAL PROGRESS.

Tyrotoxicon and Cholera Infantum.—At a recent meeting of the Michigan State Board of Health, Dr. Vaughan said:

Since my last report I have found tyrotoxicon in one sample of milk. As this case has a direct bearing on the probable relationship between tyrotoxicon and cholera infantum, I will report it somewhat in detail.

July 30, 1886, about one o'clock P.M., I was called to see the seven months' old babe of Mr. B. I found that the child had been vomiting quite constantly for some three hours. It had also passed watery stools some six or seven times. The eyes were sunken, skin cold and clammy, and pulse rapid and small. I diagnosticated cholera infantum. During the preceding night, the child had seemed as well as usual, and had taken nourishment freely from the mother's breast. Early in the morning it had been given a bottle of cow's milk, and soon thereafter the nausea and vomiting began. Later, as stated above, the child began to purge. The mother furnishing an insufficient supply of milk, it had been the habit to give the child cow's milk several times during the day. I prohibited the further use of milk, both that from the mother and from the bottle, and substituted meat preparations and rice water as foods. I also prescribed pepsin, bismuth subnitrate, chalk mixture, and camphorated tincture of opium.

The cow's milk which had been furnished the child was from an animal kept by one of the neighbors. On the evening of the same day that the child was taken sick, I obtained two quarts of the morning's milk of this animal. The milk had the appearance of very rich cream, being of a yellow tint throughout. This milk was allowed to stand through the night of the 30th in the ice-box of a refrigerator. On the morning of the 31st I began the analysis. After pouring the milk from the pitcher, there remained in that vessel about two ounces of a fluid the color of port wine. Microscopical examination of this fluid showed the presence of pus and blood corpuscles. The blood was also detected by obtaining the characteristic bands of oxyhemoglobine with the spectroscope. The milk, which had already coagulated, was filtered. The strongly acid filtrate was rendered feebly alkaline with potassium hydrate, and then agitated with absolute ether. After separation the

ether was removed with a pipette, and allowed to evaporate spontaneously. This residue was dissolved in distilled water and again agitated with ether. This ethereal solution left, after spontaneous evaporation, a residue which had a slightly brownish tint. I did not obtain the crystals of tyrotoxicon, doubtlessly owing to this trace of impurity; but the residue had the odor and taste of tyrotoxicon. This residue dissolved in some distilled water, and given to a cat, produced retching and vomiting.

That tyrotoxicon was present in the milk taken by the child shortly before the beginning of its illness, there could now be no doubt. It is true that the milk was abnormal in other respects also, inasmuch as it contained pus and blood.

After the withdrawal of all milk, and the use of the medicinal agents mentioned above, the child began to improve, and by the afternoon of August 1st it seemed so well that it was allowed a bottle of good cow's milk (from another animal); but soon after taking this milk it again began to vomit and purge. Milk was again withheld and the same medicinal treatment resorted to. This attack was slight, and after it the child continued to improve until the night of August 4th, when the grandmother, who "knew more about raising babies than the doctor," fed the child bountifully upon milk. Again the vomiting and purging began, and it was more than a week before all symptoms of gastro-intestinal irritation had disappeared. About the 15th of August milk was again allowed, at first in small quantity, and this seeming to have no harmful effect, more liberal quantities were given. The child has continued well since.

From the above observed facts, I infer that not only the poison but the ferment, by whose growth the poison is generated, was introduced to the alimentary canal, that this microörganism continued to live until some time after August 4th, and when the milk was given the poison was again formed by the growth of the ferment. Whether or not any germicide could have been borne by the child in sufficient quantity to destroy the ferment I do not know.

It now remains to ascertain with certainty the nature of the ferment concerned in the production of tyrotoxicon, and to determine by experiments upon milk inoculated with this germ the value of various germicides. Many physicians claim that the bichloride of mercury, in proper doses, is a very valuable agent in the treatment of cholera infantum.

Fortunately no other children were furnished with the milk of this cow which first supplied the B. baby. The attention of the owner of the cow was called to the nature of the milk, and its use by all was discontinued for some days. There was no sore visible upon the teats. Had this milk been mixed with that of a number of other animals, the color would have escaped detection, and all the milk might have been rendered poisonous.

Cocaine in Acute Pharyngitis.—Dr. Kurz mentions in the *Abeille Médicale* that, having a severe case of phlegmonous inflammation of the pharynx, producing dyspnœa, violent headache, and great pain in the neck, which was unrelieved by chlorate of potash, salicylic acid, quinine, and ice, he painted the pharynx with a four per cent. solution of cocaine. The first application caused a choking sensation and vomiting; it was repeated at the end of five minutes, and this time no reflex actions appeared. After two more applications the local symptoms disappeared as if by magic, the extreme tumefaction becoming scarcely perceptible, and the voice, respiration, and power of deglutition returning. The cure was ultimately completed by a two per cent. resorcine spray.

Volition and Coughing.—Thomas F. Rumbold, M.D., of St. Louis, Mo., writes as follows to the *Maryland Medical Journal* of December 4, 1886:

There is far more probability of an anodyne application relieving a little finger that is benumbed by a blow on the elbow, than that a cough will remove the sensation in the throat that is caused by an irritation due to inflammation or to a lodgement of a secretion behind the soft palate.

I have known patients cough, on an average, ten times every five minutes for two hours in the morning, making two hundred and forty spasmodic efforts to relieve the throat of tickling sensations. Now, this is tiresome to a weak individual and the relief of one-half of their efforts may be sufficient to prevent the throat becoming inflamed and thus prevent the lungs being implicated in the disease. If a healthy individual coughs two hundred and forty times in two hours every morning—not to take into account the very frequent coughing through the day that is done by every such patient—he will, in a few weeks, have his throat so highly inflamed that he may require medical aid for its relief.

A good method to help one to control the cough, is to mark each cough on a card, preserve this card, and endeavor to decrease the number of coughs each day. I have known patients to decrease these efforts seventy-five per cent. One patient coughed one thousand and eighty-five times on the first day's tallying, on the next day she coughed four hundred and fifty times, on the next, only two hundred and twenty times. This may seem to some to be trifling work, but the result is always beneficial to the cough and to the strength of the patient. Some patients have tried to control the cough without marking each effort down, but they are not certain as to the degree of decrease or increase of the cough; there is no doubt that a patient will be more certain of success in controlling his cough if he marks every effort on a piece of paper; under these circumstances the mental effort will greatly assist in resisting the sensation of tickling in the throat.

Hemichorea Symptomatic of Brain Diseases.—Dr. Bidon, in an extended essay, sums up the symptomatology, prognosis, and treatment of hemichorea as follows:

1. Cerebral diseases may be accompanied by hemichorea. Under the term hemichorea, we group all varieties of post-hemiplegic incoördination, excepting epileptiform tremors.

2. The nature of the lesion is unimportant, its location is of the greatest moment.

3. The lesion causing hemichorea must be at some point of the pyramidal tracts; there is not a distinct centre for each variety of incoördination.

4. Motor incoördination is due to disturbed equilibrium through muscular antagonism. Equilibrium is broken generally by contracture, and sometimes by paralysis.

5. The diagnosis, to be accurate, must inform us with what type of movement we have to do, and tell us the seat and nature of the lesion.

6. Intelligent gymnastics, the continuous electric current, and also the faradic, offer the best hopes in treatment.

7. The prognosis is not absolutely hopeless, but is not bright.—*Revue de Médecine*, October 10, 1886.

Aconitina.—According to Mandelin, the alkaloid obtained from *aconitum napellus* is benzoilaconine, or aconitine in crystallizable form, together with some amorphous alkaloid of less physiological activity. *Aconitum ferox*, on the contrary, contains pseudo-aconitine or veratroilaconine. The unequal activity of the roots of these two species is not the result of unequal richness in alkaloids, but of the different power of the alkaloids they respectively contain. Aconitine is one of the most energetic of poisons. For a frog, 1.2 to 2.4 milligrammes per kilo. is a lethal dose. In warm-blooded animals 0.05 to 0.75 milligramme per kilo. For a man, three milligrammes would be a fatal dose. German and French aconitine is benzoilaconine; English (especially Morson's) is veratroilaconine. The simplest method of testing the activity of the alkaloid is to inject a known quantity into a warm-blooded animal, as a rabbit or guinea-pig. Aconitine does not give color reactions; any which occur are due to impurity. The want of characteristic chemical reactions, the readiness with which it decomposes, and the minuteness of the lethal dose, render the detection of aconitine extremely difficult in toxicological cases.—*Manchester Medical Chronicle*, November, 1886.

Antagonism of Strychnia and Cocaine.—Bignon, after numerous experiments on dogs, finds that an animal which has been poisoned by strychnia, in doses not above two milligrammes to each kilogramme of body weight, can be saved from death by the hypodermatic use of cocaine, pushed to the point of delirium, and the effect maintained until elimination has occurred; this result may be obtained even after tetanic spasms have occurred.

In poisoning by three milligrammes of strychnia to each kilogramme of body weight, success may still be attained by pushing the cocaine above two centigrammes per kilogramme of weight, doses which exceed the toxic dose of cocaine.

The author observed complete recovery in animals so poisoned in about six hours.—*Bulletin Général de Thérapeutique*, October 30, 1886.

Experimental Researches concerning the Regeneration of the Tissues of the Liver.—In experimenting upon animals Podovssozki observed that wounds in the liver substance healed without manifest loss of substance or scar. The first appearance of regeneration occurred after a hyperæmic period of ten or twelve hours. In cats and rats the liver cells proper increased by nuclear segmentation; connective tissue cells and bloodvessel epithelium increased by the indirect growth of nuclei.

Especially interesting was the growth of the epithelium in the bile-ducts, which in some animals is directly reproduced, in others furnishes a starting-point for the liver parenchyma. The cells and ducts which develop from the gall-ducts grow either by direct extension of their elements or through an exuberant growth in an intermediate stage of liver tissue proper, reproducing the embryonal development of the liver.—*Centralblatt für die medicinischen Wissenschaften*, Nov. 13, 1886.

Acetophenon.—Schüder has experimented with this drug in fourteen cases, comprising heart and lung affections of varying severity, in doses varying from two to five drops given in capsules. Its effect was the promotion of a peaceful sleep in intervals of an hour or an hour and a half after taking.

No unpleasant after-effects were observed, and it was especially grateful to phthisical patients, whose cough was much lessened.—*Deutsche medicinische Wochenschrift*, November 11, 1886.

Ptyalin and Milk Ferment in Urine.—Holvotschiner has by experiment with solutions of starch found ptyalin in urine, which, under appropriate conditions, demonstrated its amylolytic power. The ferment was found to be most abundant four or six hours after eating and in the morning urine. With those suffering from gastric and intestinal catarrh it was most abundant in the afternoon.

The milk ferment was found most abundant in the urine passed four to six hours after a meal. In the urine of one or two hours after a meal the ferment is almost absent.—*Centralblatt für klinische Medicin*, October 9, 1886.

Treatment of Bronchitis in Scrofulous Subjects.—The following is Monin's formula:

Ol. morrhuæ	500 parts.
Iodal	1 "
Essence of eucalyptus . . .	8 "

Two spoonfuls daily.—*Revue de Thérapeutique*, November 15, 1886.

Treatment of Nephritic Colic.—Huchard recommends the following:

Sodii benzoat.,	
Lithii carbonat.,	
Ext. stigmat. maydis . . .	āā gr. xlv.
Ol. anisi	gtt. iij.
Divide in 60 pills.	

Sig.—Four pills daily.—*Les Nouveaux Remèdes*, November 24, 1886.

Treatment of Laryngo-pharyngitis.—The following are Coupard's formulæ:

By atomization five minutes night and morning:

Acid. carbolic.	gr. xv.
Potass. bromid.	℥jss.
Aquæ	Oj.

And as a gargle:

Acid. carbolic.,	
Zinc. chlorid.	āā gr. xv.
Syrup. morph. hydrochl. . .	℥iv.
Inf. cocæ fol.	℥viss.

—*Revue de Thérapeutique*, December 1, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 25, 1886.

THE PREVENTION OF SYPHILIS.

THERE can be no doubt that syphilis is a less frequent and, in general, a less formidable disease than it used to be. The cases are fewer, and it is becoming rare to see those horrible illustrations of its possible ravages, which were very numerous so late as the first half of this century. Nevertheless, syphilis is one of the gravest disorders to which the human race is exposed, and there should be no relaxation of the efforts of medical men to find the best way in which to treat it, or the most successful means for its prevention.

This latter question has been recently discussed quite fully in the first Congress of Russian Physicians, in January, 1886, a report of which may be found in the *Monatshefte für praktische Dermatologie*, for October, 1886. As is usual in such discussions, much was said about the utility of police supervision of prostitutes, and we are not surprised to find that a great deal of evidence was brought forward which indicates that what is known as the legalization of prostitution, or anti-contagious diseases acts, is but a broken reed, not fit to lean upon. For example, SPERK, of St. Petersburg, said that 42 per cent. of the public women in that city are in the condylomatous stage of syphilis; and HERZENSTEIN thought thus to exclude them from following their calling would simply drive them into the ranks of clandestine prostitution. POLOSEBNOW recommended the multiplication of special hospitals for venereal and skin diseases. Herzenstein seconded this recommendation, and added to it one for women physicians to treat female patients, and for the diffusion of a popular knowledge of the nature and effects of syphilis. A female physician, SINAIDE ELZIN, discussing the police supervision of the Jahrmarkt in Nishni Novgorod, said there were present from 700 to 900 public prostitutes, and a multitude of clandestine prostitutes. Upon examination of 355 women, she found 22 women with urethritis, 2 with chancroid, only 1 woman with the initial lesion of syphilis, 1 with gummata, and 18 with condylomata. The frequency of syphilis in Russia may be gathered from the fact that PETERSEN made a calculation that more than 1600 persons become infected with syphilis every year in St. Petersburg, while Herzenstein found that in the five years from 1877 to 1882, 9543 men were relieved from military duty in Russia on account of the disease.

The most important conclusions of the Section on Syphilography were in favor of the popularization of knowledge in regard to syphilis, the erection of special hospitals, the separation of syphilitic prostitutes from non-syphilitic, the proper supervision of syphilitic infants in foundling asylums, the utility of women physicians in combating the spread of syphilis, the founding of benevolent societies to assist patients—syphilitics included—dismissed from hospitals, and the proper classification of venereal diseases into urethritis, venereal ulcer, and syphilis.

Somewhat over a year ago DRS. E. W. ALLISON and W. E. ASHTON, of this city, presented to the Philadelphia County Medical Society an elaborate paper on "The Failure of Legislation in Limiting the Spread of Venereal Diseases." The general tenor of this paper may be inferred from its title. Its principal conclusions may be summarized as follows: Legislation increases clandestine prostitution; this is the most dangerous form of prostitution, and more dangerous in countries in which there is legislative regulation of prostitution than where there is none; legislation tends to the spread of syphilis on this account, and also by the false sense of security in having intercourse with certified women which it effects; and, finally, educating the public concerning syphilis and furnishing proper hospital accommodations for venereal patients, are the rational means to limit the spread of these diseases. These conclusions, it will be observed, are very like those of the Russian Congress, and they may be regarded as those of most unbiassed students of the subject. It is fortunate that syphilis has never become in this country the scourge which it has been, and still is, in certain parts of Europe. Nevertheless, it is a very grave disease, and one which involves the innocent in a common ruin with the guilty. The libertine is but little more likely to suffer for his indulgence than is his injured wife and innocent child. The chaste and trusting maiden may acquire it from the lips of her unworthy lover, or the babe from its foster-mother's breast. How this can be prevented

it is hard to say, while men have appetite and women are willing to satisfy it for gain. Prohibition has never recommended itself to those who make laws, continence seems unattainable while human nature remains as it is, restriction does not restrict, medical examination is a delusion and a snare, and it would seem that the most promising means of limiting the spread of syphilis are those recommended above, namely, popular education in regard to the risks and consequences of acquiring syphilis, and better hospital facilities for its treatment. Police regulations cannot be effectively applied to this as to other contagious diseases, for the reason that the moral stigma which attaches to indulgence of the sexual appetite must always prevent complaint or proof of wilful or negligent communication of syphilis. Increased public intelligence and an improved morality are the only hope for the future.

It is regrettable that this fact does not seem obvious to the recently founded New York Society for the Prevention of Contagious Diseases, the first announcement of which lies before us. From the announcement we gather no promise but that of a free dispensary for venereal diseases, and of female physicians who will examine gratuitously prostitutes who ask for their services. A society with so laudable an object as is expressed in the title of this one should show something which could not be even misconstrued as an advertisement of the medical men connected with it, or as an indirect effort to increase their own gains.

We hope this subject of the prevention of venereal diseases may receive the careful consideration of our readers, and that we may soon record some intelligent and unselfish effort to deal with the delicate problems which it presents.

PRURIENT SCIENCE.

In connection with the attempt to place upon a permanent basis an American opera company, the clergy of America have recently expressed their opinion of the ballet, and we observe with pleasure that their opinion is not treated as an unwarranted interference by those who hope to see this country maintain a really first-class company of this sort. One of the reasons for the way in which the action of the clergy is received, is the fact that it has not been offensive or bigoted. It is true that a number of clergymen have declared their conviction that the opera cannot be made pure; but no small number have protested that it can. With the latter we agree, but we feel sure that this desirable end can be secured only by free criticism of what seems reprehensible—criticism offered and taken with sincerity and candor.

The same condition exists in regard to certain sorts of literature, of which medical literature is an example. The modern taste for the popularization of science has led to the publication of many books of a medical or semi-medical character, which are ostensibly intended for the instruction of the community, as well as for the benefit of the author. The latter object is a legitimate one, if the former be; while, if it be not legitimate, such publications are most dangerous to the well-being of the people. Unfortunately our own country has witnessed the spectacle of medical writers issuing volumes under the guise of scientific treatises, which contain matter which it is not too severe to call obscene, and which would be confiscated by the government under our postal laws if it were not for the claim that they are scientific publications. Our review columns can bear witness to the fact that we have not hesitated to raise our protest against the indecency of some such books, and to stigmatize the apparent willingness of certain authors to appeal to the basest passions of their readers.

We recur to this subject just now because of the recent appearance of a third volume of a work by an Italian professor of anthropology, which we will not name more fully for obvious reasons. The subject of this volume would be of fascinating interest to many men and women—and unfortunately, also, to many youths—to whom its science would be of little interest and of no use. If we lived in old Pompeii the book would probably be hailed with delight, but living in a clean land, and in a clean age, we trust that all right-minded men will share our opinion that it is worse than a waste of time for an able scholar to collect such a mass of prurient material as it contains, and far worse to put it within the reach of thousands who have no business with it.

And, again, we raise our voice against the prostitution of science to the use of prurient minds. In medical books and in less pretentious medical writings, the spirit of chastity should never be missed; and, if sometimes those who use the printing press use it to promulgate facts or opinions which are calculated to lower the standard of virtue in the community, it is the duty of all who have the opportunity to emphasize the error of their course, and to let it be seen that it cannot escape notice or condemnation. Such vigilance and such fidelity will go far toward preventing new accessions to the ranks of prurient medical authors, and in time we may hope the race will become extinct.

PALPATION OF THE PELVIC ORGANS.

An interesting point in regard to the palpation of pelvic organs made by Schultze, in 1885, has recently been cited in the *Centralblatt für die medicinischen Wissenschaften*. Schultze calls attention to the possibility of error from making pressure upon the intrapelvic muscles. The obturator internus may be felt

through the rectum or vagina as a distinct swelling, when the thigh is rotated strongly outward. Pressure upon the muscle is rarely painful, but pressure on the obturator nerve, which accompanies it, produces a cramp-like pain in the thigh. The belly of the psoas magnus may be mistaken for a morbid growth, an error which will not be likely to occur if the thigh be actively flexed and extended while the finger rests upon the muscle. The pyriformis muscle may also be a source of error unless a similar procedure be employed.

In these days when displacements of the ovaries and pelvic cellulitis fill so large a portion of the horizon of gynecology, it may be well to bear in mind the errors into which the muscles within the pelvis may lead an unwary examiner, and Schultze has done a worthy service in calling attention to them.

AN INTERESTING WORK.

At the last meeting of the College of Physicians of Philadelphia in the annual report of the Library Committee allusion was made to the rapid growth of the Library, and reference to its origin one hundred years ago. There was placed on the table the first donation to the Library, which included a splendid edition of the "*De Sedibus et Causis Morborum*," given by the illustrious Morgagni to Dr. John Morgan, the founder of the Medical Department of the University of Pennsylvania, on the occasion of his visit to Padua. Dr. Rush is responsible for the statement that Morgagni claimed kindred with Dr. Morgan on account of the resemblance of their names, and says that on a blank leaf of a copy of the work he inscribed the words, "Affini suo, medico præclarissimo Joanni Morgan donat auctor." Several writers have doubted the correctness of Dr. Rush's quotation, as no such words can be found in the volumes. On the inside title-page of Vol. I. there is the inscription beginning "Viro experientissimo et Humanissimo," and in Vol. II., "Viro de re Anatomica bene merito," but no such inscription as quoted by Rush. The title-page of Vol. I. shows that it had become so frayed and worn and the lower third of the page so very defective that some careful bibliophile had pasted it upon a new sheet of paper. On the old and thumb-worn fragments can still be discerned faint traces of writing which doubtless represent the first inscription by Morgagni which Rush had seen and copied before it had become faded and defaced by time.

A unique case of polymastia is described in the *Centralblatt für Gynäkologie* for November 6th, which is interesting from the fact that there were eight accessory breasts and nipples, the largest number ever observed. The upper pair were situated in the axillæ; the others were arranged symmetrically, with the exception of the lowest pair, which were situated on the same line, but on a different level; the lowest nipple was about on a level with the last rib. Milk exuded on pressure upon the respective breasts from all the nipples, while the flow from those in the axillæ was spontaneous and constant.

Measles and diphtheria are very prevalent in New York at the present time, and the epidemic is on the increase. During last week 558 cases of measles and 66 deaths were reported to the Board of Health. Of diphtheria, 109 cases were reported, with 50 deaths.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 8, 1886.

The President, Charles McBurney, M.D., in the Chair.

Dr. Lange presented at the last meeting a young man eighteen years of age, suffering from what he had diagnosticated as

ANEURISM OF THE OBTURATOR ARTERY.

The case gave rise to an animated discussion, opinions being divided as to the nature of the tumor and its subsequent treatment. He now presented the patient for further examination, stating that he asked the boy to call at his office about eight days later, and upon examination was astonished to find the pulsating swelling had entirely disappeared, at the same time the boy had lost the pain which he had complained of before as being sciatic in character; the boy said that after the examination here by the members of the Society, during the night the pain left him and has never returned, and neither has there been any swelling since. Dr. Lange remarked that he could find no plausible explanation of the case unless that a sudden obstruction of the main vessel had taken place.

Dr. Sands remarked that there did not seem any other explanation of the disappearance of the tumor except that the manipulations the young man underwent at the last meeting cured the aneurism. At the time when he was shown here, although there was difficulty in discovering the tumor, it certainly did exist and the general opinion was that it was a true aneurism of some one of the branches of the femoral or internal iliac. This case called to his mind a somewhat similar one occurring some twelve years ago in the Roosevelt Hospital. A man having a well-marked pulsating aneurism of the left axillary artery, entered the hospital and complained of sudden pain in his left arm; on examination no pulsation could be found in the left radial or ulnar arteries. It was suspected that this man had a large clot, displaced from the aneurismal sac, and situated in the upper part of the brachial artery, and that the absence of pulsation in the arteries of the forearm was due to that cause. He was kept under observation for six weeks, at the end of which time he was perfectly cured

of his aneurism, which meanwhile had ceased to pulsate. Dr. Sands thought the same conditions might have occurred here.

DR. STIMSON remarked that the history of aneurisms indicates that the coagulated blood could hardly disappear in so short a time.

DR. SANDS asked whether there had not been some difficulty at first in finding the aneurism.

DR. LANGE replied that there was, and it was only by severe pressure upon the obturator artery that he was able to detect pulsation at all.

DR. LANGE then reported the following case of

LYMPHANGEIOMA OF THE SCROTUM.

E. S., aged sixteen, from Wilkesbarre, Pa., born in that county, noticed, about one year ago, a swelling of his scrotum under acute symptoms—pain, redness, and local heat, which gradually and first with pain, later on without pain, increased until on the 2d of October, when the patient was first seen. It had then attained the size of two fists. At times small vesicles on the surface of the scrotum would burst, and with a free discharge of a clear fluid, and the swelling would somewhat diminish in size. Treatment was without noteworthy effect, the swelling increasing steadily. Numerous elevations were visible on the skin varying from the size of a sand-grain to that of a pea or small bean. On closer examination the larger ones proved to be composed of numerous small vesicles with clear watery contents. Some of these elevations had a wart-like, papillary character, others were more flat. On the lower part of the lateral aspect of the scrotum a fine network of distended lymphatic vessels could be distinguished, clearly differing from neighboring veins by their transparent condition. The skin of the penis was also involved to some extent near the root of the scrotum, and the pendulous portion of the penis was made almost invisible through the traction of the heavy scrotum, like a large hydrocele or inguinal hernia. Both testicles seemed normally developed, but around both fluid gathering in the tunica vaginalis could be made out. On the right side one was able to press both testicle and fluid into the inguinal canal, so that a distinct large prominence above Poupart's ligament could be achieved in this manner.

The patient suffered also from a similar swelling on his right leg which he has had from infancy. The leg looked pale, cylindrical on account of its prevalent thickening above the malleoli. The swelling has the same soft, flabby character, and consists apparently in a thickening of the subcutaneous layers.

Three weeks ago the scrotum was removed and on both sides Volkmann's operation for hydrocele was done simultaneously. The neighboring edges of both tunica vaginalis were sewed together and to both a common slit in the integument was left. The operation was done with very little loss of blood, after passing an elastic ligature around the root of the external sexual organs above two needles which transfixed the organs crosswise.

Recovery took place without any trouble. Still there can be seen here and there, in the new scrotum, some of those small watery vesicles, and Dr. Lange intends to make numerous punctures, which in a similar case had done him good service.

DR. ABBE remarked that the same patient was examined by him a week before he went to Dr. Lange, while he was at St. Luke's Hospital; but he had slipped from his observation and never returned, although he had sent a letter to him. At the time he saw him Dr. Abbe tapped one of the little vesicles and had the fluid examined microscopically for filaria. The patient had never been in a hot climate, and the examination proved negative; it seemed to be more like serum than lymph, was of a straw color, and also had not the property of gelatinizing.

HYPERTROPHY OF A LIMB FROM LYMPHATIC OBSTRUCTION.

DR. WEIR presented photographs of a young girl who had been seen when aged twelve, in 1883, for lymphatic obstruction, affecting the right thigh. The enlargement had then existed four years. The thigh, which was at that time only involved, measured three and a half inches larger than its fellow; the skin, while thickened, was smooth and movable on the subjacent parts. An elastic bandage was ordered to be applied, and was worn for over a year without benefit. Two years later the patient was again seen, when the thigh was six inches larger around than the left one, and the leg was now involved, and measured two and a half inches more than that of the unaffected side. The skin was more irregular, and studded in the upper part of the thigh by several little prominences. On incision lymph freely exuded, some of which was submitted to microscopical examination with a negative result; nothing could be felt in the abdominal cavity.

VARICOSE LYMPHATIC TUMORS.

DR. WEIR also showed, in further illustration of diseases of the lymphatics, a tumor, or rather two tumors, removed from a man of twenty-two years, who, residing in the West Indies, had suffered from pain in the upper and inner aspect of the thigh and in the scrotum, for the past four years. Running slightly above Poupart's ligament on the left side, and extending nearly four inches below it was a soft, irregularly outlined tumor, uneven in surface, which subsided when the patient laid himself down, and reappeared in the erect posture, and which gave an impulse on coughing. It simulated closely a hernia. It was associated with a similarly acting mass in the left inguinal canal, which reached nearly to the testicle. In the centre of the femoral tumor, which was some five inches broad, were several small nodules that were at first taken for fatty masses of omentum, but, on being isolated, it was found that they could be made sensibly smaller on pressure; whence the diagnosis was arrived at—a dilatation of lymph vessels. A vertical section allowed the growth to be exposed, and it was seen to consist of a congress of lymph vessels, situated mostly outside the fascia lata, but at the saphenous opening, closely adherent to the femoral vein and artery, and requiring careful dissection. The divided lymph vessels allowed very free discharge of milky lymph. Through the same wound, after removal of the thigh collection, after final ligatures of the main enlarged lymph vessel above and below, another incision was made above Poupart's ligament, and the inguinal canal opened into and another set of varicose lymphatics exposed and removed of the thickness and length of the thumb. Nothing could be felt on palpating the abdomen. The patient made a prompt recovery.

Stated Meeting, November 22, 1886.

Dr. Lewis S. Pilcher read a

NOTE ON AMPUTATIONS FOR JOINT-DISEASE WHEN LUNG TUBERCULOSIS COEXISTS.

The frequency with which tuberculous joint affections are complicated with tuberculous diseases of the internal organs, is such as to make the question of their mutual reaction one of importance.

Willemer, in his report on the results obtained in tuberculous disease of the knee-joint by König at the Göttingen clinic, during the seven years ending October, 1882 (*Deutsche Zeitschr. f. Chirurg.*, Bd. 22, Hefte iii. und iv.; *Annals of Surgery*, 1885, vol. ii. p. 514), states that of 174 cases operated upon, 15 per cent. of those below 10 years of age, 20 per cent. of those between 10 and 20, and 37 per cent. of those over 20, were complicated with tuberculous diseases of internal organs. Volkmann, in his address on tuberculous surgical affections, at the German Surgical Congress of 1885, said "Local tubercular disease of other organs combines far more rarely in children than in adults with fatally progressing lung tuberculosis. In an older individual, having,—*e. g.*, caries of the wrist, it is exceptional that he does not have or is not soon attacked by pulmonary tuberculosis." Vincent, of Lyons, in his article on scrofulo-tuberculous diseases of knees, in the *International Encyclopedia of Surgery*, vol. vi. p. 925, speaking of the results of a general scrutiny of patients affected with tubercular osteitis, or osteo-arthritis, says "Too often there are found manifest signs of advanced pulmonary tuberculosis."

It is needless to multiply authorities or observations for the purpose of emphasizing the frequency of the coincidence of tuberculosis of internal organs with knee and joint disease of like character. The question which I wish to submit for consideration in the present note, is, What modifying influence, if any, should the coexistence of an actively progressing lung tuberculosis have upon the operative measures which shall be adopted in the treatment of tuberculous joint affections? How is the lung tuberculosis likely to be affected by the operation upon the extremity? What disturbance in the repair of the operation wound in the extremity is likely to arise from the coexistent pulmonary trouble? Is it worth while, in the presence of an affection of an internal organ, which with great certainty entails a fatal termination, to subject a patient to the traumatism required to rid him radically of a local affection of an extremity?

A case in point is the following: In January, 1879, nearly eight years ago, I first was consulted by a lady, then thirty-seven years of age, on account of slight lameness of the right knee. There was a tenderness on pressure on the internal condyle of the femur, with some puffiness of the overlying soft tissues. In the preceding March she had slightly bruised this knee, the injury being so insignificant that it was not considered worthy of attention, until the subsequent increasing lameness compelled attention. The father of the patient, and a maternal uncle, had both died of tuberculosis pulmonalis; and at the period of the injury and during the subsequent years, the patient was suffering a severe strain upon her constitutional vigor through domestic afflictions and deprivations. It was impracticable for her to give to the limb the rest required for its proper treatment, and I shortly lost sight of her. Three years later, June, 1882, I saw her again, when she consulted me on account of persistent cough, with debility and loss of weight. Physical examination revealed a deposit at the apex of the left lung. Her knee was still troubling her some, but she was able to walk about without any marked limp. In the interval that had passed, she had had two attacks of acute synovitis of the affected knee. Under treatment during the summer and autumn, a markedly progressive improvement in her cough and in her general health took place, but her lameness increased, with periarticular muscular rigidity and nocturnal spasms, followed by a renewed acute synovitis. Immobilization with extension was instituted, and finally, pus having been demonstrated by the aspirator, free incision into the joint with antiseptic irrigations were made. The joint suppuration soon ceased under this treatment; the wound healed, and wearing an immobilizing apparatus, the patient was able to be around upon crutches during some months. An attempt to gain increased freedom of use was then followed by a renewed acute suppurative attack, which persisted despite antiseptic irrigations and drainage as before. The pain and loss of sleep combined with the discharge to sap the patient's general strength. Meanwhile the dormant pulmonary trouble was reawakened, and the general symptoms as well as physical examination indicated a rapidly progressing lung tuberculosis present.

In this case the aggravated character of the suffering caused by the knee joint affection, together with the depressing effect of the confinement to the bed which it necessitated, determined me to undertake a radical operation for the removal of the parts involved in the joint affection, despite the extent and activity of the lung disease. Perhaps the most important guide to the surgeon's action is to be found in what is suggested by the remark just made. Any possible remote unfavorable influence upon the lung affection that an operation might entail, or any possible disturbance of healing that might later affect the operation wound is thrown into the background by the more immediately pressing necessity of relief to the present suffering, which the knee and joint affection is inflicting. In a condition such as I have described, the joint affection constitutes an acutely urgent condition, the indications for the relief of which are of supreme importance.

Accordingly, in the case under consideration, I proceeded to operate in August, 1884. The joint was opened by the usual anterior semilunar incision as per exsection; the articular surfaces of the femur and tibia were extensively eroded, the crucial ligaments had disappeared, and the whole of the exposed surface was soft and friable. Upon attempting to apply the sharp spoon to it, the instrument passed almost without resistance for some distance up the shaft of the knee into a caseous mass. The evident tuberculous degeneration of the lower end of the femur was so extensive that complete removal of all the affected tissue by excision was out of the question. I therefore proceeded to amputate, making the section of the femur at about its middle third. The local result was all that could have been wished; healing per primam throughout most of the wound was effected. A simple small sinus persisted for some weeks,

but finally spontaneously closed. In three weeks the patient was able to leave her bed, and soon resumed the direction of her household affairs. The effect upon the lung tuberculosis was also very marked; the activity of its further progress was greatly hindered, cough diminished, appetite improved, and general strength increased. Two years and three months have now passed since the amputation, and the patient is still living, though she is far from being a well woman; being distinctly tuberculous, with cough, dyspnœa on exertion, and general debility. No extension of her lung trouble, however, has been manifested up to the present date. The stump is firm, and free from any signs of tubercular degeneration whatever.

In connection with this case, I would like to cite two cases which were embodied in a memoir by Dr. Mabbous, of Lisle, and commented on by Dr. Chauvel at the meeting of the French Surgical Society of February 10, 1886. In the first case, tuberculous caries of the metatarsal bones of a young soldier having been treated by resection, there followed synovitis of the periosteal sheath, and later, suppuration of the tibio-tarsal articulation and concomitant pulmonary tuberculosis. After three months, all the symptoms continuing to be more unfavorable, the foot was amputated; rapid cure followed; the pulmonary symptoms abated, and, finally, disappeared, and robust health was regained.

In the second case, likewise in the person of a young soldier, suppurating knee-joint disease and beginning pulmonary tuberculosis coexisted. Arthrotomy was done, the pus evacuated, the fungosities removed, and the denuded bone scraped; this was followed by redoubled suffering, probable meningitis, and more pronounced pulmonary symptoms. At the end of a month the pain was atrocious, emaciation extreme, the exhaustion almost complete, and early death certain. At the earnest wish of the patient, and in spite of the gravity of the condition, amputation of the thigh was done. Great improvement followed for one month, then the stump ulcerated, fever reappeared, tuberculosis of the abdominal viscera declared itself, and, finally, death at the end of four months after the amputation, but no recurrence of the intense suffering for which the operation had been performed.

In the discussion which followed M. Chauvel's report, a number of additional instances were adduced in which either apparent complete recovery, or great improvement in a lung tuberculosis had followed amputation for coexisting joint disease. All, however, were not ready to accept the tentative proposition of Chauvel, that local tuberculosis, as in osseous and articular affections, is to be considered as a neoplasm, the more malignant from its tendency to generalization, and to be treated under the same rules as sarcoma and carcinoma; and that early amputation is indicated whenever the extirpation of the disease in place is impossible, or when the anatomical conditions do not permit the complete and certain ablation of all the infected tissues.

Without attempting any elaborate discussion of the many phases which are presented by coexisting lung tuberculosis and osteoarthritic tuberculosis, the materials for which have amassed in great abundance during the last few years, I desire to close the present brief note by the following theses, which seem to be in accordance with present experience:

1. The probabilities of a spontaneous cure, or prolonged abeyance of a tubercular bone or joint trouble, as the result of expectant and palliative treatment—*e. g.*, improved hygiene, rest, counter-irritation—is much greater in children than in adults.

2. The probability of the presence or early development of lung tuberculosis in case of tubercular bone and joint affections, is much greater in adults than in children.

3. Incomplete operations, as drainage and irrigation of joints, évidement, and resections in which all of the diseased tissue is not removed, are less likely to be followed by ultimate good results in adults than in children.

4. Operative interference of a radical character is justifiable at an earlier date, in the history of a bone or joint tubercular affection, in an adult than in a child.

5. When a lung tuberculosis is present, and an operation for the relief of a coexisting bone or joint affection is indicated, as the result of such operation the lung affection, while in some cases influenced, is more frequently temporarily checked in its progress, and in some instances is apparently entirely removed.

6. Local relapse after operation for an osteo-arthritic tubercular disease, lung tuberculosis coexisting, is exclusively conditioned upon incompleteness of the operation,—the fact that somewhere tubercular tissue escaped removal—and not upon any influence exerted by the lung affection.

7. In any case of osteo-arthritic tuberculosis demanding operation, in which a doubt exists as to the possibility of removing absolutely all the diseased tissue by the more conservative methods of arthrectomy or excision, the coexistence of lung tuberculosis would be a circumstance that would add weight to the reasons for having recourse to the more radical operation of amputation.

8. After an amputation in perfectly healthy parts, as prompt healing may be expected in persons suffering from lung tuberculosis, as after such an operation in a healthy person. Relapses at the stump do not occur even in persons with advanced lung disease.

DR. LANGE presented a boy, ten years of age, upon whom he had performed

RESECTION OF THE HUMERUS FOR FRACTURE.

The boy fell from a tree seven weeks ago, a distance of about eight feet, striking on his right shoulder. On admission to the German Hospital, two days later, a fracture of the right humerus was found immediately below the head. The lower fragment had apparently entered the deltoid muscle, and, with a sharp edge, was fixed within the deep layer of the skin, without penetrating it. In this way a distinct protrusion was formed on the anterior aspect of the shoulder, the elbow being thrown backward, so that the axis of the humerus was directed abnormally in front. There existed a very extensive extravasation of blood, but no general disturbance. It was quite impossible to detach the lower fragment from its abnormal attachment; even the skin was so tightly fixed to the bone that it could not be made loose. On the seventh day, after swelling and tension had markedly subsided, the patient was put under ether, but it was found impossible by manipulations to replace the bone. An incision was then made over the displaced

fragment, the slit in the deltoid muscle enlarged, and, by proper manipulations, efforts were made to bring the fragments into coaptation. The fracture itself presented the following condition: There was separation exactly in the epiphyseal junction as far as the middle of the bone; from there the line of fracture went in an oblique downward and backward direction, its lowest point being about two inches below the level of the epiphyseal line. In order to bring the fragments into proper apposition, it was necessary to elevate the arm above the horizontal line, and to give it a strong outward rotation, at the same time bringing it slightly forward. The periosteum and fibrous attachments on the edge of the upper fragment, were not torn exactly in the line of fracture, but at a short distance below, so that they overlapped the edge of the upper fragment, and had to be turned upward. The periosteum had to be slightly indented, and then the coaptation of the fragments could be effected; the long tendon of the biceps was not torn, but lifted out of its ridge, and dislocated to the inside. With the lower fragment it returned to more normal relationship. The wound, after some days of high temperature, but without other general disturbances, healed kindly. For some time after the removal of the drainage tube, bare bone co ld be felt; the periosteum having been lifted off the lower fragment to a great extent; but no necrosis occurred, and complete cicatrization has taken place.

The case was very interesting, in that the upper fragment, by the action of the muscle insertion on the tuberculum majus, is abducted and rotated outward. Consequently, during the after-treatment, the corresponding position of the arm was maintained with slight extension, and a splint which passed from the posterior aspect of the arm over the back to the opposite scapula. Recently, that way of treating fractures of the uppermost portion of the humerus has been recommended by Bardenheuer. It confines the patient to bed for a long time, but it certainly secures the physiological relations of the fragments.

Very shortly after this operation was done, a man was admitted to the German Hospital who had a fracture of the surgical neck of the humerus. He was treated on the same principle, was kept in bed for nearly five weeks; during the last week the arm was gradually brought down and, though the patient was discharged before complete recovery had taken place, it could be seen from the comparative freedom of the movements in the shoulder at that time that the treatment would yield a very good final result.

From these two observations he felt entitled to recommend Bardenheuer's method of treating fractures in the upper part of the humerus. In fractures of the upper third of the thigh he had for a number of years followed a similar principle and has every reason to be satisfied. The task in treating fracture being at all times to bring the fragments into a position most similar to the normal, if the upper fragment is not under our control we must make concessions with the lower.

Dr. Stimson said that abduction of the joint was still lacking by about a half, and rotation almost entirely. The angular and rotatory displacement of the upper fragment after fractures of the upper part of the humerus was, he thought, generally recognized, as was also the necessity of placing the lower one in a corresponding position during treatment.

The President remarked that the arm could be raised to nearly a right angle with the body without moving the scapula; but at that point the scapula began to move.

Dr. Lange stated that this was almost the condition of the normal subject.

Dr. Weir thought this variety of fracture was not at all unique, as he could recall a good many instances where the result in usefulness of the limb did not differ from this materially. The only advantage which the operation affords, is, that there is less deformity from reposition of the lower fragment, as a rule, though it is not at all easy to overcome the displacement; yet securing the arm to the chest wall and carrying of the forearm in a sling, have given results far from unsatisfactory. He would be very loath to follow the example suggested by Dr. Lange, which, though successful, has the disadvantages which of necessity appertain to an operative procedure, even though conducted under antisepsis. Bardenheuer's method he had not tried, but thought it would be very awkward to carry out. In his experience the fracture was a less difficult one than it looked to be.

Dr. Lange remarked that if Dr. Weir believed he preferred the radical operation, he was mistaken. But that in this patient there were perforation and interposition of the deltoid, and from the position of the fragments an operation was indicated; he did not think in this case the result would have been satisfactory unless operative procedure were effected. In the second case he mentioned, he had only carried out the principles of elevation and rotation. He considered the method of treatment very rational.

Dr. Weir could recall two recent cases in which one fragment of the bone projected through the muscle and was lodged under and in the skin; but although reduction could not be made good union resulted; as in each case, the lower portion of the fractured surface, from its great obliquity, was opposed.

Dr. Lange had very strong doubts if reduction and a satisfactory result could have been secured in the patient he presented, without the operative procedures he had followed.

Dr. Wyeth presented a young man upon whom he had operated for

CONTRACTION OF THE PALMAR FASCIA,

and fixation of the tendon of the superficial flexor of the ring finger to this fascia, giving the following history:

W. R., seventeen years of age, on the 15th of last June fell and received a deep wound of the palm of the hand. He suffered from contraction of the palmar fascia, and the superficial tendons of the ring finger of the left hand. Five weeks ago he was seen by Dr. Wyeth, who found the finger drawn down in contact with the palm and incapable of being extended, although there was limited motion. An Esmarch bandage was applied and sixty minims of a four per cent. solution of cocaine injected into the hand in the line of the proposed dissection. The contracted tendon was then exposed and found to be adherent to the palmar fascia. The adhesions were divided and the fingers restored to their normal position. It was a perfectly dry operation and the patient suffered no pain. There was very marked ab-

duction of the little finger caused by injury to the minimi digiti which was cut through at the time of the accident. To correct this deformity a second cocaine operation was made and about one inch of the abductor minimi digiti was exsected, so that the patient can now carry the finger into line. He now uses the palmar interosseous muscle to a certain extent and has some adduction in the little finger, and has perfect motion in the finger which was bound down. One of the principal features of the operation was,—the perfect immunity from pain under the use of cocaine.

DR. PILCHER presented a woman whose case he had reported in his paper on prophylactic arterial ligation about a year ago, the case being one in which a

SIMULTANEOUS LIGATION OF BOTH THE SUBCLAVIAN AND INTERNAL JUGULAR VEINS

had been done for a wound sustained during an operation for the removal of a carcinomatous glandular tumor at the base of the neck. One year and a half had elapsed since the operation, and Dr. Pilcher thought it might be of interest to show the ultimate result of such an unusual interference with the blood supply to the upper extremity. Amputation of the breast for carcinoma had been done first some years ago; the disease, however, again made its appearance in the axilla and base of the neck above the clavicle. The operation by Dr. Pilcher consisted in the removal of all diseased tissues: the axilla was cleaned out, and in the course of lifting the tumor up from the base of the neck, for the purpose of enucleating it, a strong hemorrhage took place from the inner angle of the wound.

On exposing the field of operation it was found that a slit had been torn in both the internal jugular and subclavian veins just previous to their convergence to form the innominate. The original incision was enlarged and the tissues drawn aside to bring the wounded parts into view; a double ligature was applied to both bleeding vessels. In consequence of the great turgidity of the veins of the extremity that immediately followed, Dr. Pilcher ligated the axillary artery high up. The immediate consequence of the operation was considerable œdema of the arm coming on at the end of a week, and persisting for several weeks, but finally leaving the arm in its present condition, which shows a somewhat increase of size when compared with the other. It seems as though the tissues in this arm were a little more succulent. There has been no recurrence of the disease since the operation and the woman is apparently perfectly well to-day.

He also referred to a case reported in one of the Russian journals in which ligation of the subclavian vein and artery had been done at the same time to arrest the hemorrhage from a blind cut, which had been made in an attempt to enlarge an abscess sinus for the introduction of a drainage tube. In this case also the result was good; but during convalescence it was complicated by suppurative inflammation of the shoulder and elbow-joint. He knew of no other case on record where the internal jugular and subclavian veins had been tied simultaneously: the case he referred to in the Russian journal being the only one of a similar nature so far as the simultaneous ligation of the main artery at the root of the arm is concerned.

Dr. Pilcher, in reply to inquiries, stated that there were two rents, and that ligatures were placed on either side of the rents both in the internal jugular and subclavian veins.

DR. LANGE remarked that about an hour ago he had the mishap to open the crural vein immediately below Poupart's ligament at the entrance of the saphenous vein, while operating for the extirpation of a malignant tumor in the groin. The edges of the wounded vein were drawn together with catgut sutures, but did not include the lumen of the vessel; a complete and perfect closure was effected in this manner. The loss of blood was not considerable. A lateral ligature did not hold in this case, the walls of the vessel being thickened and resistant.

DR. WYETH remarked that the condition of the arm in Dr. Pilcher's case reminded him of a case in which he operated for the removal of carcinomatous glands of the axilla, during an operation for removal of cancer of the breast. The carcinomatous tissue was studded along the axillary vein so closely, that in order to remove all of the diseased tissue he was compelled to ligate this vein and all the branches emptying into it, and exsect the part from just below the clavicle down to the brachial region. The patient recovered: and although the circulation of the arm upon that side was good, there resulted the same flabby condition of the forearm as observed in Dr. Pilcher's patient; but she had a very useful arm for sewing and light work. He had seen her a month ago, now more than two years after the operation; when she had the first symptoms of a return of her old disease in the glands of the neck and in the lung.

THE PRESIDENT asked Dr. Pilcher if he believed that ligation of the artery would diminish the chances of œdema.

DR. PILCHER replied in the affirmative, and stated that in his patient the conditions were peculiar, as not only were the veins of the axilla cut off; but the veins of the shoulder, the transverse cervical veins and supra-clavicular veins had been cut off during the operation for the removal of this supra-clavicular growth; so there seemed to be nothing but the capillaries through which the blood might return to the trunk.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 16, 1886.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. HENRY E. CRAMPTON, Secretary of the Section on Hygiene, Public Health, and State Medicine, reported that at the first meeting of the Section, which was held Friday evening December 3d, DR. BLAINE, of the Willard Insane Asylum at Ovid, N. Y., read a paper on

BOVINE TUBERCULOSIS; ITS COMMUNICATION BY INHALATION, INGESTION, AND HEREDITARY TRANSMISSIONS, AND ITS DANGERS TO PUBLIC HEALTH.

His attention was especially drawn to the subject by an outbreak of bovine tuberculosis among the cows belonging to the Asylum. He was enabled to make a very careful and thorough series of observations, and on this occasion presented a large number of pathological specimens of much interest. Tuberculosis had been

induced in a number of rabbits and other animals by inoculations from the diseased cows, and in calves by the drinking of their milk. Hence, it was reasonable to suppose that human beings were liable to become infected from tuberculous animals, and the subject was, therefore, one of very great practical importance. In the course of the paper Dr. Blaine expressed the opinion that two per cent. of the cattle slaughtered for market, and no less than twenty-one per cent of milch cows, were affected with tuberculosis.

Dr. Herman Knapp made an address on

FERMENTATION, PUTREFACTION, AND SUPPURATION; WITH DEMONSTRATIONS AND EXPERIMENTS.

He had been particularly impressed, he said, with a remark made by Professor Briege, of Berlin, a short time since, to the effect that the great majority of all diseases seem, in the light of recent investigations, to be of bacterial origin. He then referred to the health reports of New York for a single week in the latter part of August. 33 per cent. of the deaths were reported as being due to infectious diseases; 16 per cent. to consumption; and about 5 per cent to croup and diphtheria. Here were nearly 55 per cent. of the mortality attributable to diseases of undoubtedly bacterial origin. In addition, 20 per cent. of the deaths were from diarrhœal diseases, and at least 90 per cent., if not all of these, were cases of germ disease. This brought the percentage up, therefore, to 75; but this did not include such affections as pneumonia, peritonitis, syphilis, gonorrhœa, and skin affections, which were not entered as infectious diseases; and if only 10 per cent. of these were classed as of this character, it would increase the percentage to 85. Still, nothing had been said of surgical diseases in which undue suppuration was caused by microbes, and estimating the deaths from these at 5 per cent., we have a grand total of 90 per cent of the deaths due to diseases of bacterial origin. It seemed, therefore, that Professor Briege was right.

Bacteriology has shown its principal fruit in surgery. It is antisepsis that has advanced this branch of medical science to its present high position. Antisepsis, however, is nothing but the practical application of fermentation, putrefaction, and suppuration.

He next gave a *résumé* of the history of fermentation from the year 1788, when Lavoisier found that sugar was split into carbonic acid and alcohol by the process of fermentation, which he thought was simply chemical in character, knowing nothing of the animated life that was concerned in it. He spoke of the researches of Carnéature (who discovered the yeast-plant in 1835), Ampère, Guélumae, Turpin, Franz Schultze, Liebig, Schwann, Helmholz, Schröder, Pasteur, Tyndall, and Lister; and showed that four principles had been applied in excluding germs, so that no fermentation could take place. Fermentation he described as the decomposition of carbohydrates through the agency of the yeast-plant; and he compared the action of the latter to that of the bacteria which cause putrefaction and suppuration.

Putrefaction is produced by different kinds of bacteria, fifteen or twenty varieties of which had now been discovered. There are two grades of putrefaction. The first is met with when there is but little oxygen present, and the products are water, carbonic acid, and ammonia. The process of decomposition is accompanied by little or no offensive odor. The second grade, or putrefaction proper, is seen when there is a larger quantity of oxygen.

Dr. Knapp then went on to ask, Are suppuration and putrefaction the same thing? Surgeons used the two terms promiscuously, and it seemed that suppuration, if not identical with putrefaction, was its consequence. There was, however, one point of difference as would be seen. Having spoken of the experiments of Recklinghausen, and others afterward, with the cornea of the frog, he referred to the common assertion of surgeons that if germs were excluded, suppuration would not take place. He had undertaken to investigate three special points in this connection, viz.:

(1) Does mere traumatism produce suppuration?

(2) Do foreign bodies alone produce suppuration?

(3) Do chemical agents alone produce suppuration?

In the first place, then, Does mere traumatism produce suppuration? In Berlin and at home he had made a number of experiments on the eyes of rabbits. If a wound had been made by a perfectly clean instrument he had found that it would heal by first intention, with no suppuration whatever; but if the wound was made by a contaminated instrument, suppuration invariably resulted. Dr. Knapp exhibited a rabbit in which extraction had been practised on one eye with a clean knife, and the other eye had been operated on with an instrument contaminated with pyogenic organisms. The result was, that in one case the parts had perfectly healed without any suppuration whatever, and in the other profuse suppuration had been at once set up, and pronounced staphyloma finally produced. He said he had performed a number of similar operations, and the wounds made by clean instruments had never suppurated.

One of the axioms on which antisepsis rests is, that simple fractures never suppurate. This is true, as a rule; though there are rare exceptions. When suppuration does occur, however, it is always in cases where some other form of suppuration is found in the body. Whenever the patient is healthy, therefore, no suppuration takes place. In support of this statement, he mentioned the experiments of Becker, who, having made fractures in animals, injected pyogenic fungi into the ear; with the result of at once producing suppuration, although the existing injury was only a simple fracture. Other similar experiments showed how ulcerative endocarditis and other suppurative processes could be produced by the introduction into the system of pyogenic organisms.

Dr. Knapp next took up the inquiry, Are foreign bodies by themselves capable of producing suppuration? The conclusion at which he arrived was that if they were introduced antiseptically they would produce no suppuration, and that they could remain indefinitely without this being the case. By way of illustration, he exhibited a rabbit into the cornea of one of the eyes of which he had introduced, by means of sterilized instruments, a piece of rusty hair-pin, after having first brought the latter to a glow for the purpose of destroying any organic matter that might be attached to it. The result was, that no suppuration whatever had been produced, although the foreign body had now been in the eye for quite a long time. Into the cornea of the other eye of the same

rabbit, however, he had introduced a piece of the same rusty hair-pin, which had been dipped in fluid containing pyogenic fungi; and within twenty-four hours a violent phlegmon was set up which soon completely destroyed the eye. Still, the truth of the proposition that foreign bodies alone will not cause suppuration was not yet generally admitted, and Pasteur, in 1878, had stated that even if foreign bodies were introduced antiseptically they were capable of producing suppuration. Whether he still adhered to this view Dr. Knapp was unable to say.

He then came to the third question, Do chemical agents by themselves ever produce suppuration? This, he said, was almost universally answered in the affirmative. Especially in the case of croton oil it is claimed that suppuration is caused without the intervention of germs. If this exception could stand, however, the theory of suppuration would not stand. It is a very difficult question to test satisfactorily in a practical manner; but the problem had been undertaken by four observers under very strict rules. The results of their experiments went to show that chemical agents do not of themselves produce suppuration. In repeating some of their experiments Dr. Knapp had experienced much difficulty, especially as regards croton oil, on account of the extreme irritation which it causes. Oil of turpentine, however, he had found much more manageable. He had followed the method of J. Straus, which he proceeded to describe. On account of the practical impossibility of otherwise completely disinfecting the fur of the animal, he sterilized the skin of the rabbit by means of the actual cautery. Then having made the injection under the skin of the chemical agent to be tried by means of the sterilized apparatus, the opening made by the needle was sealed up by the actual cautery. Some of the experiments were made by means of a pipette, the opening in the skin being made with a heated knife. With the experiments made with oil of turpentine and croton oil (although there were only five in which the latter was used) suppuration resulted in only ten per cent. of the cases. As a rule, there was coagulation necrosis, but no suppuration. In the cases in which suppuration did occur, it was found that there were always germs present, on account of some imperfection in the experiment.

Boice, of Utrecht, had performed the same experiments in connection with the anterior chamber of the eye, which had the great advantage of allowing the whole process set up by the chemical agent to be observed by the experimenter; and Dr. Knapp had followed Boice's procedure. He had also in one instance introduced the chemical agent into the abdominal cavity. No appreciable effect was produced upon the animal, and when, two weeks afterward, it was killed, no pathological changes whatever could be observed. He then exhibited Koch's syringe, which, he said, he had found very useful in making his experiments. In his experiments on the eye inflammation was caused, but no suppuration, even with croton oil, which he found could be used with more satisfaction when mixed with olive oil in the proportion of one to two. In some of his experiments the injection was made through the sclerotic. When the same chemical agent (either croton oil or turpentine) was introduced into the other eye in connection with pyogenic fungi, the most violent inflammation and suppuration were always produced.

He also made cultures from the two classes of eyes, using staphylococci principally for this purpose. From the eyes containing pus an immense number of microbes, with pus, resulted. But microbes (although no pus) were also obtained from the eyes from which pyogenic fungi had been excluded, and this required an explanation. The animals were killed, and microbes were found, not only in the eyes, but also in the kidneys and the blood, although there appeared to be some in the brain. It was evident, therefore, that the system had become infected through the suppurating eye, and the microbes which were found in the other eye had originated from this source. Hence it was determined to make the control experiments in two different series of animals, instead of operating upon the two eyes of the same animal. This experiment was, he thought, satisfactory and conclusive. In the eyes into which pyogenic germs were introduced, suppuration occurred, and microbes were found in larger numbers; but in the eyes from which such germs were excluded there were neither suppuration nor microbes. The results found in the latter were merely coagulated fibrin and fibrino-leucocytic exudation. Dr. Knapp thought, therefore, that so far as these experiments went, we were justified in formulating the proposition that suppuration is always produced by microbes, and hence there can be no suppuration without the intervention of these morbific agents.

In conclusion, he asked, What is suppuration? Just as in the case of fermentation, he said, the microbe ought to enter into the definition. We say that fermentation is the splitting up of a hydrocarbon into simpler forms through the agency of the yeast-plant. Putrefaction, again, is the similar splitting up of a nitrogenous substance through the agency of microbes. Suppuration, then, is likewise the splitting up of a nitrogenous substance through the same kind of agents. The difference between the two is that in putrefaction the process is always concerned with dead nitrogenous substances, while suppuration always takes place in living nitrogenous tissues. In this way the parallelism of these processes is established.

Dr. Charles Heitzman remarked that the great stress which the latter laid upon the importance of bacteriology was abundantly justified in the light of recent advances in this department of medical science. Twenty years ago it was found that if acid urine were injected into any part of the body, no results ensued; but if alkaline urine were injected, the most intense disturbance was excited. The experiments of Koch and others had shown that this marked disturbance was due to the presence of microbes.

While Dr. Knapp's experiments, and the others to which he had referred, showed that suppuration could not be produced without microbes, other experimenters of the highest authority had come to the conclusion that there could be pus absolutely without the presence of microbes. Dr. Knapp, however, would explain that by saying that it was not pus which those observers saw, but a collection of leucocytes; and he (Dr. Heitzman) was inclined to think that he was right. Still, Koch, the great master of bacteriology, was as yet by no means convinced of the correctness of the view that suppuration is absolutely dependent on the action of microbes.

Dr. Heitzman said that he had been deeply impressed with the results obtained by Dr. Knapp, and that, for one, he was willing to admit that not a single microbe could be found in the cases where care was taken to exclude absolutely all pyogenic germs, and that there was likewise no suppuration whatever. Suppuration is by no means synonymous with inflammation, and it is entirely possible to have severe inflammation, characterized by hyperplastic manifestations, but entirely devoid of suppuration. It is difficult to understand, however, how in cases of osteomyelitis developing suddenly in healthy subjects apparently as the result of traumatism, the microbes could be introduced into the middle of the bones.

CORRESPONDENCE.

THE EXTRACTION OF A COCKLE-BUR FROM THE LARYNX.

To the Editor of The Medical News,

Sir: *A propos* an article in the number of The Medical News for December 11th, on the successful removal of an extraneous body (cockle-bur) from the larynx, by Dr. Crawley, of King, Mississippi, I would like to call attention to the following case:

I operated upon a boy, æt. fifteen, about one year ago, who had inspired a cockle-bur, which, being firmly impacted between the vocal cords, resisted all attempts at extraction by laryngeal forceps of different shape and size. The cause of these vain attempts was, that the bur, from its position, encroached on the mucous membrane on three sides, where it was impacted by numerous prickles, whilst the forceps could grasp only a small part of the periphery. Finally I introduced, with the aid of the laryngoscope, the sponge instrument (a small sponge fastened to a strong laryngeal probe) of Voltolini into the larynx, behind and below the cockle-bur; and, the numerous prickles of the bur twining into the meshes of the sponge succeeded, by the first forcible traction, in dislodging the bur from its position, and it flew to a considerable distance out of the oral cavity.

I reported this case to the Cincinnati Academy of Medicine on January 28, 1886, and it is, I believe, the *first* case of removal of a foreign body from *that region of the larynx* by this simple method.

Very respectfully yours,

Max Thorner, M.D.

Cincinnati, December 14, 1886.

THE COLLECTIVE INVESTIGATION OF DISEASE.

To the Editor of The Medical News,

Sir: At the session of the International Medical Congress of Copenhagen, I was appointed the American member of the Committee of Collective Investigation, and permitted to select a colleague in the United States. Thus the pamphlets and circulars prepared by, or with the authority of, the General Committee in London, were distributed under the names of N. S. Davis and the undersigned. They were made returnable to my address on January 1, 1887.

As I have resigned my position on the above committee, I require the permission and privilege of notifying, through your journal, the holders of the above pamphlets that they ought to be sent to N. S. Davis, M.D., 85 Randolph Street, Chicago, Ill., instead of to the undersigned.

Very respectfully,

A. Jacobi, M.D.

New York, December 19, 1886.

BERI-BERI.

To the Editor of The Medical News,

Sir: Referring to the editorial in the current number of The Medical News relative to the cases of *Beri-beri* described by Dr. E. C. Seguin, and making the statement that this disease had not heretofore been described in this country, I beg to inform you that eighteen cases of beri-beri were admitted to the Marine Hospital at San Francisco, then under charge of Surgeon E. Hebersmith, in August, 1880.

A full clinical report of these cases with autopsies of those fatal, microscopical examinations of the blood by Prof. Wythe, and consular reports of the disease as it occurs in the Orient, will be found in the annual report of the Marine Hospital Service for 1881.

Very respectfully,

Fairfax Irwin,
Passed Ass't Surgeon, M. H. S.

Washington D. C., Dec. 18, 1886.

NEWS ITEMS.

Fernandez on a New Anti-rabies Inoculation.—Dr. Fernandez, of Barcelona, claims to have discovered a new vaccine to preserve men and animals from the contagion of rabies. He has collected a great number of observations, showing that dogs bitten accidentally by vipers are never affected by rabies, either spontaneously or when bitten by affected animals. He has made certain direct experiments, inoculating dogs with a small quantity of the viper's poison. After inoculation the animals were ill for four or five days, with symptoms of slight fever, prostration, and more or less profound somnolence. He maintains that the animals thus operated on are protected from rabies, and that neither when inoculated with the saliva, nor when bitten by affected animals, do they contract the disease.

Solubility of Morphine in Lime-water.—Doubtless many physicians who have given sulphate of morphine in solution in lime-water have not settled in their minds the chemical compatibility of the mixture. Some recent experiments in the assay of morphine by Wrampelmeiner & Meexert, show the mutual solubility of lime-water and morphine.

Benjamin Franklin on Wells.—This great man, who was the munificent founder of Philadelphia's water works, had observed that the water of wells in populous places gradually became unfit for use, and therefore bequeathed the city £100,000 for the purpose of bringing pure water from Wissahickon Creek. But he had a curious notion of the cause of the deterioration in well water, which came near being the reverse of the truth. In his will, referring to the bequest, he said:

"Having considered that the covering of the grand plot of the city with buildings and pavements, which carry off most of the rain, and prevent its soaking into

the earth, and renewing and purifying the springs, whence the water of the wells must gradually grow worse, and in time be unfit for use, as I find has happened in all old cities, I recommend that at the end of the first one hundred years, if not done before, the corporation of the city employ a part of the one hundred thousand pounds, in bringing by pipes the water of the Wissahickon Creek into the town, so as to supply the inhabitants, which I apprehend may be done without great difficulty, the level of the creek being much above that of the city, and may be made higher by a dam."

THE PIROGOFF SURGICAL SOCIETY OF ST. PETERSBURG is taking the lead in a movement for providing a central place of meeting for all the medical societies, where also accommodation will be found for all their libraries.

THE JOURNAL OF NERVOUS AND MENTAL DISEASE will hereafter be issued under the imprint of J. H. Vail & Co., New York.

THE AMERICAN RHINOLOGICAL ASSOCIATION would be pleased to have authors send any monographs, papers, or books, treating of any disease pertaining to the nose, throat, and ear, to the librarian, Dr. N. R. Gordon, Springfield, Ill. Due acknowledgment will be made by the Association.

LADY STUDENTS IN DUBLIN.—At the recent first professional examination of the Royal College of Surgeons in Ireland, there were seventy-eight candidates. A lady student took the first place. She is now attending the wards of one of the Dublin clinical hospitals, in company with the ordinary class of students.

THE PLAGUE OF EELS IN LONDON.—The inhabitants of the east end of London are suffering from a plague of eels. Everybody knows that the monthly reports of the chemists employed by the water companies show conclusively that the water is absolutely free from living organisms, and the explanation seems to be that the organisms are too large to get into the microscopes. The fish which the East London Company are distributing to their customers are indeed easily visible to the naked eye, for some have been found no less than eighteen inches long, and the mains abound with them to such an extent that the local board of West Ham has complained to the local government department, with the view of having some remedy applied. The eels, instead of fulfilling their destiny by being legitimately caught, skinned, and cooked, have a fashion of committing suicide in stop-cocks and taps. There they decompose, with the result, as illustrated lately, of causing the water to become horribly putrid, and of giving something very like typhoid fever to the unlucky consumers. A whole family has just been laid prostrate in this way, and one or two of its members are still seriously ill. The company has been appealed to, with little result. They say that three years ago some of their filter-beds burst, and that the unfiltered water on that occasion made its way into the mains, carrying with it a number of minute eels and other fish, which have since spawned and multiplied in the pipes. The mains have been repeatedly flushed, with the object of getting rid of the intruders, but without success; and the company's engineer is only able to tell the sanitary authority that he does not consider that the water is injured by the eels as long as they are alive, though he admits that a dangerous nuisance may arise from them when dead. The matter is really a very serious one, for the evil is steadily on the increase. There is one consideration, too, which does not seem to have occurred either to the local board or to the company, and that is whether water that can under the conditions of its distribution here support the life of fish, is fit for human consumption? On what do the eels feed? Clearly not on weeds or other vegetable substances, for the water is confined in iron mains. If, however, they find enough animalcules in the water to enable them to live and grow to a considerable size, is it certain that what is eel's food may not be man's poison?

MERLATTI, THE FASTER, had, at last accounts, fasted for fifty days. He has been under strict surveillance, and has, it is said, taken only filtered water. He has lost twenty-two pounds of flesh. The daily excretion of urea has fallen to eight grammes. The heart beats sixty-six times per minute, and sphygmographic tracings show low arterial tension. There is a reduplication of the second sound.—*Medical Record*, December 18, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM DECEMBER 14 TO DECEMBER 20, 1886.

WILLIAMS, JOHN W., *Major and Surgeon.*—Ordered for duty at Jackson Barracks, Louisiana.—*S. O. 205, Division of the Atlantic*, Dec. 14, 1886.

POPE, BENJ. F., *Major and Surgeon.*—So much of S. O. 285, A. G. O., Dec. 9, 1886, as directs him to report in person to the President of the Army Medical Examining Board, New York City, for duty as member and Recorder of the Board, is revoked.—*S. O. 287, A. G. O.*, Dec. 11, 1886.

CORSON, JOS. K., *Captain and Assistant Surgeon.*—Leave of absence extended seven days.—*S. O. 288, A. G. O.*, Dec. 13, 1886.

ANDERSON, C. L. G., *First Lieutenant and Assistant Surgeon.* Assigned temporarily to duty at Whipple Barracks, Arizona.—*S. O. 132, Department of Arizona*, Dec. 7, 1886.

BALL, R. R., *First Lieutenant and Assistant Surgeon.*—Ordered for duty at Fort Riley, Kansas.—*S. O. 144, Department of Missouri*, Dec. 13, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING DECEMBER 18, 1886.

BANKS, C. E., *Passed Assistant Surgeon.*—Granted leave of absence for twelve days, Dec. 16, 1886.

CARRINGTON, P. M., *Assistant Surgeon.*—Granted leave of absence for fifteen days, Dec. 6, 1886.

WILLIAMS, L. L., *Assistant Surgeon.*—Upon expiration of leave, to proceed to Boston, Mass., for duty, Dec. 17, 1886.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

Dermatitis, exfoliative, 297
Desk, a hygienic school, 121
Detergent, lime-water as a, 140
Diabetes, albuminuria in, 539
climacteric, in women, 41
mellitus, 299
Diagnosticians, lay, 335
Diarrhœa, acorn cocoa in treatment of, 492
treatment of a form of, in children, 353
Diathesis, contracture, 574
Digestion, gastric, 152
Digitalis in pneumonia, 68
Dilators, glottis, paralysis of, 8
Diphtheria, 43
analysis of forty five cases of, Carter, 593
hydrogen dioxide in, 405
identity of, and croup, 52
laryngeal, 664
potassium iodide in, 404
Diplopia, 520
method of overcoming, 190
Dipsomania, 520
Disease, Basedow's, 210
Bright's, and apoplexy, 589
and herpes, 631
cardiac complications of, Whittaker, 113
chloride of sodium in, 263
complications of, 574
detection of, Dulles, 231
cold as a cause of, 44
collective investigation of, 717
Hodgkin's, Hinsdale, 65
joint, amputations for, 711
malignant, operation for, in throat, 325
mastoid, 614
Thomsen's, 292
milk and throat, 417
ovarian, abdominal section for, 359
Diseases, abdominal, condition of urine an aid to diagnosis and prognosis in, 185
contagious, immunity from, produced by products of bacteria multiplication, 329
contagious, theory of immunity from, 328
cutaneous, theory of resorcin, ichthyol, and lanolin in, 273
infectious and contagious, inter-State notification of, 558
diagnosis of certain, 74
renal, classification, prognosis and treatment of certain, Satterthwaite, 449
skin, arsenic in, 167
nervous and mental, castration of women in, 577
tea-drinkers', 305
Disinfection, intrauterine, 690
Dudley, production of catharsis by means of hypodermatic medication, 509
Dujardin-Beaumetz, alimentary rations, 505
azotized aliments, 337
Clinical Therapeutics, review of, 359
Diseases of Stomach and Intestines, review of, 359
hygienic treatment of obesity, 561
Donaldson, causes of dyspnœa in high altitudes, 318
Dosage, electrical, 159
Drainage or pressure, 47
Druggists, responsibility of, 306
Drugs, absorption of, from lanolin ointment, 289
Drugs, chemical constitution and physiological action of, 97
Drunkards, "pig-backed" or alcoholic kidney of, Formad, 370
Dulles, detection of Bright's disease, 231
Dyslexia, 631
Dyspnœa, causes of, in high altitudes, Donaldson, 318

EAR, connection between noise in, and stomach affections, 416
frequent dependence of disease of, upon catarrhal disease of nose, Burnett, 29
middle, acute and purulent inflammation of, 128
soft chancre of, 211
treatment of chronic purulent inflammation of, 128
Echinococcus, chemistry of, 106
diagnosis of, 108
genesis of, 79
medical treatment of, 137
of eye, 220
pathology of, 107
surgery of, 219
Eclampsia, 241

Element, a new, 112
Emmett's cervix operation, a modification of, 383
Emphysema, pulmonary, 499
Endocarditis, ulcerative, 77
Bruen, 115
Entomology, necroptic, 308
Epilepsy, drunkard's, 123
treatment of, 210, 240, 354
Ergot, 666
proper use of, 352
Ergotine, decomposition of solutions of, 491
Eruption, bullous, after ingestion of iodine compounds, 271
Erysipelas, treatment of, 154, 376
Erythanthema syphiliticum, 269
Eserine, sulphate of, in diseases of eye, 70
Ethoxycaffeine, therapeutic action of, 630
Evans, intestinal calculus, 401
Exercise and over-exercise, 101
Expedient, a novel obstetrical, 361
Experiment, an undesirable, 447
Experts, scientific, as witnesses, 363
Expression, rectal, 26
Eye, echinococcus of, 220
effect of electric light upon, 190
eserine sulphate in disease of, 70
severe traumatism of, 216
Eyes, new formation of vitreous in both, 218
adolescent and adult, changes in refraction in, 191
refractive character of mammalian, 322
squinting, amblyopia of, 192
Theobald, 258

FASCIA, palmar, contraction of the, 713
FEEDING, infant, 324
Femur, fracture of, 22
Ferment, milk, in urine, 706
Fermentation, lactic acid, microörganisms of, Beyer, 511
putrefaction, and suppuration, 715
Fever, cold applications to præcordia in, 211

Fever, equine relapsing, 195
hay, contribution to study of, Robinson, 59
malarial, elements found in blood of, 12
puerperal, value of antipyrin in, White, 39
rheumatic, treatment of, 688
scarlet, and scarlatiniform eruptions following injuries and operations, 296
duration of infectiveness in, 575
the Biloxi, 493
treatment of, by electricity, 378
typhoid, bacillus of, Sternberg, 197
investigations on bacillus of, 290
bacillus of, 18
Gerhard, 86
in the United States, 55
jugulation of, 238
low water in wells and, 532
use of cold inhalations in, 491
yellow, inoculation for, 28
Fevers, malarial, treatment of, Frontis, 653
Fibroids, uterine, treatment of, 103
Field, auditory, 131
Field, Dr. Cridland Crocker, obituary notice of, 672
Finger, trigger, 638
Fish as an invalid diet, 545
fresh, preservation of, 251
Fissures, human cerebral, 275
Flames, Reichenbach's research on the reality of, 263
Flint, Principles and Practice of Medicine, review of, 663
Fluorine, 560
Fœtus, human, collocation of a suture and fissure in, 155
influence of mental impressions upon, 388
Food adulteration, 418
inspection of, in Ohio, 305
Foot, backward dislocation of, Daggett, 684
Forceps, placental, combined sponge and, 110
trephining, 642
Forearms, paresis of, 553
Formad, "pig-backed" or alcoholic kidney of drunkards, 370
rare form of multiple sarcoma, 146
Foster, Sir Balthazar W., honors to, 224
Fracture, Colles's, treatment of, 53
resection of humerus for, 712
Fractures, compound, treatment of, Dennis, 533
subcutaneous, effect of, on body temperature, 185
Franklin, Benjamin, on wells, 717
French, arthritis deformans, 395
Frobelius, Dr. Wilhelm, death of, 166
Frog, a decerebrized, 161
Frontis, treatment of malarial fevers, 653
Frostbites, potassium permanganate in, 323
Future, a bald and toothless, 420

GALL-STONES, intestinal occlusion by, 407
Galvanopuncture in gynecology, 596
Gastrostomy, successful, 70
Gas, water, dangers of, 643
Gelsemium, differential toxicological behavior of, and strychnia, 239
Genitals, correlation of, and tonsils, 634
German Gynecological Congress, 81
Girl, microcephalic, 160
Gland, cardiac lymphatic, 559
Glans, slow inflammation of submucous tissue of, 693
Glaucoma, treatment of, 416
Glomerulo-nephritis, experimental study of, 16
Gloves, poisonous, 84
Gonorrhœa, epidemic of, Winslow, 180
spermatorrhœa in, 599
treatment of, 442
Gout, a definition of, 336
diseases of the skin in subjects of, 544
Gray, John Purdue, obituary notice of, 642
modification of Weigert's method of staining, 515
Gross, Prof. S. D., memorial poem of, 476
Gross, S. W., successful nephrolithotomy, 677
Gudden, Dr. von, 56
Gummata, precocious, 272
Gynecology, galvanopuncture in, 596

HAIR, human, indestructibility of, 307
Hamilton, Dr. Frank Hastings, obituary record of, 195
Principles and Practice of Surgery, review of, 216
Hansell, acute optic neuritis, 144
Hare, physiological action of heavy oil of wine, 35
Harris, intestinal suture of Appolito, 236
mortality of the Cæsarean section, 63
in the United States, 431
Sänger Cæsarean operation, 317
Harvard, two hundred and fiftieth anniversary of, 585
Hatchett, operation for torn perineum, 348
Haynes, congenital tumor of rectum, 119
Head, after-coming, extraction of, 523
Health, influence of earthquake shocks upon, Porcher, 651
officer, suit against a, 27
Heart, illustration of movements of, by photography, 556
inhibition of, in diphtheria, 301
Height and weight, 307
Helminthiasis, Whittaker, 309
Hemianopsia, bitemporal, 583
clinical report of eight cases of, 18
Hemichorea, 705
Hemirheumatism, 97
Hemorrhage, acute, intraperitoneal injections in, 321
cerebral, different forms of, 24
intracerebral, in the young, 162
secondary puerperal, 53
Hemorrhoids, carbolic acid in treatment of, Reading, 490
cocaine in removal of, 402
Vallez's ointment for, 687
Henry, pernicious anæmia, 5
Hernia, radical cure of, 668
strangulated, Conner, 621
inguinal, Morton, 457
Smith, 260
Herpes and Bright's disease, 631
zoster, treatment of, 168
Hinsdale, lymphadenoma, 65
Hip-joint, gunshot wound of, 248
Hirst, cocaine in obstetrics, 490
treatment of prolapsus uteri, 703
Histohæmatins, researches on, 323
Holidays, heat, 447
Holmes, Dr. Oliver Wendell, honors to, 55
Homans, Dr. Charles D., obituary notice of, 308
